PREFACE

The Faculty of Engineering, Ahmadu Bello University Zaria is happy to introduce the proceedings of the 1st International Conference on Engineering Innovations for Sustainable Development (ICESID 2026) held between 8th–10th September 2026. The Conference drew the attention of researchers, developers and policy makers in academia and industries, from various fields of engineering. The conference was organized by the faculty with theme; Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Sustainable Development. The theme was later divided into the following sub-themes;

- Smart Infrastructure and Sustainable Systems for National Development
- Engineering Innovations, Technology Commercialization and Industrial Policy
- Emerging Technologies and Digital Transformation in Engineering Education and Practice
- Renewable Energy Integration and Smart Grid Applications in Power Systems
- Intelligent Systems, Automation and Control Engineering
- Strategies for Infrastructural and Industrial Transformation through Engineering Innovations
- Green Mobility and Next Generation Automobile Technologies
- Sustainable Engineering Processes and Systems
- Emerging Technologies for Safe Engineering Practices and Environmental Protection
- Telecommunication Infrastructure for Sustainable Urban Development and Economic Growth
- Advanced Manufacturing, Materials and Sustainable Production

The work of the technical committee is highly appreciated for smooth and effective review of the 167 submitted manuscripts for the conference, the committee did extremely well by completing the peer review process of the technical papers and also compiled a high quality technical program. We are of the belief that the ICESID 2026 provided a good platform for knowledge sharing, networking, research collaborations, which involves researchers, developers and practitioners to discuss recent advancements in various fields of Engineering. We also hope that the next ICESID will be even more stimulating than the just concluded one.

September 2026

KEYNOTE ADDRESS

INNOVATING TOMORROW: HARNESSING ENGINEERING TO DRIVE NIGERIA'S SUSTAINABLE DEVELOPMENT

Prof Idris Bugaje
Executive Secretary, National Board for Technical Education (NBTE), Kaduna

A Keynote Address Delivered at the International Engineering Conference (ICESID 2026), Faculty of Engineering, Ahmadu Bello University (ABU), Zaria, Kaduna State, Nigeria, September 8-10, 2026.

PROTOCOLS

- The Vice-Chancellor, Ahmadu Bello University, Zaria,
- The Dean, Faculty of Engineering, Ahmadu Bello University, Zaria,
- Presidents and Executives of Professional Bodies (COREN, NSE, N.Acad.Eng.),
- Distinguished Professors, Scholars, and Researchers,
- Future Engineers, Our Resilient Students,
- Ladies and Gentlemen.

I bring you warm greetings from the National Board for Technical Education (NBTE).

INTRODUCTION: THE ZARIA ENGINEERING LEGACY

It is an extraordinary honour to stand before you today in Zaria, a historic citadel of academic excellence, where I was trained as a Chemical Engineer. For generations, the Ahmadu Bello University has served as the intellectual forge of Nigeria’s technological backbone, producing visionary engineers who built our national grid, designed our transport corridors, and structured our industrial landscape. However, as we gather today, our nation stands at a critical historical junction. Nigeria faces a complex, interlocking set of macroeconomic and environmental challenges: severe grid instability with one of the lowest per capita electric energy, rising energy costs, urban infrastructure collapse, rapid desertification in the North, insecurity, and ecological degradation.

We can no longer afford to rely on traditional, post-colonial engineering models that favor quick imported fixes over long-term structural resilience. The theme of this conference, "Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Sustainable Development," is therefore not just an academic concept, it is an urgent operational imperative.

First and foremost, as we harness Engineering, Nigeria must allow its Engineers to practice. At the moment, as we speak, most engineering designs are done offshore. From refineries built in the 1950s to 2023, to superhighways till date, the only minor exception being aspects of the building construction industry. This unwholesome practice must stop. Let's own our space.

The theme of this conference, could not be more fitting, nor more urgent. Nigeria stands at a defining moment. Our population is young, our ambitions are large, and our development needs, in power, transportation, water, housing, manufacturing, and digital infrastructure, are immense. Every one of these needs is, at its core, an engineering problem. And every engineering problem, in turn, is a question of whether we have built the human capacity to solve it ourselves, rather than perpetually importing the solution.

I want to use this platform, this morning, to speak plainly about three things: first, the state of engineering and technical capacity in Nigeria today; second, why I believe our informal and technical education systems, if properly harnessed, are Nigeria's most under-utilised engineering assets; and third, a set of concrete commitments the National Board for Technical Education is prepared to make alongside this university, and alongside all of you, to turn today's innovation into tomorrow's national capacity.

THE PILLARS OF ENGINEERING-LED SUSTAINABLE DEVELOPMENT

To engineer a resilient tomorrow for Nigeria, our domestic engineering ecosystem must pivot across these fundamental fronts. Sustainable development is not an abstraction. It is measured in kilometres of durable roads, in megawatts of reliable power, in litres of clean water delivered, in tonnes of locally fabricated machinery that no longer needs to be imported. Every item on that list depends on engineers and, just as critically, on the technicians, artisans, and craftspeople who build, install, operate, and maintain what engineers design.

Too often, our national conversation about engineering capacity begins and ends with our universities and polytechnics. That conversation is necessary, but it is incomplete. Nigeria's true engineering base is broader, more distributed, and more resilient than our formal institutions alone, and nowhere is that clearer than in our informal technical and artisan clusters, the Panteka being a typical example.

The recurring failure of public infrastructure, manifested in building collapses, premature road degradation, and industrial hazards, demands uncompromising regulatory leadership. The Council for the Regulation of Engineering in Nigeria (COREN), through its Engineering Regulation Monitoring (ERM) framework, must maintain strict field oversight. Every project site in Nigeria must be audited for structural calculations, quality material blends, and certified professional supervision. We must enforce strict, proportional consequences for non-compliance, ranging from administrative stop-work orders for minor site log errors, to license cancellations, corporate blacklisting, and criminal prosecution for gross negligence that endangers public safety.

THE UNTAPPED POTENTIAL OF THE INFORMAL SKILLS SECTOR

Allow me to speak of a place many of you may already know, or used: the Panteka market in Kaduna. By our own assessment, and by the assessment of independent observers, this is the largest informal technology and artisan hub in Africa, home to an estimated 38,000 artisans and apprentices working in metal fabrication, mechanics, electrical installation, welding, and allied trades. Panteka was not built by any government. It was not designed by any faculty of engineering. It grew organically, through a master-apprentice tradition, driven by necessity and sustained by the ingenuity of ordinary Nigerians. And yet, within its workshops, one finds the same instincts that animate this conference: the instinct to solve a practical problem with the materials and tools at hand, to innovate under constraint, to build rather than merely import.

The National Board for Technical Education has taken deliberate steps to bring this informal capacity into our national framework. Since November 2017, Kaduna Polytechnic, supported by the NBTE, had worked with Panteka, to formalise skills training within Panteka. In November 2023, the first cohort of Panteka artisans graduated with National Skills Qualification Level 3 certification. And Kaduna Panteka has now been registered under Nigeria's National Skills Qualification Framework (NSQF), alongside similar hubs such as those in Jos, Ikeja, Araria-Aba, etc., a first step towards ensuring that a skill acquired informally is a skill that can be recognised nationally. Recognition of Prior Learning (RPL) is, therefore, taking centre stage across Nigeria’s informal landscape.

We are also looking outward for successful models of upgrading. Pakistan's Ustadh-Shagird apprenticeship tradition, structurally similar to what we see in Panteka, has, over past decades, been formalised and scaled through institutions such as Punjab's Vocational Training Council and the National Vocational and Technical Training Commission (NVTTC), and has helped power industrial clusters such as in Sialkot, and Gujranwala, into globally competitive, export-oriented manufacturing hubs. If Pakistan's informal artisans can become the backbone of an export industry, there is no reason why Panteka cannot follow a similar trajectory. NBTE is actively pursuing this collaboration, and we invite this Faculty of Engineering, and the researchers gathered here, to help us think rigorously about what that upgrading path should look like.

BRIDGING THE GAP BETWEEN CURRICULA AND INDUSTRY

Engineering innovation, however brilliant, does not drive national development if it stays within the walls of a laboratory or the pages of a journal or book of proceedings. This conference's sub-themes (advanced manufacturing and sustainable production, digital transformation in engineering practice,

green mobility, technology commercialisation, and industrial policy, among others) all point to the same underlying imperative: the distance or gap between what we teach, what we research, and what our industries and communities actually need must continue to close.

This is precisely NBTE's statutory mandate: to accredit and coordinate technical and vocational education in a way that keeps curricula honest to the demands of the real economy (within limits of available budgets). We do not do this work alone. We do it through partnerships: with universities such as this one, with polytechnics, international collaborators, and industry players, including engineering firms undertaking major infrastructure works in Nigeria, who are training, mentoring, and absorbing our graduates directly into productive work.

A DIRECT CALL TO ACTION FOR ABU ENGINEERS

To the distinguished lecturers and researchers of ABU: Let your laboratories solve immediate, local challenges. Design low-carbon agricultural ash cement blends to reduce construction costs; engineer precision solar irrigation pumps for northern farmers; build waste gasification systems to convert municipal refuse into clean electricity, and find engineering solutions to the current insecurity.

To our engineering students, the leaders of tomorrow: Reject the illusion that engineering is purely a white-collar office profession. True engineering happens where theory meets real-world application, in construction sites, in bio-processing pilot plants, and in industrial fabrication workshops. You are not just studying to earn degrees; you are training to construct the structural foundation of a sovereign nation, Nigeria.

To the researchers and postgraduate scholars in this hall: let your papers this week be judged not only by their theoretical rigour, but by a simple additional question: could this be built, deployed, and maintained by a Nigerian technician?

To the industry participants: engage seriously with our technical institutions, not as a corporate social responsibility afterthought, but as a genuine talent pipeline and innovation partner.

And to my colleagues in government and academic leadership: let us match today's enthusiasm with the institutional follow-ups, such as funding, accreditation pathways, and policy that innovation requires to survive beyond a conference hall.

CONCLUSION

The future of Nigeria will not be built by policy papers or political rhetoric. It will be drawn on CAD design screens, calculated through rigorous thermodynamics, forged in metal fabrication yards, and verified by strict regulatory inspectors on the ground. Let us leave this conference committed to building a nation where our bridges hold, our power grids remain stable, our local industries thrive on clean energy, and our youth are empowered with practical, globally competitive skills.

'Innovating Tomorrow' is not a slogan we should leave behind when we leave Zaria this week. It is a discipline, one that asks every engineer, every technician, every policymaker in this conference, to treat Nigeria's development challenges as solvable problems, and to treat our own people, from the postgraduate laboratories of Ahmadu Bello University to the workshops of Panteka, as fully capable of solving them. That confidence is the key! On behalf of the National Board for Technical Education, I reaffirm our commitment to walk this path with you, to keep our technical education system honest, responsive, and connected to the real engineering work this nation needs to get done.

I congratulate the Faculty of Engineering, its Dean and the organising committee, for convening this important conference, and I wish all of you a productive and thought-provoking three days in this ancient city of Zaria.

Thank you, God bless the Ahmadu Bello University, and God bless and guide Nigeria.

Prof. Idris Bugaje, ES, NBTE 8th September, 2026
#SkillsNotJustDegrees

COMMUNIQUÉ

THE COMMUNIQUÉ AT THE END OF THE INTERNATIONAL CONFERENCE ON ENGINEERING INNOVATION FOR SUSTAINABLE DEVELOPMENT (ICESID 2026)

Theme: *Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development*
Date: 8th–10th September, 2026
Venue: ACENPEE Building, Faculty of Engineering, Ahmadu Bello University, Zaria

The International Conference on Engineering Innovation for Sustainable Development (ICESID 2026), organised by the Faculty of Engineering, Ahmadu Bello University, Zaria, was held from 8th to 10th September, 2026, under the theme *"Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development."* The conference brought together researchers, academics, engineers, industry professionals, policymakers, and students to exchange knowledge, present research findings, and deliberate on the role of engineering innovation in addressing Nigeria's developmental challenges.

A total of 205 abstracts were accepted, while 167 research presentations were made during the conference. The presentations covered a broad range of engineering disciplines and emerging areas of technology, reflecting the depth of research and innovation taking place within the engineering community. The conference provided a platform for participants to share research findings, exchange professional knowledge, showcase emerging technologies, and explore opportunities for collaboration.

The keynote address by Professor Idris Muhammad Bugaje, Executive Secretary of the National Board for Technical Education (NBTE), emphasised that Nigeria's engineering capacity should extend beyond universities and polytechnics to include the informal technical sector. He highlighted Panteka Market, Kaduna, with an estimated 38,000 artisans and apprentices, as an important hub for practical engineering skills. Professor Bugaje stressed the need to formalise and integrate such skills into national development, citing collaboration between NBTE, Kaduna Polytechnic, and Panteka. He urged stakeholders to bridge the gap between education, research, industry, and community needs by translating engineering knowledge into practical solutions for sustainable economic development.

RESOLUTIONS

Following the presentations, technical sessions, and deliberations, the conference resolved as follows:

1. Government should increase and sustain funding for engineering research, laboratories, technical education, innovation, and local manufacturing, with priority given to Nigeria's critical development challenges.
2. Universities, researchers, and industry should strengthen collaboration to transform research outcomes into prototypes, patents, products, processes, and commercially viable technologies.
3. Major infrastructure and industrial projects should incorporate technology transfer and deliberate Nigerian capacity development to ensure that imported technologies strengthen local expertise rather than create permanent dependence.
4. Government, educational institutions, and industry should strengthen technical and vocational education, apprenticeships, and practical training while recognizing, certifying, and integrating skilled artisans and technicians into the formal engineering ecosystem.
5. Academic institutions should align engineering curricula, teaching, research, and practical training with industry and societal needs, while providing students with meaningful exposure to real engineering projects.
6. Universities, Government, industry, and professional bodies should provide opportunities for students and young engineers to develop technical, digital, entrepreneurial, and innovation skills that enable them to create solutions and address national challenges.

7. Researchers and institutions should prioritize interdisciplinary research that addresses pressing Nigerian challenges in areas such as energy, infrastructure, manufacturing, agriculture, water, transportation, and the environment.
8. Government, industry, and other stakeholders should support, adopt, finance, and promote credible Nigerian-made technologies through appropriate procurement policies, market access, and other incentives.
9. Professional bodies, universities, polytechnics, research institutions, industry, artisans, technicians, and entrepreneurs should establish and sustain partnerships for skills development, research, innovation, standards, certification, technology development, and knowledge exchange.
10. All stakeholders should work collectively to build a productive national engineering ecosystem in which Government provides enabling policies and funding, institutions generate knowledge, researchers develop solutions, students acquire practical skills, industry commercializes innovations, and artisans and technicians contribute hands-on expertise towards local manufacturing, technological independence, and sustainable national development.

This communiqué signifies and formally declares the conference concluded.

Professor Abdoulie M. S. Tekanyi
Chairman, Technical Committee
International Conference on Engineering Innovation for Sustainable Development (ICESID 2026)
Faculty of Engineering, Ahmadu Bello University, Zaria

10/09/2026

TABLE OF CONTENTS

ADVANCED MANUFACTURING, MATERIALS AND SUSTAINABLE PRODUCTION

1. ADVANCING SUSTAINABLE FRUCTOSE SYRUP PRODUCTION FROM SWEET SORGHUM **2**
Abdulkareem Abubakar, Alhaji Zanna Umara, Suleiman Mohammed Shuwa, Muhammad Bashir Tijjani, Suleiman Yunusa, Toyese Oyegoke & Alewo Opuada Ameh

2. BIODEGRADABLE STRUCTURE-DIRECTING AGENTS FOR SUSTAINABLE SYNTHESIS OF ZSM-5 ZEOLITE: A REVIEW OF AMINO-ACID AND BIOPOLYMER ROUTES **10**
Emmanuel John, Abdulazeez Yusuf Atta, Baba Jibril El-Yakubu & Ajayi Olusegun Ayoola

3. COMPARATIVE STUDY OF THERMAL, ZEOLITE-Y CATALYTIC AND NI-DOPED ZEOLITE-Y CATALYTIC CRACKING OF GAS CONDENSATE **16**
Jonathan Danladi Gaiya, Shuaibu Musa, Suleiman Shehu, Mansur Suleiman, Abdullahi Nuraddeen Bakori, Narcillina Nkechi Adegboro, Muhammad Aminu Abubakar, Aliyu Ibrahim, Abdullahi Bukar, Muazu Ibrahim, Toyese Oyegoke & Abdulazeez Yusuf Atta

4. DENSITY FUNCTIONAL THEORY INVESTIGATION OF METHANE STEAM REFORMING ON NI(111) AND PD1–CU(111) SINGLE-ATOM ALLOY SURFACES **27**
Abdulrauf Onimisi Ibrahim

5. DETERMINATION OF LOW-TEMPERATURE LOW-PRESSURE (LTLP) FILTRATION PROPERTIES OF DRILLING MUD FORMULATED FROM ARAWA BENTONITE CLAY FOR OIL AND GAS DRILLING APPLICATION **34**
Bala Usman, Bilal Sabiu, Hamza Abdulhamid, Muhammad Tukur, Abubakar Sadeeq Hussain & Kabiru Suleman

6. DEVELOPMENT AND MICROSTRUCTURAL CHARACTERIZATION OF AL-SI-MG / GIRO CLAY NANOPARTICLE COMPOSITES FABRICATED VIA STIR CASTING **41**
Youshau Najee Abdusalam, Kasim Auwal, Abdulwahab Malik, Gaminana Jimoh O., Abdullahi Ibrahim & Adegbite Dauda A.

7. EFFECT OF DOUBLE PRESSING AND DOUBLE SINTERING ON THE MECHANICAL AND TRIBOLOGICAL PROPERTIES OF ALUMINIUM MATRIX REINFORCED RICE HUSK ASH COMPOSITES **53**
Abdulrahman Adeiza Musa, Kamilu Adeyemi Bello, Agbo E. Oloture, Mohd A. Maleque, Jimoh O. Gaminana, Rayyan M. Dodo, Hayatu M. Abdullahi & Abdullahi Umma

8. EFFECT OF HEAT TREATMENT AND QUENCHING MEDIA ON THE MECHANICAL, TRIBOLOGICAL, AND MICROSTRUCTURAL BEHAVIOUR OF A6082-SNSA/MWCNT HYBRID COMPOSITES **63**
Abdullahi Mohammed, Malachy Sumaila, Muhammad Dauda & Laminu Shattima Kuburi

9. GEOSPATIAL ASSESSMENT OF SOIL TEXTURAL CLASSES AND THE IMPLICATIONS ON ACHIEVING SDG 2 IN NORTHWESTERN NIGERIA **76**
Garuba H.s, Mujahid, M.m & Mukhtar, M.k

10. INVESTIGATION INTO THE USE OF LOCALLY AVAILABLE MATERIALS FOR THE PRODUCTION OF INVESTMENT CASTING MOULD **83**
Nura Lawal, Mahadi Makoyo, Adamu Umar Alhaji & Yakubu Shuaibu Ochetengwu

11. MECHANICAL, OPTICAL AND ENGINEERING ASSESSMENT OF POLYPROPYLENE/FIBREGLASS COMPOSITES FOR TRANSLUCENT LPG CYLINDER APPLICATIONS **94**
Usman Sani, Fatima Mohammed & Simon N.n

12. PERFORMANCE EVALUATION OF GRANITE POWDER-STABILIZED LATERITIC ADOBE BRICKS: MECHANICAL STRENGTH, MOISTURE RESISTANCE AND THERMAL PERFORMANCE **107**
Yunusa Tsoho Abdullahi, Nasiru Zakari Muhammad, Ado Ma'aruf, Mujitafa Sariyyu & Zaharaddeeen Baffa Baba

13. PRODUCTION OF SILICA FROM AGRICULTURAL WASTES FOR APPLICATION IN FCC/RFCC CATALYST DEVELOPMENT: A MINI REVIEW **114**
Usman Sani, Daniel Adanenche, Mustapha Yusuf, A. Y. Atta & B. J. El-Yakubu

14. SUGARCANE BAGASSE ASH AS A SUSTAINABLE SILICA PRECURSOR FOR ZEOLITE SYNTHESIS: A REVIEW OF EXTRACTION ROUTES **133**
Gabriel Christopher, Abdulazeez Yusuf Atta, Baba Jibril El-Yakubu, Olusegun Ayoola Ajayi & Mustapha Yusuf

EMERGING TECHNOLOGIES AND DIGITAL TRANSFORMATION IN ENGINEERING EDUCATION AND PRACTICE

15. AN EDGE AI-DRIVEN CYBER-PHYSICAL FRAMEWORK FOR GREEN NETWORK OPTIMIZATION AND RESILIENT IT INFRASTRUCTURE IN EMERGING ECONOMIES **140**
Sani Muhammed Hassan, Muhammad Ahmad Abdulkadir, Abdullahi Usman Mohammad, Mohammad Hussaini Faskari, Najib Sayyadi & Mubarak Idris

16. COMPUTATIONAL INVESTIGATION OF ACTIVE PALM OIL COMPONENTS AS ECO-FRIENDLY CORROSION INHIBITORS FOR COPPER METAL **153**
Usman Sani, Abdulazeez Abdulateefa, Amaram Jonah Adams & Toyese Oyegoke

17. DEVELOPMENT OF A HYBRID SUPPORT VECTOR MACHINE AND BAT OPTIMIZATION ALGORITHM FOR ENHANCED **159**
Yahaya Hamisu Abubakar & Mathew Ehikhamenle

18. FACTORS INFLUENCING THE ADOPTION OF MIXED REALITY TECHNOLOGY FOR CONSTRUCTION PROJECTS COST ESTIMATION **182**
Raphael Olarewaju & Olubunmi Comfort Ade-Ojo

19. INTELLIGENT ENERGY MANAGEMENT IN AGRICULTURE: A SYSTEMATIC REVIEW OF INTERNET OF THING, RENEWABLE INTEGRATION, AND ARTIFICIAL INTELLIGENCE TECHNIQUES **198**
Vandi Jusu, Eugene Okenna Agbachi & Jibril Abdullahi Bala

20. MEASUREMENT OF LIQUID FILM HEIGHT IN GAS-LIQUID TWO-PHASE FLOWS USING TWIN-WIRE CONDUCTANCE PROBES..... **214**
Mohammed Kabir Abdullahi

21. STUDENT VERIFICATION ASSISTANT: A LOW-COST MULTIMODAL BIOMETRIC SYSTEM FOR SECURE EXAMINATION IDENTITY AUTHENTICATION..... **225**
Zainab Mukhtar Abubakar, Abdulfatai Dare Adekale, Risikat Folashade Adebiyi, Abubakar Umar, Anas Zakari & Habeeb Bello-Salau

EMERGING TECHNOLOGIES FOR SAFE ENGINEERING PRACTICES AND ENVIRONMENTAL PROTECTION

22. APPLICATION OF ARTIFICIAL INTELLIGENCE IN TRANSPORTATION SAFETY AND ENVIRONMENTAL ADMINISTRATION: A SYSTEMATIC REVIEW **234**
Ahmad Abubakar & Shehu Mohammed Yusuf

23. ASSESSING THE IMPACT OF CLIMATE CHANGE ON GROUNDWATER RECHARGE POTENTIAL IN PALLADAN, ZARIA, KADUNA STATE, NIGERIA. **240**
Samuel Adebamidele Morohunkola, Aliyu Adamu Dandajeh, Nura Idris Abdullahi, Shamsuddeen Jumande Mohammad, Sani Yakubu Khalifa & Bashir Tanimu

24. ASSESSMENT OF ELECTRICAL POWER QUALITY ISSUES IN AIRCRAFT DC SYSTEMS: ANALYSIS OF VOLTAGE DROP AND HARMONIC DISTORTION **253**
Alum Ikechukwu Otu, Muyideen Omuya Momoh, Princess Love David, Abdussalam El-Suleiman, Gowon Sule, Godwin Eseosa Abbe & Kumater Peter Ter

25. CALIFORNIA BEARING RATIO OF GEOPOLYMER-STABILIZED LATERITIC SOIL USING SUGARCANE BAGASSE ASH AND RICE HUSK ASH AS PRECURSORS **260**
Aliyu Mani Umar, Mustapha Amin Muhammad, Ashiru Mohammed, Nura Shehu Aliyu Yaro, Yaseer Adam Nabage, Adam Ado Sabari & Surajo Abubakar Wada

26. COMPARATIVE ASSESSMENT OF PAVEMENT DISTRESS USING CONVENTIONAL MEASUREMENTS AND UAV PHOTOGRAMMETRY ALONG THE GOMBE - KWAMI HIGHWAY, NIGERIA..... **268**
Salisu Ibrahim & Aminu Suleiman

27. COMPARATIVE ASSESSMENT OF CLAY POT AND PLASTIC CONTAINERS ON WATER QUALITY DURING 14-DAY HOUSEHOLD STORAGE IN ZARIA, KADUNA STATE **281**
Aminu Ohueyi Ahmed, Mohammed Aliyu Aliyu, Mohammad Shamsuddeen Jumande & Akinola Abdulwasiu Olalekan

28. REMAINING USEFUL LIFE PREDICTION OF TURBOFAN ENGINE USING ATTENTION AUGMENTED LSTM BASED NETWORK..... **288**
Oluwafemi Daniel Oluwapelumi, Samuel David Iyaghigba, Marcus Aul Maafan, Sadiq Thomas & Abbas Abdullahi

29. DESIGN AND PERFORMANCE EVALUATION OF A DUAL-MEDIA FILTRATION SYSTEM USING PALM KERNEL SHELL ACTIVATED CARBON FOR WASTEWATER TREATMENT **311**
Aminu Ohueyi Ahmed, Mohammed Aliyu Aliyu, Abdullahi Mohammed Dalhatu, Umar Abdullahi & Yakubu Joseph Nlira

30. DESIGN OPTIMISATION AND IMPACT ASSESSMENT OF A BIOGAS-INTEGRATED ANAEROBIC BAFFLED REACTOR WASTEWATER TREATMENT SYSTEM AT NIGERIAN CORRECTIONAL CENTRE **320**
Philip Ayodele Balogun, Donatus Begianpuye Adie, Igboro Sunday Bamidele & Aliyu Adamu Dandajeh

31. DESIGNING ENFORCEMENT FOR SAFETY, NOT HAZARD: EVIDENCE FROM A TRAFFIC MANAGEMENT SYSTEM FAILURE IN KANO METROPOLIS **339**
Muwaffaq Safiyanu Labbo, Abubakar Idris & Suraj Abubakar Wada

32. DEVELOPMENT AND PERFORMANCE EVALUATION OF A WASTE PLASTIC SHREDDER.. **346**
Akeem Adekunle Adebesin & Ogundemuren Victor Oluwatobi

33. DEVELOPMENT OF AN OPTIMAL CONTROL STRATEGY FOR LOAD FREQUENCY CONTROL OF THE TWO-AREA POWER SYSTEM USING ARITHMETIC OPTIMIZATION ALGORITHM **355**
Mustapha Abdullahi & Sani Salisu

34. EFFECT OF MUNICIPAL SOLID WASTE LEACHATE ON PLASTICITY CHARACTERISTICS OF CLAY SOIL **363**
Adamu Umar Chinade, Musa Umar Chinade, Isa Zubairu, Muhammad Abdu Nasara & Yakubu Hyelmura

35. EFFECTS OF HYDROCARBON IMPURITIES ON CONCRETE STRENGTH AND DURABILITY: A COMPREHENSIVE REVIEW **374**
Otu Nnamdi Johnson, James Olayemi James & Abubakar Mahmud

36. EMERGING TECHNOLOGIES FOR SAFE ENGINEERING PRACTICES AND ENVIRONMENTAL PROTECTION: A SYSTEMATICALLY INFORMED, EVIDENCE-GRADED REVIEW WITH A PROPOSED NIGERIAN ADOPTION FRAMEWORK **382**
Emmanuel Adie, John Wasiu & Ibrahim Abdulrazaq Olayinka

37. ENHANCED ANAEROBIC DIGESTION OF COW DUNG AND POULTRY DUNG VIA A COUPLED MICROBIAL ELECTROLYTIC CELL: OPTIMIZATION, KINETICS, AND THERMODYNAMIC STUDIES. **400**
Ijuptil Ndumari, Olakunle Michael Sunday & Auwal Aliyu

38. FLOOD INUNDATION RISK ASSESSMENT OF AN EARTHEN DAM UNDER PIPING FAILURE USING HEC-RAS AND QGIS: **408**
Aliyu Yahaya Muhammad, Auwal Jarmai Babagirei, Alamin D Bello, Khalid Sulaiman, Abdulaziz Ahmad Imam & Raji Olasunkanmi Sheriffdeen

39. GEOSPATIAL ANALYSIS OF ANTHROPOGENIC HEAVY METAL SOURCES AND DISTRIBUTION IN SOIL AND GROUNDWATER IN FUNTUA, KATSINA STATE **419**
Al-Mustapha Abubakar, Aliyu Ishaq, Badruddeen Saulawa Sani, Umar Alfa Abubakr & Abubakar Sadiq Isah

40. HYDRODYNAMIC ASSESSMENT OF PIPING-INDUCED DAM-BREAK AND DOWNSTREAM FLOOD HAZARD CLASSIFICATION AT ZOBE DAM, NIGERIA. AN INTEGRATED HEC-HMS AND HEC-RAS MODELING APPROACH **428**
Abdulaziz Imam Ahmad, Umar Abdullahi, Shamsuddeen Jumande Mohammad, Raji Olasunkanmi Sheriffdeen, Mohammed Aliyu Aliyu, Aliyu Yahaya Muhammad & Auwal Jarmai Babagirei

41. INFLUENCE OF SLICE THICKNESS AND DRYING TEMPERATURE ON THE PROXIMATE COMPOSITION OKRA: IMPLICATIONS FOR NUTRITIONAL QUALITY AND DRYING PROCESS OPTIMIZATION **448**
Muhammad Mujahid Muhammad, Abba Yahaya, Mohammed Abdulsalam, Al-Amin Danladi Bello, Daniel Onwude, Ibrahim Babangida Dalha, Muhammad Bashir Abdulrazaq, Badruddeen Saulawa Sani & Abdullahi Argungu Sule

42. IMPACT OF AGEING WATER INFRASTRUCTURE ON WATER SUPPLY IN NIGER STATE: CASE STUDY OF SULEJA AND MINNA **454**
Stephen Osu & Mohammed Saidu

43. IMPACTS OF ROAD CONSTRUCTION SITE ACTIVITIES ON THE OCCURRENCE OF ACCIDENTS: A CASE STUDY OF THE ZARIA–KADUNA ROAD **463**
Muhammed Mustapha Musa, Kasimu Yusuf Gojara, Ibrahim Bello & Yusuf Ya'u

44. INFRASTRUCTURE CHARACTERIZATION AND PHYSICAL INTEGRITY ASSESSMENT OF URBAN WATER DISTRIBUTION SYSTEMS: A RISK-BASED FRAMEWORK FOR SUSTAINABLE ASSET MANAGEMENT IN MINNA, NIGERIA **483**
Abdulrahman Aminu, Johnson A. Otun & Aliyu Ishaq

45. INTEGRATED EXERGETIC–ECONOMIC ASSESSMENT OF THERMAL AND CATALYTIC PYROLYSIS OF HOUSEHOLD THERMOPLASTIC WASTE FOR SUSTAINABLE WASTE-TO-ENERGY APPLICATIONS **502**

Zhidaya Jude, Eyitayo A. Afolabi & O. S. Azeez

46. MINIMIZATION OF POWER LOSSES IN DISTRIBUTION NETWORKS THROUGH SMART GRID TECHNOLOGIES (SGT): A CASE STUDY OF BWARI 33 KV DISTRIBUTION NETWORK **508**
Francis Igbinosa, Eronu Emmanuel & Ngang Bassey Ngang

47. NON-PARAMETRIC ASSESSMENT OF WIND-SECTOR AND ELEVATION EFFECTS ON CONTAMINANT DISTRIBUTION AROUND A CEMENT FACTORY **524**
Taiwo Abadunmi, Ayodele Olanrewaju Ogunlela & Kamorudeen Olaniyi Yusuf

48. OPTICAL EMISSION SPECTROSCOPY (OES) ANALYSIS OF CORROSION OF HIGH-GRADE CONVENTIONAL 5 MM UKRAINIAN METALLIC PLATE USED IN TANKER TRUCK FABRICATION IN NIGERIA **537**
Jamilu Haruna, Abdulkareem Abubakar, Usman Abubakar Zaria & Abdulmajid M. Nainna

49. PERFORMANCE EVALUATION OF MODEL REFERENCE ADAPTIVE CONTROLLER FOR STRING STABILITY IN HEAVY-DUTY TRUCK PLATOONING **545**
Hassan Maharazu, Z. Haruna, O. Ajayi, Muktar Abubakar & Mohammed Babakolo Adamu

50. PROBABILISTIC FREQUENCY ESTIMATION OF BOILING LIQUID EXPANDING VAPOUR EXPLOSION IN A LIQUEFIED PETROLEUM GAS ADD-ON SKID SYSTEM USING INTEGRATED FAULT TREE AND EVENT TREE ANALYSIS **557**
Shuaibu Musa, Abdullahi, Nuraddeen Bakori & Mohammed-Dabo, I. A.

51. PROCESS INTENSIFICATION OF A 50 BPD MODULAR MINI-REFINERY: A SIMULATION-DRIVEN PINCH ANALYSIS APPROACH FOR ENHANCED HEAT RECOVERY AND SUSTAINABLE REFINING IN NIGERIA **564**
Habib Ahmed Tijjani, Muhammed-Dabo I. A., Waziri S. M. & Mustapha M. Sugungun

52. SPATIAL VARIATION ASSESSMENT OF GROUNDWATER QUALITY IN IWO LOCAL GOVERNMENT AREA, OSUN STATE, NIGERIA. **580**
Yuusuf Oluwaseun Adetona & Kamar Taiwo Oladepo

53. STUDY OF THE CORROSION RATE OF NIGERIAN HIGH-GRADE CONVENTIONAL 5 MM UKRAINIAN METALLIC PLATE USING WEIGHT LOSS (GRAVIMETRIC) METHOD..... **598**
Jamilu Haruna, Abdulkareem Abubakar, Usman Abubakar Zaria, Abdulmajid M. Nainna & Abubakar Ado Datti

ENGINEERING INNOVATIONS, TECHNOLOGY COMMERCIALISATION AND INDUSTRIAL POLICY

54. A COMPREHENSIVE REVIEW ON THE POULTRY BROODING REQUIREMENTS AND FORCED AIR METHODS OF HEAT GENERATION FOR BROODING **608**
George Akwec, Adebayo Segun Emmanuel & Caroline Omoanatse Alenoghena

ABSTRACT

The increasing demand for high-fructose syrup, coupled with the need to reduce dependence on imported sweeteners and conventional corn-based production systems, has intensified interest in alternative and renewable feedstock. This review studied the potential of sweet sorghum, sustainable feedstock for fructose syrup production, with particular emphasis on clarification technologies, catalytic conversion pathways and process optimization strategies. The physicochemical characteristics of these feedstocks, together with juice extraction, clarification, hydrolysis, glucose isomerization, and purification approaches, are examined. Sweet sorghum demonstrates considerable potential owing to its high fermentable sugar content, relatively low agricultural input requirements, adaptability to semi-arid environments and suitability for decentralized processing. The review further highlights the importance of effective purification, catalyst selection, reaction-condition optimization and integrated processing systems in improving fructose yield, product quality and process efficiency. Consequently, the utilization of this non-conventional feedstock could support value addition, reduce biomass losses and contribute to more sustainable and locally adaptable sweetener production systems.

Keywords: *Enzymes; feedstock; fructose; optimization; syrup; valorization*

1. INTRODUCTION

Global sweetener industry dwelled on fructose syrup production in food and beverage which is highly cost-effective (Khorshidian *et al.*, 2021; Bulbul *et al.*, 2024). However, conventional corn, sugarcane and sugar beet usage has become a serious problem due to cultivation challenges which necessitate alternative biomass feedstock such as sweet sorghum, (Taylor *et al.*, 2023)

This alternate feedstock is easily cultivated with minimum farming input, care to achieve reasonable outcome (Almodares and Hatamipour, 2011; Velmurugan *et al.*, 2020), waste material like stalk also can be utilized as bagasse in bioenergy production (Appiah-Nkansan *et al.*, 2019).

This review involves the characterization, clarification and purification strategies including the catalytic pathways and process optimization for fructose production from the sweet sorghum.

2. NON-CONVENTIONAL BIOMASS FEEDSTOCKS FOR FRUCTOSE SYRUP PRODUCTION

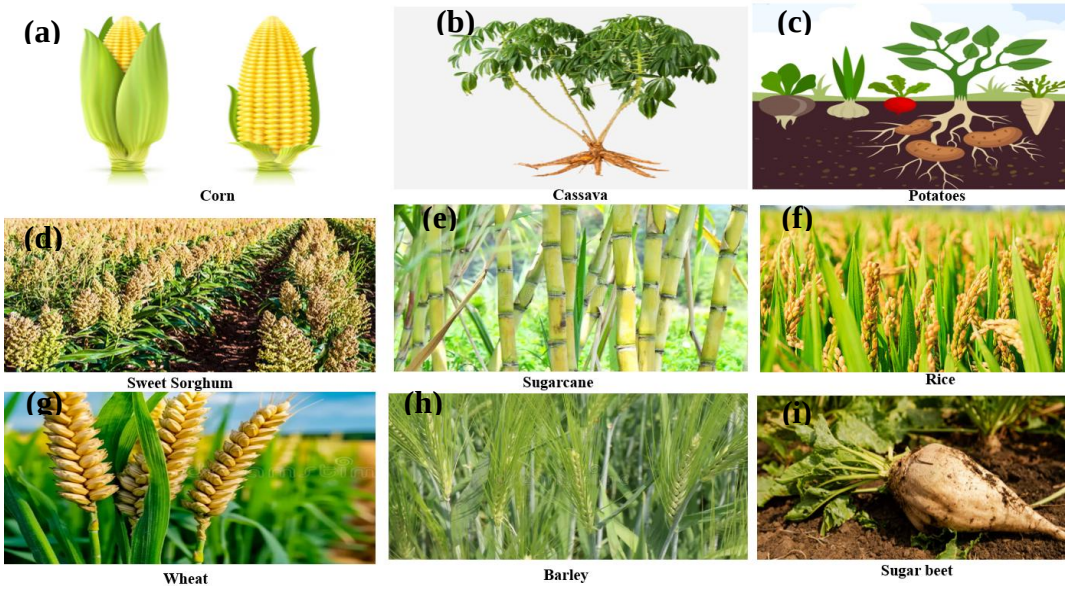

Figure 1: Biomass image of (a) Corn, (b) Cassava, (c) Potatoes, (d) Sweet Sorghum, (e) Sugarcane (f) Rice, (g) Wheat, (h) Barley and (i) Sugar beet for fructose production

Figure 1 depicted the various images of alternative biomass feedstocks for production of fructose syrup, the potential fructose yield, cost-effectiveness, and environmental influence are reviewed in this section. Corn (Figure 1a) produces the highest fructose yield (50–60%). However, high production costs, intensive water and fertilizer demand, soil degradation are matters of economic and environmental concern. Furthermore, cassava (Figure 1b) representing lower fructose yield (30–40%). Nevertheless, is cost effective, readily available in tropical regions, has low water demand and can grow on poor soils. However, it is competitive in terms of human consumption. In addition, plantain contained lowest fructose yield (20–30%), even though it inexpensive, abundant in the locality, and environmentally friendly.

Similarly, sweet sorghum (Figure 1d) possessed average yield of about 40–50%, it is an example widely cultivated in northern Nigeria; therefore, industrial utilization of this material as an alternate feedstock will improve commercialization, food security and economy of the nation (Yahaya *et al.*, 2020), production of potatoes (Figure 1c) also does not require heavy agricultural duty and input, local availability, non-competitive, affordable, non-sensitivity to a particular region and environmentally friendly (Agbaeze *et al.*, 2020) therefore there is potential and need to commercially sustain the farming of sweet sorghum to high value added product for example fructose syrup production in line with Nigeria's agricultural value chain such as development in technology, innovation and infrastructure under the National Agricultural Technology and Innovation Policy (NATIP) 2022-2027 (Federal Ministry of Agriculture and Rural Development [FMARD], 2022).

3. PROCESSING OF SWEET SORGHUM FOR HIGH-FRUCTOSE SYRUP PRODUCTION

3.1 Raw Material Harvesting and Extraction

Matured sweet sorghum stalks are harvested, defoliated and milled or blind in mechanical roller mill or electric blinder to extract raw juice, cellular debris, suspended solids, insoluble fibers particulates are filtered out (Shirvani *et al.*, 2023), followed by thermal treatment to prevent microbial fermentation and other bacteria, wet-milling operations isolate the starch fraction, yield high purity starch slurry as presented in figure 2 (Zhou *et al.*, 2020).

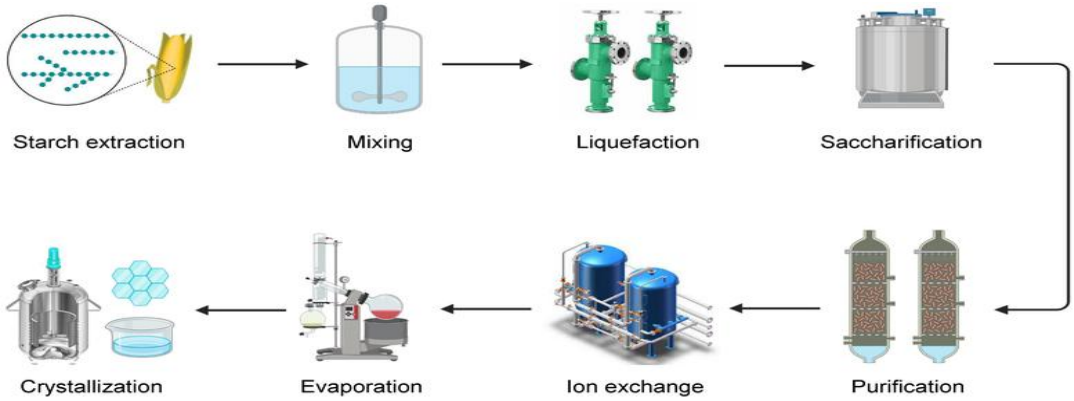

Figure 2: General Process Flowchart for Fructose Syrup Production

3.1 Purification Methods

Conversion of non-conventional biomass into high-quality fructose syrups requires adequate purification to remove impurities such as suspended solids, colloids, proteins, phenolic compounds, minerals, pigments and microbial contaminants. These impurities can inhibit the catalytic activity of enzymatic reaction which could affect product quality (Harlen & Ristiarini, 2023; Zhao *et al*., 2022). Therefore, this section discusses the various clarification methods depicted in Table 2. For example, Chemical clarification applying calcium hydroxide and alum rapidly clarifies extracted juice via neutralisation and precipitation with effective cost. However, chemical residues and environmental impacts existence is considered as a challenge (Bourguerra *et al.,* 2024; Kameneva *et al*., 2021). Furthermore, mechanical clarification such as membrane filtration, chromatography, and ion exchange limits chemical consumption and highly efficient. Despite this, it has high energy demand and equipment wear (Almodares & Hatamipour, 2011; Zhou *et al*., 2020). In addition, natural clays such as bentonite are a cheap, available and active adsorbent for pigments and proteins removal. Nevertheless, it affects juice quality (nutrient) when used in excess, also cause environmental challenges in terms of waste management (Teetor *et al*. 2011; Rajvanshi *et al*. 2020). Similarly, according to Amaral-Fonseca *et al*. (2021), Moringa *et al.* (2021) plant-based clarification is done by deploying natural clarification agents, for example moringa oleifera seed extract, okro mucilage, and guar gum are locally source, cost effective, non-toxic, and environmentally friendly options, that eliminate impurities via binding or trapping the undesired juice extracts.

Table 1: Comparison of Traditional and Natural Clarification Methods

Clarification method	Material	Mechanism	Advantage	Disadvantage	Reference
Chemical	Calcium Hydroxide (KOH). Aluminium sulfate (Alum).	Neutralizes acid and promotes precipitation. Forms aluminium hydroxide to bind particles	Cost-effective, fast, established technology	Chemical residues, environmental impact, health risks	Bourguerra *et al*. (2024), Kameneva *et al*. (2021)
Mechanical	Membrane. Chromatography. Ion exchange.	Filters particles and extraction residues. Adsorbs pigment, colour. Binding base on charge Interactions.	High efficiency, scalable, less chemical use	High energy consumption, equipment wear	Wibisono *et al*. (2023), Kameneva *et al*. (2021), Zhao *et al*. (2022)
Natural Clay	Bentonite	Adsorbs impurities such as pigments, and protein.	Low-cost, effective at removing pigments and proteins	Excess clay can affect nutrient content, waste management issues	Teetor *et al*. (2011), Rajvanshi *et al*. (2020)
Plant Based	Moringa Oleifera Seed Extract. Okro Mucilage. Guar Gum.	Bind pigments, proteins, and Solids. Bind particulate matter. Forms gel-like network, traps biocompatible.	Sustainable, non-toxic, biodegradable	Variability in raw material quality, scalability issues	Saïed *et al*. (2020), Amaral-Fonseca *et al*. (2021), Moringa *et al*. (2021)

4. CATALYTIC REACTION PATHWAYS

The popular industrial production of fructose syrup relies on three (3) stages of enzymatic pathway that breaks down biomass feedstock to glucose prior to reversible isomerisation to produce fructose.

4.1 Enzymatic reactions.

4.1.1 Liquefaction (Starch to Dextrins) entailed the use of catalyst like thermostable α-amylase which cleaves α-1,4-glucosidic bonds randomly at pH 5.8–6.5, temperature 95°C–105°C, requires Ca^{2+} ions for enzyme stability. This reduces viscosity and yields shorter-chain maltodextrins (Li *et al.*, 2017; Frey *et al.*, 2020).

4.1.2 Saccharification (Dextrins to Glucose), is the process in which a catalyst such as glucoamylase (enzyme) hydrolysis α-1,4 and α-1,6 linkages sequentially from the non-reducing ends, typically under the following conditions pH 4.0 - 4.5, temperature 60°C- 62°C and employed Glucoamylase to yield a high-purity glucose hydrolysate (D-glucose) (Frey et al., 2020; Chen et al., 2022; Gromada et al., 2008)

4.1.3. Isomerization (Glucose to Fructose), this reaction converts aldose sugar (glucose) to its ketose isomer (fructose) at pH 7.5-8.2, temperature 55°C-60°C with the facilitation of Immobilized Glucose Isomerase/Xylose Isomerase. However, the reaction typically has an equilibrium challenge

with roughly 42 % fructose, 52% glucose, and 6% other sugars (known as HFCS-42) (Amaral-Fonsera *et al.* 2021; Taibi *et al.* 2023)

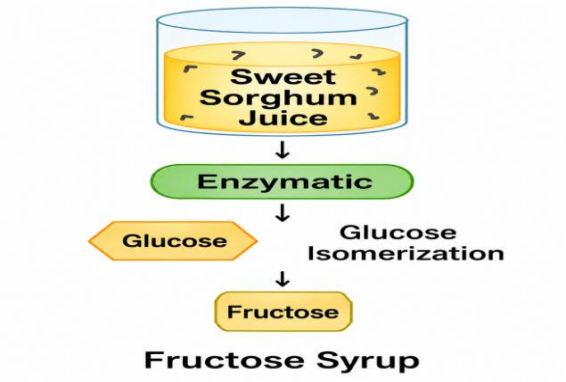

Figure 3: Enzymatic Hydrolysis and Glucose Isomerization for Fructose Syrup Production

4.2 Chemical and Chemocatalytic Reactions.

To bypass the slow reaction kinetics and high costs of enzymes, researchers considered chemocatalysts to convert glucose or directly transform biomass into fructose which involve the following methods.

4.2.1 Homogeneous Base Catalysis such as Sodium hydroxide (NaOH), calcium hydroxide ($Ca(OH)_2$), or soluble amines is employed, limitation involves high byproduct formation (psicose, mannose) (Chen *et al*., 2022; Frey *et al*., 2020; Li *et al*., 2017)

4.2.2 Heterogeneous Lewis Acid Catalysis for example, Lewis acid center (like Sn^{4+}) coordinates with the carbonyl oxygen of glucose, facilitating an intramolecular 1,2-hydride shift to form fructose leading to highly selective, water operation and easy catalyst recoverability (Moliner *et al*., 2010; Frey *et al*., 2020)

4.2.3 Bronsted Base Solid Catalysts promotion of isomerization via proton abstraction at C2 position using catalysts such as hydrotalcites, basic resins or functionalized silica (Wang *et al*., 2022; Frey *et al*., 2020)

5. PROCESS OPTIMIZATION FOR FRUCTOSE SYRUP PRODUCTION

The optimization of catalytic reaction conditions are pH, temperature, concentration, catalytic loading for high percentage yield, stability, quality and economic viability (Dai *et al*., 2020; Ma *et al*., 2022). However, optimization faces drawbacks from feedstock variability, impurity, seasonal availability and scale constraints.

In optimization, conditions such as temperature and pH play a critical path in affecting the glucose isomerase, degradation, reaction rates which are determined by the microbial source (Dai *et al*., 2020; Ma *et al.*, 2022). The catalyst loading and concentration specifically influences the mass transfer during the reaction depends on enzymatic (hydrolysate) conditions (Okpalanma *et al*., 2024; Debora *et al*., 2024).

6. CONCLUSION

The non-conventional use of biomass feedstock such as sweet sorghum, cassava, sweet potato and especially waste food leads to waste valorization, circular economy, reduce greenhouse gas emissions, and above all less cost effective. The sweet sorghum demonstrated the potential of catalytic pathway for high percentage yield, purity with high stability. Membrane technologies, enzyme immobilization and the catalyst loading improved the fructose production efficiency and the quality.

ABSTRACT

Zeolite Socony Mobil–5 (ZSM-5), a high-silica MFI-type molecular sieve, is central to downstream petroleum processing, catalytic cracking, and environmental remediation. Its conventional hydrothermal synthesis depends on quaternary ammonium organic structure-directing agents (OSDAs) such as tetrapropylammonium hydroxide and bromide, which are costly, toxic, and release hazardous gases during template removal by calcination. These drawbacks, together with Nigeria's heavy reliance on imported catalysts, motivate the search for greener alternatives. This review examines biodegradable structure-directing agents—amino acids (L-arginine, glycine), organic acids (citric and lactic acid), and biopolymers such as modified chitosan—for the synthesis of ZSM-5 and related zeolites. Reported routes are compared by silica and alumina precursor, SiO_2/Al_2O_3 ratio, pH, crystallisation temperature (90–180 °C) and time, achievable crystallinity, and characterisation by XRD, SEM, FTIR, BET, and TGA. Evidence indicates that biodegradable agents can direct crystalline zeolite frameworks under milder, less hazardous conditions, although attaining the high Si/Al ratios required for ZSM-5 remains challenging with these weaker templates. Coupling such agents with low-cost local feedstocks—rice husk ash as a silica source and metakaolin as an alumina source—offers a sustainable, lower-cost pathway to ZSM-5 suited to Nigeria's downstream petroleum sector and circular-economy goals. The review identifies gaps in reproducibility, template–framework interactions, and scale-up, and outlines directions for developing fully green, waste-derived zeolite catalysts.

Keywords: *ZSM-5 zeolite; biodegradable structure-directing agents; green synthesis; rice husk ash; metakaolin*

1. INTRODUCTION

ZSM-5 is an important MFI-type zeolite whose medium-pore structure, hydrothermal stability and tunable acidity make it valuable in petroleum refining, methanol-to-olefins (MTO), aromatization and environmental applications (Kamaluddin *et al.*, 2022; Bensafi *et al.*, 2023). However, conventional ZSM-5 synthesis often requires organic structure-directing agents (OSDAs), substantial water and energy, and high-temperature calcination, creating environmental concerns (Zhang *et al.*, 2022; Parvulescu & Maurer, 2022). Consequently, interest has increased in biodegradable structure-directing agents (SDAs), template-free synthesis and waste-derived precursors.

Although conventional quaternary-ammonium OSDAs effectively control crystallization, studies demonstrate that ZSM-5 can also be synthesized without organic templates. However, template elimination does not necessarily ensure sustainability because increased water consumption, longer crystallization times or additional processing may offset environmental benefits.

Biodegradable molecules, particularly amino acids such as L-lysine and L-carnitine, can influence nucleation, crystal growth and hierarchical porosity (Zheng *et al.*, 2023). Similarly, HPMC may modify crystal growth and promote mesoporosity rather than directly replicating conventional OSDA behaviour (Hoang & Thao, 2022,) nonionic polymer and amino-acid-assisted (Zhan *et al.*, 2024). Their effectiveness depends on pH, concentration, Si/Al ratio and synthesis conditions.

Waste-derived silica and alumina, including RHA and metakaolin, can further reduce dependence on commercial raw materials, although compositional variability and impurities may

affect crystallization (Jia *et al.*, 2021). Therefore, sustainable ZSM-5 synthesis requires an integrated strategy combining biodegradable SDAs, waste-derived precursors, controlled nucleation, reduced-water synthesis and recycling. Sustainability should ultimately be assessed across the entire process, including precursor origin, directing chemistry, energy, water, crystallization, reproducibility and catalytic performance, rather than biodegradability alone.

2. LITERATURE SEARCH AND SELECTION METHODOLOGY

A structured literature search was conducted to identify studies on ZSM-5 synthesis, biodegradable structure-directing agents (SDAs), amino acids, biopolymers, and waste-derived silica/alumina precursors. Relevant publications were identified using Scopus, Web of Science, ScienceDirect, SpringerLink, Wiley Online Library, ACS Publications, and Google Scholar. Keywords included ZSM-5, MFI zeolite, biodegradable SDA, amino-acid template, L-arginine, glycine, L-lysine, L-carnitine, chitosan, hierarchical ZSM-5, rice husk ash, and metakaolin. Peer-reviewed experimental and review studies were prioritized. Studies were selected based on reported gel composition, Si/Al ratio, pH, crystallization temperature/time, SDA concentration, crystallinity, pore structure, and characterization results. Irrelevant or insufficiently documented studies were excluded.

3. ZSM-5 AND THE NEED FOR SUSTAINABLE SYNTHESIS

ZSM-5 is characterized by the MFI framework topology and a system of interconnected medium-pore channels. Its catalytic properties are determined by the combination of pore architecture, framework composition, crystal morphology and acidity. The Si/Al ratio is particularly important because framework aluminium is associated with the generation of acidic sites. Changes in the framework composition can therefore influence conversion, selectivity, coke formation and catalyst lifetime.

The versatility of ZSM-5 has made it a major catalyst in petroleum and petrochemical processing. Kamaluddin *et al.* (2022) reviewed the relationship between ZSM-5 physicochemical properties and methanol-to-olefins performance, emphasizing that synthesis conditions can strongly influence the catalytic behavior of the resulting material. This relationship creates a major challenge for green synthesis. A synthesis route cannot be considered successful merely because it produces an XRD pattern corresponding to MFI. The resulting material must also have an appropriate pore structure, acidity, crystal morphology and catalytic performance.

Conventional synthesis therefore provides a useful benchmark. Tetrapropylammonium-based OSDAs can efficiently promote MFI crystallization, but their use involves additional chemical cost and subsequent template removal. A study of TPAOH concentration, for example, demonstrated that the highest crystallinity and favorable pore properties were obtained at an optimum rather than maximum SDA concentration, suggesting that template consumption can potentially be reduced without sacrificing material quality.

This finding is significant because it demonstrates that sustainability does not necessarily require complete replacement of conventional materials. Optimization can itself be a sustainability strategy. However, reducing the amount of OSDA is only one possible solution. The more ambitious approach is to develop synthesis routes that eliminate the organic template altogether.

4. BIODEGRADABLE STRUCTURE-DIRECTING AGENTS

4.1 Amino acids

Amino acids are attractive because they are commercially available, water-compatible and biodegradable, while their amino, carboxyl and, in some cases, additional functional groups provide opportunities for interaction with aluminosilicate species. Because the protonation states of the amino and carboxyl groups change depending on the conditions of the solution, their behavior is strongly influenced by pH. As a result, a molecule of the same amino acid that is used in an alkaline zeolite gel may behave differently under neutral or acidic conditions. Instead of being a direct molecular replica of tetrapropylammonium, it might be used as an auxiliary template, mesoporogen, nucleation promoter, or crystal-growth modifier. Amino-acid-assisted hierarchical ZSM-5 synthesis is strongly supported by recent evidence.

L-arginine and glycine

Glycine and L-arginine are appealing options because they are relatively straightforward amino acids with well-established biodegradability and acid-base chemistry. L-arginine contains a guanidino group that can become strongly protonated, whereas glycine contains only one amino and one carboxyl group. These differences can influence electrostatic interactions with negatively charged silicate species. Nevertheless, the recent literature is stronger for L-lysine and L-carnitine than for direct substitution of tetrapropylammonium by L-arginine or glycine in conventional ZSM-5. Therefore, claims that any amino acid will produce high-quality ZSM-5 should be avoided unless the experimental evidence demonstrates MFI crystallinity, framework incorporation and reproducible yield.

More recent peer-reviewed work provides stronger evidence for L-lysine and L-carnitine. Zheng *et al.* (2023) reported hierarchical ZSM-5 using L-lysine and L-carnitine as secondary/mesoporous templates; characteristic MFI XRD reflections were observed, and the amino acids generated mesopores of approximately 2–10 nm. Excessive L-carnitine, however, produced amorphous phases, demonstrating that amino-acid dosage is important.

4.2 Biopolymers: Chitosan

Chitosan is a chitin-derived polysaccharide that has been deacetylated. It has a strong capacity for hydrogen bonding and interaction with inorganic species due to the presence of hydroxyl and amino groups in its polymer chain. In zeolite synthesis, chitosan can function as a macropore or mesopore-forming additive, a crystal-growth modifier, or an assisting template during recrystallization. Because of its size, it has a different effect than a small SDA molecule does: it can affect aggregation and interparticle voids as well as the molecular-scale channels. A recent study by Fu *et al.* (2024) demonstrated the application of chitosan as an assisting template during the alkaline reassembly of HZSM-5. Chitosan promoted the formation of micro–mesoporous structures and altered the acid-site distribution. The resulting hierarchical HZSM-5 exhibited improved catalytic performance in the co-pyrolysis of corn stover and high-density polyethylene, enhancing the production of monocyclic aromatic hydrocarbons (MAHs) while suppressing polycyclic aromatic hydrocarbons (PAHs) and coke formation. Under the reported optimum conditions, the MAH carbon yield reached 36.9% at 550 °C with 15% chitosan, while the chitosan-modified catalyst increased the synergistic production of MAHs by 38.2% relative to the corresponding reference system (Fu *et al.*, 2024).

Table 1: Summary of Biodegradable Structure-Directing Agents

Biodegradable SDA	Specific Examples	Mechanism/Role	Key Characteristics & Finding
Amino Acids	L-arginine, Glycine, L-lysine, L-carnitine	Auxiliary template, mesoporogen, nucleation promoter, or crystal-growth modifier.	Behavior is strongly pH-dependent; functional groups interact with aluminosilicates. Evidence is stronger for L-lysine/L-carnitine than L-arginine/glycine in ZSM-5 synthesis.
Biopolymers	Chitosan	Macropore/mesopore-forming additive, crystal-growth modifier, or assisting template during recrystallization	Affects aggregation/interparticle voids; promotes micro–mesoporous structures in hierarchical HZSM-5; improves aromatic hydrocarbon production during biomass/plastic co-pyrolysis.

Table 2: Recent Synthesis of Zeolite using Biodegradable OSDA

Zeolite Type	Silica Source	Alumina Source	Biodegradable SDA	pH	Crystallinity	Temperature (°C)	Crystallization Time (hrs)	Si/Al Ratio	Characterization	Reference
ZSM-5	Rice Husk Ash	Kaolin	L-lysine/L-carnitine	10-11	≈90–95%	140-160	24-48	≈25	XRD, SEM, FTIR, BET, TGA	Zheng *et al.*, 2023

5. WASTE-DERIVED SILICA AND ALUMINA PRECURSORS FOR ZSM-5 SYNTHESIS

High-purity silica and alumina can account for a substantial part of material cost, and their production has its own environmental footprint. Therefore, natural minerals, clays, and agricultural residues are highlighted in recent reviews as alternative precursors (Nguyen *et al.*, 2023). Rice husk ash (RHA) is one of the most appealing agricultural residues due to its silica-rich ash that can be produced through controlled combustion. Jia *et al.* (2021) demonstrated that RHA can be the source of silica for template-free ZSM-5 by combining the utilization of waste with a reduction in the utilization of organic templates. Under low temperatures, their work produced ZSM-5 with Si/Al ratios of 20, 30, and 40. This is important for developing nations because the method does not use an organic template and uses agricultural residue instead of purified silica. The condition of the ash is critical. Uncontrolled burning can produce carbon-rich ash or promote transformation of amorphous silica into less reactive crystalline phases at excessive temperatures. As a result, the chemical composition, combustion temperature, residence time, atmosphere, washing or acid-leaching steps, and ash preparation should be described. XRF is particularly useful for determining Si, Al, Fe, Ca, Mg, Na and K contents before gel formulation.

Kaolin calcination removes structural hydroxyl groups and increases reactivity. The resulting metakaolin is therefore a useful alumina-containing precursor.. Combining

RHA-derived silica with metakaolin can produce a locally sourced aluminosilicate system. However, the Si/Al ratio must be adjusted because metakaolin contains substantial silicon as well as aluminium. The resulting ZSM-5 should be evaluated using XRD, SEM, FTIR, BET, TGA and acidity measurements.

6. RESEARCH GAPS AND FUTURE PERSPECTIVES

The key research gaps in biodegradable-SDA ZSM-5 synthesis involve mechanistic understanding, reproducibility, high-Si/Al synthesis, scale-up, and sustainability. Future research should clarify the actual structure-directing role of biodegradable additives, standardize RHA and metakaolin precursors, and explore the use of biodegradable co-directing agents and ZSM-5 seeds to achieve high-Si/Al materials. Scale-up should incorporate process intensification, mother-liquor recycling, reduced water use, dry-gel conversion, and lower-temperature crystallization. In addition, **l**ife-cycle and techno-economic assessments are needed to verify environmental and economic benefits. Ultimately, synthesis conditions should be directly linked to catalytic performance, considering not only crystallinity but also crystal size, diffusion, conversion, selectivity, stability, and coke formation.

7. CONCLUSION

This review establishes that sustainable ZSM-5 synthesis cannot be achieved simply by replacing conventional organic structure-directing agents (OSDAs) with biodegradable alternatives. Nevertheless, evidence from Zheng *et al.* (2023) demonstrates that biodegradable amino acids, particularly L-lysine and L-carnitine, have considerable potential as functional synthesis additives for ZSM-5. These amino acids successfully facilitated the formation of hierarchical ZSM-5 and generated ultra-small mesopores of approximately 2–10 nm by overcoming phase separation during crystallization. Their hydrophilic functional groups also provide favourable interactions with zeolite precursors and developing crystals, enabling control over crystal morphology, grain size, porosity and, consequently, acid properties.

However, the effectiveness of L-lysine and L-carnitine remains dependent on their dosage and synthesis conditions. Zheng *et al.* (2023) showed that moderate addition of the amino-acid template did not adversely affect ZSM-5 nucleation and crystal growth, whereas excessive L-carnitine resulted in increased amorphous phases. Thus, these findings support the view that L-lysine and L-carnitine are strong SDAs for sustainable ZSM-5 synthesis, but their use should be based on optimized compositions rather than simple one-to-one substitution for conventional OSDAs.

ABSTRACT

This study investigated the modification of zeolite-Y and its application in the cracking of gas condensate using thermal, catalytic, and nickel-doped catalytic processes. Raw zeolite-Y (ZY-1) was chemically pretreated (ZY-2) and subsequently modified with nickel to produce Ni-doped zeolite-Y (ZY-3). The catalysts were characterized using Brunauer–Emmett–Teller (BET) analysis, X-ray diffraction (XRD), and Fourier-transform infrared spectroscopy (FTIR), while the hydrocarbon products were evaluated by GC-MS/PIONA analysis. BET analysis showed progressive increases in the surface area from 181.549 m²/g for ZY-1 to 245.368 and 278.956 m²/g for ZY-2 and ZY-3, respectively, accompanied by increases in total and micropore volumes. XRD confirmed the preservation of the characteristic zeolite-Y framework after modification, with additional reflections in ZY-3 consistent with crystalline NiO. FTIR further confirmed the retention of the principal aluminosilicate framework vibrations following pretreatment and nickel incorporation. GC–MS/PIONA analysis revealed substantial changes in the hydrocarbon-class distribution following cracking. The raw gas condensate (G-1) contained 47.47% paraffins and 30.49% aromatics, while thermal cracking (G-2) produced 46.10% paraffins and 32.10% aromatics. Catalytic cracking (G-3) increased the aromatic fraction to 40.90% while reducing the paraffin fraction to 38.40%. Ni-doped catalytic cracking (G-4) resulted in 39.48% aromatics, 39.98% paraffins, and a slight increase in olefins from 0.40% to 0.91% relative to G-3. Overall, the results demonstrate that pretreatment and nickel incorporation significantly modified the textural and structural properties of zeolite-Y, while catalytic and Ni-doped catalytic cracking produced distinct changes in the gas-condensate hydrocarbon composition.

INTRODUCTION

The increasing demand for transportation fuels, petrochemical intermediates, and high-value hydrocarbon products has intensified interest in technologies that can convert and improve the efficiency of underutilized petroleum fractions into more valuable products. Among these resources, natural gas condensate is an attractive feedstock because it consists predominantly of relatively light hydrocarbons and can serve as an intermediate source of gasoline-range and petrochemical hydrocarbons. Gas condensates have attracted attention not only as blending components but also as feedstocks for catalytic upgrading, particularly where their hydrocarbon distribution can be selectively shifted toward products with improved octane quality and greater commercial value (Salim & Saed, 2023; Ganiyu et al., 2026). Recent work on Nigerian gas condensate has further demonstrated the potential of catalytic conversion over modified zeolitic materials to alter the distribution of paraffins, naphthenes, aromatics, and isoparaffins to obtain more desirable gasoline-range products (Ganiyu et al., 2026).

The conversion of petroleum-derived hydrocarbon streams is driven by competing pathways, such as thermal and catalytic cracking. While thermal cracking operates at high temperatures and often produces undesirable secondary reactions, such as excessive coke and gas, catalytic cracking offers better product control at lower temperatures. Ultimately, the specific pore architecture, acidity, and stability of zeolite catalysts determine the exact cracking pathways and product selectivity for complex feeds (Wei et al., 2025; Magaji et al., 2024).

Zeolites are highly attractive catalytic materials for hydrocarbon upgrading because their crystalline frameworks combine tunable acidity with precise microporous structures that ensure shape selectivity while promoting key chemical reactions. Despite these benefits, narrow micropores often impose severe diffusion limitations when handling large or complex petroleum fractions, thereby restricting access to internal acid sites and increasing both secondary reactions and coke deposition (Dong et al., 2024; Wei et al., 2025). Zeolite-Y is widely used in petroleum refining due to its large-pore architecture and established role in fluid catalytic cracking, yet even conventional zeolite Y topologies face mass-transport constraints when processing bulky hydrocarbon feeds. To mitigate these transport limitations, current research focuses on designing hierarchical Y zeolites that combine intrinsic micropores with larger mesoporous pathways to balance selectivity, molecular transport, and structural stability. Recent studies have demonstrated that hydrothermal and post-synthetic modifications of Y zeolites successfully engineer these hierarchical networks, thereby significantly improving acid-site accessibility and hydrocracking performance (Zhou et al., 2024; Wei et al., 2023).

The incorporation of nickel into zeolitic materials introduces additional metal-associated functionalities that can complement the intrinsic acidity of the zeolite, thereby influencing hydrocarbon conversion and product distribution through synergistic metal–acid interactions.. The interaction between nickel and the framework directly influences acidity, active site dispersion, and accessibility. Recent work has demonstrated that nickel-modified hierarchical zeolites enhance hydrocracking performance and mass transfer by combining metal functionality with interconnected larger pores rather than relying on metal loading alone (Zhang et al., 2024; Hu et al., 2024).

Despite these advances, an important gap remains in understanding how controlled Zeolite Y pretreatment, followed by nickel incorporation, affects the structural characteristics required for the catalytic cracking of actual gas condensates, particularly under continuous-flow conditions. Most existing studies focus on modeling hydrocarbons or heavier feeds, overlooking the integrated relationship between modified Zeolite Y, nickel active sites, and complex condensate streams. This study addresses these limitations by systematically examining the structure-property relationship of raw, pretreated, and Ni-modified Zeolite Y and its effect on pore accessibility and hydrocarbon transformation.

2. MATERIALS AND METHODS

2.1 Materials

The materials used in this study included commercial zeolite-Y, nickel nitrate hexahydrate ($Ni(NO_3)_2 \cdot 6H_2O$), sodium hydroxide (NaOH), ammonium chloride (NH_4Cl), deionized water, nitrogen (N_2), glass beads, and gas condensate. Commercial zeolite-Y (ZY-1) was used as the parent material for the preparation of the pretreated zeolite-Y (ZY-2) and Ni-doped zeolite-Y (ZY-3) catalysts. Nickel nitrate hexahydrate was used as the nickel precursor, while NaOH and NH_4Cl were employed during the alkaline treatment and conversion of the zeolite to the acidic H-form, respectively. Deionized water was used to prepare the treatment and precursor solutions, while glass beads served as an inert packing material in the fixed-bed reactor. Nitrogen was used as the carrier/diluent gas during the cracking experiments.

The gas-condensate feedstock was obtained from the Ogunu field in the Niger Delta region of Nigeria**.** The raw gas condensate was designated **G-1**, while the products obtained after thermal cracking, catalytic cracking over ZY-2, and catalytic cracking over ZY-3 were designated G-2, G-3, and G-4, respectively. All materials and reagents were used as received, unless otherwise stated.

2.2 Catalyst Preparation

2.2.1 Preparation of Pretreated Zeolite-Y (ZY-2)

Commercial zeolite-Y (20 g) was initially calcined in a muffle furnace at 550 °C for 5 h. The calcined zeolite was subsequently treated with 100 mL of 0.5 M NaOH solution at 70 °C for 2 h under continuous stirring. After alkaline treatment, the solid was repeatedly washed and centrifuged with deionized water while monitoring the pH until neutrality (pH 7) was achieved. The washed material was dried at 90 °C for 1 h and subsequently converted to the acidic H-form by treatment with 100 mL of 0.5 M NH_4Cl solution at 70 °C for 3 h under continuous stirring. The resulting material was dried at 100 °C for 2 h and calcined at 550 °C for 5 h to obtain the pretreated zeolite-Y, designated ZY-2.

2.2.2 Preparation of Ni-Doped Zeolite-Y (ZY-3)

Nickel-doped zeolite-Y was prepared using the incipient-wetness impregnation (IWI) method using $Ni(NO_3)_2 \cdot 6H_2O$ as the nickel precursor. The required quantity of $Ni(NO_3)_2 \cdot 6H_2O$ was calculated to obtain a target nickel loading of 5 wt.% and dissolved in 100 mL of deionized water. The resulting solution was added dropwise to the pretreated zeolite-Y (ZY-2) under continuous stirring and subsequently aged for 4 h at ambient conditions. The impregnated material was dried at 120 °C for 12 h and then calcined at 550 °C for 4 h to obtain the Ni-doped zeolite-Y catalyst, designated as ZY-3.

2.2.3 Catalyst Characterization

The structural and textural properties of the prepared catalysts were evaluated using powder X-ray diffraction (XRD), Fourier-transform infrared spectroscopy (FT-IR), and nitrogen (N_2) adsorption–desorption analysis. Analyses were performed on raw Zeolite-Y (**ZY-1**), pretreated Zeolite-Y (**ZY-2**), and Ni-doped Zeolite-Y (**ZY-3**) to determine the effects of pretreatment and nickel incorporation on the zeolite structure and textural properties.

Powder X-ray diffraction (XRD) patterns were recorded using a PANalytical X'Pert PRO MPD diffractometer equipped with Cu Kα radiation ($\lambda = 0.1541$ nm), operated at 40 kV and 30 mA, over a 2θ range of 5–60° at room temperature. The diffraction patterns were used to identify the characteristic crystalline phases and assess changes in the crystallinity and structural integrity of the Zeolite-Y framework following pretreatment and Ni incorporation.

The Fourier transform infrared (FT-IR) spectra of ZY-1, ZY-2, and ZY-3 were obtained using an Agilent MicroLab instrument to identify characteristic zeolite framework vibrations and surface functional groups. The spectra were compared to identify changes in the zeolite's structural features resulting from alkaline treatment, conversion to the acidic form, and subsequent nickel incorporation.

N_2 adsorption–desorption measurements were conducted using an ASAP 2020 V4.02 analyser at 77 K to determine the textural properties of the catalysts. Before analysis, each sample was evacuated under vacuum at 573 K for 8 h. The BET method was used to determine the specific surface area. The total pore volume was determined from the amount of nitrogen adsorbed at $P/P_0 = 0.9915$, while the pore-size characteristics were obtained from the adsorption–desorption data.

2.3 Catalytic Cracking of Gas Condensate

The catalytic cracking of gas condensate was conducted at atmospheric pressure in a continuous-flow fixed-bed reactor using nitrogen (N_2) as the carrier/diluent gas. Prior to each experiment, the reactor bed was purged under a continuous N_2 flow of 400 mL/min at 550 °C for 1 h. The N_2 supply pressure was maintained at 3 bar at the regulator, whereas the reactor itself remained at atmospheric pressure.

Thermal cracking was first conducted under the same reaction conditions to provide a baseline for comparison with catalytic cracking. Both thermal and catalytic experiments were performed at 550 °C, atmospheric pressure, and reaction duration of 1 h. For the catalytic experiments, 0.5 g of either ZY-2 or ZY-3 was mixed with 0.5 g of glass beads and packed into the reactor. The gas-condensate feed was introduced continuously using a positive-displacement peristaltic pump at 4 mL/min, while the N_2 flow rate was maintained at 400 mL/min. The heating lines were maintained at 100 °C.

The reactor effluent was passed through a condenser maintained at 2.5 °C to recover the condensable liquid products, while the uncondensed gaseous products were collected in a gas collection bag. The condensed liquid products were subsequently analyzed using an Agilent 7890 gas chromatograph equipped with a DB-624 capillary column**.** The identified compounds were subsequently classified according to the PIONA groups (paraffins, isoparaffins, olefins, naphthenes, and aromatics).

The apparent liquid recovery was calculated as the ratio of the recovered condensable liquid to the total feed introduced, as expressed in Equation (1):

$$\text{Liquid recovery}(\%) = \frac{V_{Liquid\ recovered}}{V_{feed}}$$

3.0 RESULTS AND DISCUSSION

3.1 Surface Functional Group Analysis

The FTIR spectra for raw Zeolite-Y (ZY-1), pretreated (ZY-2), and Ni-doped (ZY-3) are shown in Figure 1. The FTIR spectrum of raw zeolite-Y (ZY-1), recorded over approximately 400–4000 cm^{-1}, exhibited the characteristic vibrational features of an aluminosilicate zeolite, with prominent bands at approximately 459, 529, 613, 837, 1080, 1209, 1408, and 1645 cm^{-1}. The strong absorption near 1080 cm^{-1} is attributed mainly to the asymmetric stretching of the Si–O–Si/Si–O–Al framework, while the bands in the lower wavenumber region arise from framework bending and deformation vibrations. Such bands are characteristic of zeolitic aluminosilicate structures and are widely used to evaluate changes in their framework chemistry (Eren et al., 2024). The absorption near 1645 cm^{-1}, together with the broad O–H stretching region around 3400 cm^{-1}, is associated with H–O–H bending and O–H stretching of adsorbed water and surface hydroxyl species. Water-related absorption around 1650 cm^{-1} is commonly observed in zeolitic materials because of their ability to retain physically adsorbed water within their porous structure (Uygun et al., 2023). The ZY-1 spectrum represents the characteristic aluminosilicate framework and hydrated surface environment of the starting zeolite-Y.

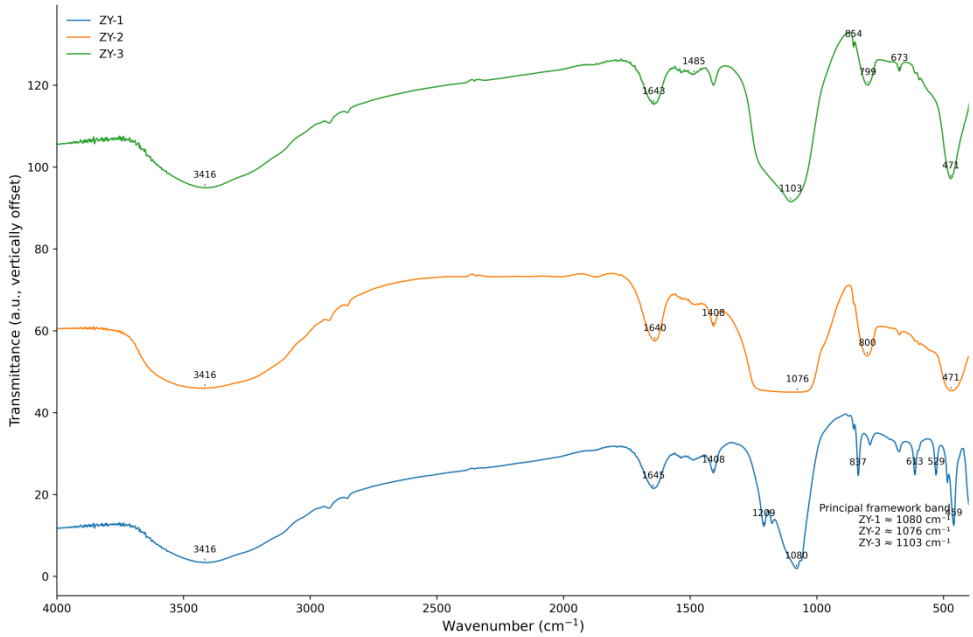

Figure 1: The FTIR spectra for raw Zeolite-Y (ZY-1), pretreated (ZY-2) and Ni-doped (ZY-3)

Following pretreatment, ZY-2 retained the principal framework vibrations observed in ZY-1, indicating preservation of the characteristic aluminosilicate structure. The most notable change was a small displacement of the principal framework-stretching band from approximately 1080.17 cm^{-1} in

ZY-1 to 1076.32 cm^{-1} in ZY-2, corresponding to a shift of approximately 4 cm^{-1} toward lower wavenumbers. This displacement indicates a change in the local chemical environment of the aluminosilicate framework following pretreatment and may reflect the redistribution or modification of the framework-associated and extraframework species. The water-associated band also shifted from approximately 1645.34 cm^{-1} in ZY-1 to 1639.55 cm^{-1} in ZY-2, suggesting a change in the amount or environment of adsorbed water. Importantly, the persistence of the major framework bands indicates that pretreatment modified the chemical environment of the zeolite without eliminating its characteristic aluminosilicate structure. This interpretation is consistent with recent studies showing that chemical treatment of zeolitic materials can alter framework associated species and surface chemistry while retaining identifiable zeolitic vibrational features (Eren et al., 2024).

The incorporation of nickel produced a more pronounced change in the FTIR spectrum, with the principal framework stretching band shifting from 1076.32 cm^{-1} in ZY-2 to 1103.32 cm^{-1} in ZY-3, indicating a change in the local aluminosilicate environment. Nevertheless, the characteristic framework vibrations remained evident, suggesting preservation of the zeolitic structure. The H–O–H bending band was also retained near 1643.41 cm^{-1}, indicating the continued presence of adsorbed water. Similar Ni zeolites have shown that Ni incorporation can modify the local metal support environment without necessarily disrupting the zeolite framework (Zhang et al., 2024).

3.2 Crystalline Phase and Structural Analysis

The XRD pattern of ZY-1 (Figure 2) displayed the characteristic reflections of the faujasite (FAU) type zeolite-Y framework. Prominent reflections were observed at approximately 6.5°, 10.5°, 12.3°, 16.1°, 19.2°, 20.9°, 24.3°, 27.7° and 32.1°**,** confirming the crystalline nature of the starting material. The characteristic low-angle and high-angle reflections are consistent with the established diffraction pattern of FAU type zeolites and provide a suitable structural reference for assessing the effects of subsequent modification. Manrique et al. (2024) similarly used the persistence and intensity of characteristic zeolite Y reflections to evaluate the structural integrity following chemical modification.

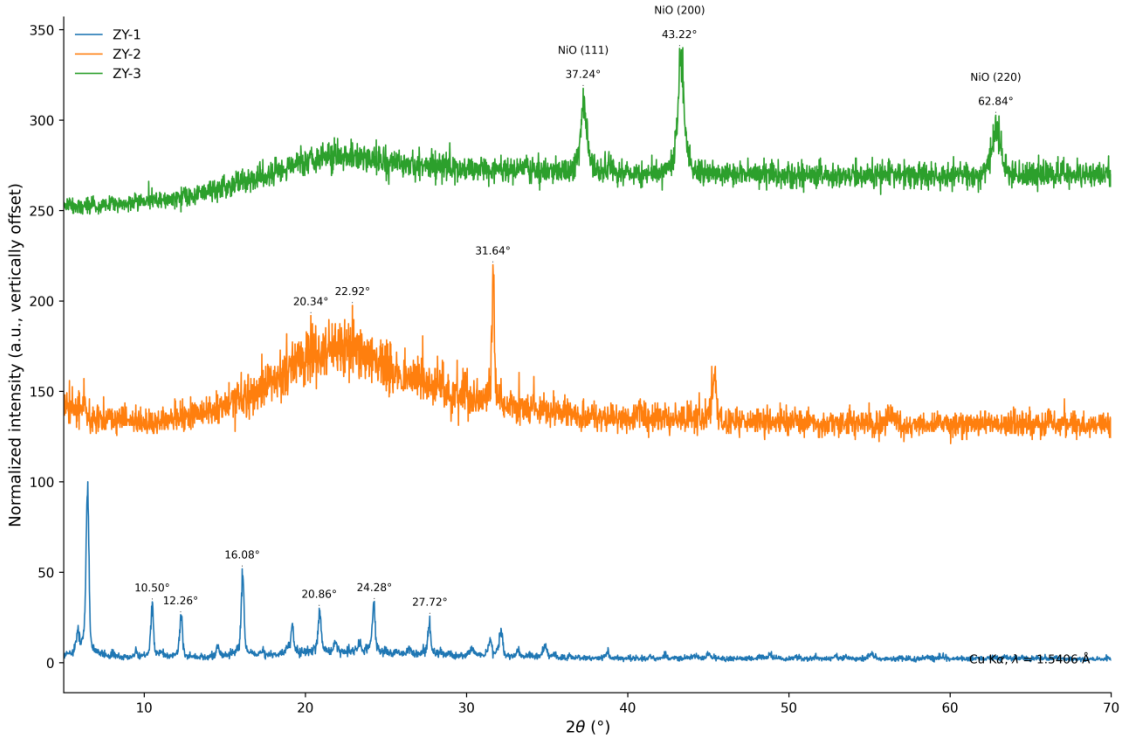

Figure 2: The XRD profiles for raw Zeolite-Y (ZY-1), pretreated (ZY-2) and Ni-doped (ZY-3)

After pretreatment, the sharp, multi-peak reflections observed in ZY-1 were largely replaced in ZY-2 by a broad amorphous hump, with only weak shoulder features near 20.3° and 22.9°. This indicates a substantial loss of long-range crystalline order following alkaline treatment. The changes in diffraction intensity may reflect alterations in framework ordering, extraframework species, or crystallite characteristics resulting from pretreatment. Similar observations have been reported for chemically modified zeolite Y, where changes in diffraction intensity can accompany structural modification, while the principal zeolitic framework remains detectable (Manrique et al., 2024). The observed changes can be more appropriately described as structural modifications with partial loss of the crystalline zeolite-Y framework.

In Ni-doped zeolite-Y, the diffractogram likewise shows a broad amorphous background.. In addition, new reflections appeared at approximately 37.2°, 43.4°, and 62.8°**,** corresponding to the (111), (200), and (220) planes of crystalline NiO, respectively, which is in agreement with the reported NiO diffraction patterns (Miskan et al., 2024; Zhang et al., 2024). The coexistence of partial zeolite-Y framework and NiO reflections indicates that nickel modification introduced a detectable crystalline NiO phase in the catalyst. However, the presence of NiO peaks does not necessarily mean that all nickel occurs as crystalline NiO, since highly dispersed or poorly crystalline Ni species may remain undetectable by conventional XRD.

3.3 Surface Area and Pore Structure

The textural properties of ZY-1, ZY-2, and ZY-3 (Table 1) showed clear evolution in accessible porosity following pretreatment and Ni incorporation. The BET surface area increased from 181.549 m^2/g for ZY-1 to 245.368 m^2/g for ZY-2, representing an increase of approximately 35.2%**,** while the total pore volume increased from 0.096 to 0.133 cm^3/g. This indicates that the pretreatment substantially increased the accessible surface area and pore volume of the zeolite. This behaviour may be associated with the generation or opening of secondary pore environments through alkaline modification, thereby improving access to the intrinsic microporous network. However, the accompanying loss of sharp XRD reflections indicates that the textural enhancement may not arise solely from beneficial hierarchical pore development. Partial dissolution of the zeolite framework and associated loss of crystallinity may also have contributed to the increased accessible surface area and pore volume. Thus, the combined BET and XRD results suggest that alkaline pretreatment produced enhanced textural accessibility, but with some degree of structural degradation. This balance is consistent with the need to control alkaline treatment severity, since excessive framework extraction can compromise microporosity and crystallinity (Han et al., 2024).

Table 1: Textural properties of ZY-1, ZY-2, and ZY-3.

Parameter	**ZY-1**	**ZY-2**	**ZY-3**
BET area (m^2/g)	181.549	245.368	278.956
Total pore volume (cm^3/g)	0.096	0.133	0.163
Micropore volume (cm^3/g)	0.063	0.092	0.110

The effect of nickel incorporation is also evident from the textural data. Following Ni modification, the BET surface area increased further to 278.956 m^2/g, while the total pore volume increased to 0.163 cm^3/g. The micropore volume also increased from 0.092 cm^3/g in ZY-2 to 0.110 cm^3/g in ZY-3, indicating that Ni incorporation did not cause substantial blockage of the zeolite micropore network. The simultaneous increase in the surface area and pore volume suggests that the modified catalyst retained appreciable internal accessibility after metal incorporation. Comparable studies have shown that maintaining accessible micro- and larger-pore networks in metal-modified zeolites is beneficial because the additional transport pathways can improve access to active sites and facilitate the diffusion of relatively bulky hydrocarbon molecules (Manrique et al., 2024; Hu et al., 2024).

The pore size distributions in Figure 3 further showed that the modified zeolites retained predominantly small pores. The DFT profiles showed pore width between 1.8 to 2.8 nm while the BJH adsorption profiles (insert) concentrated within approximately 1.4–2.4 nm. The DFT distributions reflected a progressive change in the pore width profile from ZY 1 through ZY 2 to ZY 3, consistent with modification of the accessible pore environment following pretreatment and Ni incorporation. However, DFT-derived distributions exhibit a pronounced minimum near 2.1 nm, whereas the BJH distributions show a continuous pore-volume contribution through this region. This difference highlights the sensitivity of calculated pore-size distributions to the underlying pore-size analysis methodology and suggests that the DFT minimum should not be interpreted directly as evidence for the absence or blockage of pores at approximately 2.1 nm. Such differences are expected because DFT based pore-size distributions depend on the selected theoretical model and kernel, which can influence the calculated position and intensity of features within the narrow micropore to mesopore range (Gor et al., 2017).

Overall, the BET results indicate a progressive improvement in textural accessibility from ZY-1 to ZY-2 to ZY-3, with the highest values observed for the Ni-modified material. When considered alongside the retained Zeolite-Y reflections observed by XRD, the increased surface area and pore volume are consistent with enhanced pore accessibility and partial development of a hierarchical pore structure, rather than complete framework destruction. This balance between additional porosity and preservation of the zeolitic framework is particularly desirable for hydrocarbon conversion because hierarchical Y zeolites can reduce diffusion limitations while retaining the catalytic functionality of the parent microporous structure (Han et al., 2024; Manrique et al., 2024).

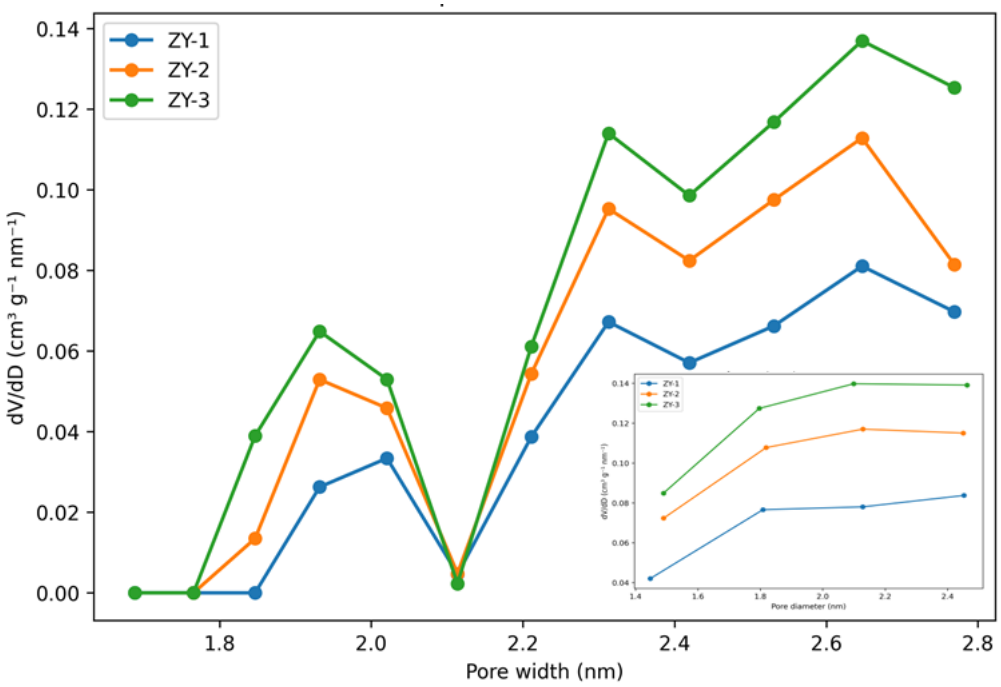

Figure 3: Catalyst pore size distributions using DFT and BJH (insert) methods

3.4 Hydrocarbon Composition and Product Distribution

Thermal treatment of the gas condensate (S1 → G-2) in Figure 4 resulted in only fractional compositional redistribution, with saturates decreasing from 67.47 to 60.80 area% and aromatics increasing from 30.49 to 32.10 area%. The persistence of the C10–C28 n-alkane series and the negligible olefin formation suggest that the thermal step resulted in limited cracking, with redistribution of existing hydrocarbons rather than extensive C–C bond scission. In contrast, the introduction of ZY-2 produced a pronounced change. The n-paraffins decreased from 46.10 to 38.40

area%, while aromatics and naphthenes increased from 32.10 to 40.90 and 3.80 to 6.70 area%, respectively. The high acidity and accessible pore structure of zeolite-Y are known to favour hydrocarbon conversion through acid-catalysed cracking, isomerisation and related secondary reactions (Ding et al., 2021).

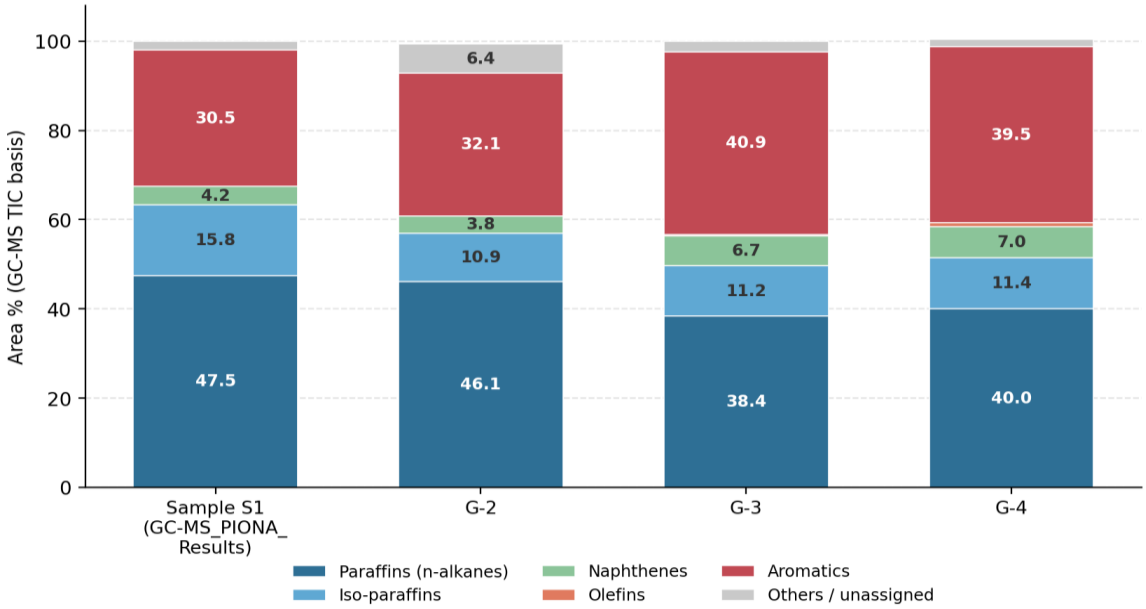

Figure 4: Composition distributions across gas condensate samples

The increase in aromatics following ZY-2 treatment is particularly significant, indicating that paraffin transformation was accompanied by cyclisation and aromatisation rather than being limited to C–C bond cleavage. Metal-modified zeolites have been shown to facilitate dehydrogenation pathways that contribute to aromatic formation (Uslamin et al., 2020), the present ZY-2 results primarily demonstrate the contribution of the acidic zeolite framework to hydrocarbon transformation.

3.5 Liquid Recovery

The apparent liquid recovery (Figure 5) decreased progressively from 25.00% for thermal cracking (G-2) to 18.33% over ZY-2 (G-3) and 14.17% over Ni-ZY-3 (G-4), corresponding to reductions of 26.7 and 43.3%, respectively, relative to thermal cracking. This decline indicates that the catalysts promoted greater transformation of the feed beyond the condensable-liquid fraction, potentially through secondary cracking to lighter non-condensable hydrocarbons. For the Ni-containing catalyst, additional reactions such as dehydrogenation and aromatization may also have contributed to the observed reduction in liquid recovery.

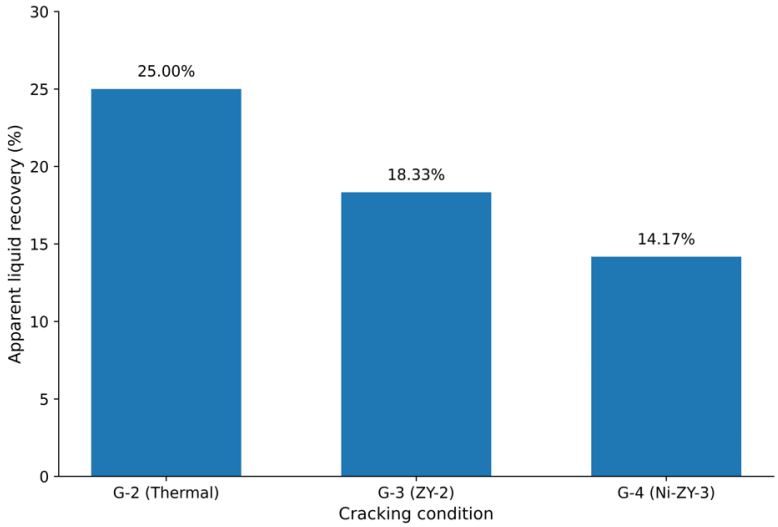

Figure 5: Apparent liquid recovery of cracking products

The lower liquid recovery is consistent with the PIONA and carbon-number distribution results, which show increased hydrocarbon transformation over the catalysts, evidenced by the reduction in n-paraffins and enrichment of aromatics and naphthenes, particularly after ZY-2 treatment. These compositional changes indicate that catalytic cracking promoted secondary reactions beyond simple C–C bond scission.

4.0 CONCLUSION

Characterization of the catalysts showed that alkaline pretreatment and nickel incorporation altered both the textural and structural properties of zeolite-Y. BET analysis indicated a progressive increase in surface area and pore volume from ZY-1 (181.5 m^2/g) to ZY-2 (245.4 m^2/g) and ZY-3 (279.0 m^2/g); however, XRD showed that this gain was accompanied by substantial loss of long-range crystalline order in ZY-2 and ZY-3, indicating that the increased porosity partly reflects framework degradation rather than purely beneficial hierarchical pore development. XRD further confirmed the formation of crystalline NiO in ZY-3, while FTIR confirmed retention of the principal aluminosilicate framework vibrations, with modest band shifts following pretreatment and nickel incorporation.

The study showed that zeolite-Y pretreatment significantly influenced gas condensate conversion, with ZY-2 promoting greater hydrocarbon redistribution toward aromatic and naphthenic products. The apparent liquid recovery also decreased from 25.00% for thermal cracking to 18.33% with ZY-2 and 14.17% with Ni-ZY-3, indicating greater transformation of the feed beyond the recovered condensable-liquid fraction. Ni incorporation produced a comparatively subtle change, including a slight increase in the olefin and naphthene fractions. Overall, the results confirmed that both zeolite modification and Ni incorporation influenced the hydrocarbon distribution during gas condensate cracking.

ABSTRACT

Density functional theory (DFT) calculations were performed to investigate the elementary reaction steps involved in methane steam reforming on Ni(111) and Pd_1–Cu(111) single-atom alloy catalyst (SAAC) surfaces. The reaction pathway includes methane and water dissociation, oxidation of CH by adsorbed oxygen to form CHO*, and subsequent dehydrogenation of CHO* to CO. The objective of this study is to evaluate the catalytic potential of the Pd_1–Cu(111) SAAC as a carbon-tolerant alternative to conventional Ni catalysts while maintaining high reforming activity. The results show that methane activation on Pd_1–Cu(111) proceeds with an activation barrier of 0.97 eV, which is 0.32 eV lower than that on Ni(111), indicating enhanced CH4 activation. In contrast, water dissociation is less favourable on Pd_1–Cu(111), with an activation barrier 0.39 eV higher than that on Ni(111). Notably, the formation of surface carbon from CH* is kinetically inhibited on the Pd_1–Cu(111) SAAC because of its substantially higher activation barrier, thereby suppressing coke formation. Overall, these findings demonstrate that the Pd_1–Cu(111) single-atom alloy effectively promotes methane activation while minimizing carbon deposition, highlighting its promise as a highly active and coke-resistant catalyst for methane steam reforming.*

1. INTRODUCTION

Methane steam reforming (MSR), $CH_4 + H_2O \rightarrow CO + 3H_2$, remains the principal industrial route to hydrogen and syngas, which underpin ammonia synthesis, methanol production, and emerging hydrogen-energy technologies (Blaylock et al., 2009). Nickel-based catalysts dominate commercial MSR because Ni combines high intrinsic activity for C–H bond activation with low cost and broad availability. However, the strong methane-activation capability of Ni also promotes sequential dehydrogenation of CH_x intermediates, particularly at low-coordination sites, leading to surface carbon accumulation and the nucleation of graphitic coke. Carbon deposition blocks active sites, alters the catalyst surface, and ultimately accelerates deactivation (Wang et al., 2017). Thermal sintering of Ni under reforming conditions further compromises catalyst stability (Che et al., 2017). These limitations have therefore driven the search for catalyst architectures that retain efficient C–H activation while suppressing the elementary steps responsible for carbon formation.

Single-atom alloys (SAAs), in which isolated catalytically active metal atoms are embedded in a less reactive host-metal surface, offer a distinctive strategy for addressing this challenge (Ibrahim et al., 2023). Site isolation can electronically and geometrically modify the reactivity of the active atom while restricting ensembles of contiguous reactive sites required for multidentate adsorption, extensive dehydrogenation, and carbon–carbon coupling (Hannagan et al., 2020). Among emerging SAA platforms, Pd–Cu systems are particularly attractive for reforming chemistry. Although Cu exhibits limited activity toward methane activation, isolated Pd atoms can provide highly reactive sites for C–H bond cleavage within an otherwise relatively inert Cu matrix (Cao et al., 2015). At the same time, the spatial isolation of Pd atoms may limit the contiguous ensembles that facilitate deep dehydrogenation and coke-precursor formation (Cao et al., 2015). Pd_1–Cu(111) thus provides a well-defined model system for determining whether single-atom site isolation can preserve the methane-activation

characteristics required for MSR while mitigating the carbon-forming chemistry inherent to conventional Ni surfaces.

The overall MSR mechanism comprises a complex network of competing elementary reactions, including CH_4 activation, H_2O dissociation, sequential CH_x dehydrogenation, oxidation of carbon-containing intermediates, and CO formation (Blaylock et al., 2011). Consequently, overall catalytic performance cannot be rationalized solely from adsorption properties or a single apparent activation barrier. Periodic density functional theory (DFT) provides a direct means of resolving these elementary processes and quantifying their reaction energies and kinetic barriers at the atomic scale (Ibrahim et al., 2024). Despite increasing interest in single-atom catalysts for hydrocarbon conversion, the mechanistic relationship between methane activation and carbon suppression on Pd_1–Cu(111) remains insufficiently established. In particular, a direct comparison of the competing CH* oxidation pathway toward CO and CH* dehydrogenation pathway toward surface carbon on Pd_1–Cu(111) and Ni(111) is lacking. Establishing this competition is essential for determining whether Pd_1–Cu(111) can overcome the activity–coking trade-off that constrains Ni-based MSR catalysts. A coke-resistant, highly active MSR catalyst is of direct relevance to Nigeria and other gas-endowed African economies, where methane steam reforming underpins existing and planned syngas, ammonia/fertilizer, and hydrogen-energy value chains built on the region's substantial natural gas reserves; catalysts that resist deactivation by carbon deposition can improve the operating economics and reliability of such reforming processes, supporting broader sustainable-energy and industrial-development objectives (Omuboye & Nweke-Eze, 2026).

This study addresses that gap using periodic DFT calculations to map the complete elementary reaction network of MSR on Ni(111) and Pd_1–Cu(111), directly comparing activation barriers for methane activation, water dissociation, and coke-forming dehydrogenation. The novelty of this work lies in demonstrating, at the mechanistic level, that Pd1–Cu(111) simultaneously lowers the barrier for methane activation and kinetically suppresses surface carbon formation relative to Ni(111), establishing a mechanistic basis for its use as a coke-resistant reforming catalyst.

2. METHODOLOGY

Periodic, spin-unrestricted DFT calculations were performed using the DMol^3 code (Delley, 2010). Exchange–correlation effects were treated within the generalized gradient approximation (GGA) using the Perdew–Burke–Ernzerhof (PBE) functional. Self-consistent field convergence was set to a threshold of 10^{-5} Ha for the total electronic energy, and geometry optimizations were converged to a maximum force criterion of 0.005 Ha Å^{-1}. Brillouin-zone integration was performed using a 4 × 4 × 1 Monkhorst–Pack k-point mesh.

The Ni(111) and Pd_1–Cu(111) single-atom alloy (SAA) surfaces were modelled using a p(3 × 3) periodic supercell of a four-layer slab. For the Pd_1–Cu(111) SAA, a single Pd atom was substituted for a Cu atom in the topmost layer of the Cu(111) slab, embedding an isolated Pd site within the Cu host. During optimization, the two uppermost slab layers were allowed to relax fully, while the two lower layers were fixed at their bulk-optimized positions to approximate bulk-like behaviour. Periodic slab images were separated by an 18 Å vacuum region along the surface normal to eliminate spurious interactions between periodic replicas.

Transition states (TS) for each elementary reaction step were located using the linear synchronous transit (LST) and quadratic synchronous transit (QST) methods, followed by conjugate-gradient refinement. Each optimized TS was confirmed by vibrational frequency analysis, requiring exactly one imaginary frequency along the reaction coordinate, corresponding to the reaction pathway. Zero-point energy (ZPE) corrections, reported as ΔE^{ZPE} and E_a^{ZPE} in Table 1, were obtained from the vibrational frequencies computed for each initial, transition, and final state and added to the corresponding electronic-energy differences. The activation energy (E_a) and reaction energy (ΔE) for each elementary step were calculated as:

$$E_a = E_{TS} - E_{IS} \quad (1)$$

$$\Delta E = E_{FS} - E_{IS} \quad (2)$$

where E_{IS}, E_{TS}, and E_{FS} are the total electronic energies of the slab system in the initial, transition, and final states, respectively. All reported E_a and ΔE values correspond to electronic-energy differences. The zero point energy (ZPE) was calculated using the following equation 3.

$$ZPE = \sum h\nu/2$$

Where h is Planck's constant and v is the vibrational frequency. Adsorbed species are denoted throughout using an asterisk (*) to indicate surface-bound intermediates: CH_4*, CH_3*, CH_2*, CH*, C*, H_2O*, OH*, O*, HCO*, COH*, CO*, COOH*, and CO_2*, consistent with standard surface-science notation.

3. RESULTS AND DISCUSSION

The reaction mechanisms of MSR on Ni(111) and Pd1–Cu(111) single-atom alloy (SAA) surfaces were systematically investigated. The kinetic parameters associated with the individual reaction steps were determined and are summarized in Table 1.

Table 1: *Activation energy and reaction energy of the reaction steps in MSR*

	elementary reaction step	Ni(111)		Pd_1-Cu(111)

3.1 Elementary reaction step kinetics

3.1.1 CH_4 Dehydrogenation

The initial C–H bond activation in methane represents a critical step in MSR because it initiates the sequential dehydrogenation of CH4 and ultimately generates surface carbon species. On the Pd1–Cu(111) single-atom alloy (SAA) surface, CH4* dehydrogenation to CH_3* is endothermic by 0.59 eV and proceeds with an activation energy of 0.97 eV. This barrier is 0.32 eV lower than that calculated for Ni(111), indicating that isolated Pd atoms embedded in the Cu surface facilitate the initial C–H bond cleavage relative to the parent Ni surface.

The subsequent dehydrogenation sequence, CH3* → CH2* → CH* → C*, remains endothermic on Pd_1–Cu(111), with reaction energies of 0.15, 0.41, and 1.22 eV, respectively. The corresponding activation energies are 1.11, 0.92, and 1.77 eV. Notably, Ni(111) exhibits lower barriers for CH_3* → CH_2* and CH_2* → CH* by 0.33 and 0.52 eV, respectively, demonstrating that Ni is kinetically more effective for these intermediate dehydrogenation steps. In contrast, the final CH* → C* step requires a 0.23 eV higher activation energy on Pd_1–Cu(111) than on Ni(111). Thus, although Pd_1–Cu(111) promotes the initial activation of methane, the subsequent conversion of CH* to atomic carbon is less kinetically favorable on the SAA surface. This distinction is important because the balance between facile methane activation and carbon formation can strongly influence both reforming activity and carbon accumulation.

3.1.2 H_2O Dissociation*

Water activation constitutes another essential elementary process in MSR because it provides surface OH* and, subsequently, O*-containing species required for carbon oxidation and CO_2 formation. Previous DFT calculations by Blaylock and co-workers (2011) reported that H_2O* dissociation on Ni(111) is exothermic by 0.28 eV with an activation energy of 0.90 eV [Blaylock et al., 2011]. In the present calculations, H2O* → OH* + H* on Ni(111) is also exothermic, with a reaction energy of −0.22 eV, while the corresponding activation energy is 0.71 eV. In contrast, H_2O* dissociation on Pd_1–Cu(111) is endothermic by 0.14 eV and requires an activation energy 0.39 eV higher than that on Ni(111). The subsequent OH* → O* + H* step exhibits activation energies of 1.01 and 1.11 eV on Ni(111) and Pd1–Cu(111), respectively. The Ni(111) value is consistent with previous DFT calculations reported by Du and co-workers (Du et al., 2017) . These results indicate that, unlike the initial C–H bond cleavage in CH4, water activation is kinetically more favorable on Ni(111). Consequently, the overall reforming performance of Pd1–Cu(111) may depend strongly on the availability and reactivity of adsorbed hydroxyl species.

3.1.3 COH and HCO* Formation*

Following methane dehydrogenation, surface carbon-containing intermediates can undergo oxidation through reactions with oxygen-containing species. The oxidation of CH* to HCO* on Pd_1–Cu(111) is highly exothermic, releasing 1.82 eV, and proceeds with a relatively low activation energy of 0.41 eV. This barrier is 0.79 eV lower than that calculated for Ni(111), indicating that the SAA surface strongly facilitates this oxidation route. COH* can alternatively form through the recombination of C* and OH*. The strongly exothermic character of this reaction on both surfaces indicates that COH* formation is thermodynamically favourable, although its overall contribution to MSR must also be assessed from the corresponding kinetic barriers.

3.1.4 CO Formation*

CO* represents a key product intermediate in MSR and can form through several competing pathways. One route involves the recombination of C* and O*, whereas alternative routes proceed through the decomposition of HCO* or COH*. On Ni(111), C* + O* → CO* is strongly exothermic, with a reaction energy of −1.92 eV, but requires an activation energy of 1.08 eV, consistent with previous theoretical studies. The corresponding barrier on Pd1–Cu(111) decreases to 0.73 eV, demonstrating that the SAA surface facilitates CO* formation through direct C–O coupling. The decomposition of HCO* provides another kinetically accessible route. On Ni(111), HCO* → CO* + H* is exothermic and has a very low activation energy of 0.11 eV, consistent with the value reported for Ni-based surfaces by Blaylock and co-workers [Blaylock et al., 2011]. On Pd1–Cu(111), however, the barrier increases by 0.34 eV, indicating that HCO* decomposition is less favorable on the SAA. COH* decomposition to CO* also proceeds with a moderate activation energy on Pd1–Cu(111), calculated as 0.75 eV, while the reaction remains exothermic by 0.35 eV. Collectively, these results demonstrate that Pd1–Cu(111) favors direct C–O coupling over HCO* decomposition, whereas Ni(111) provides a particularly facile pathway through HCO*.

3.1.4 COOH and CO_2* Formation*

COOH* formation represents a subsequent oxidation pathway toward CO_2*. On Ni(111), the interaction of CO* with OH* to form COOH* is endothermic by 0.63 eV and requires an activation energy of 1.40 eV. On Pd_1–Cu(111), the same reaction is substantially more accessible, with a lower activation energy of 0.69 eV and a smaller endothermicity of 0.46 eV. Thus, the SAA surface

significantly facilitates COOH* formation relative to Ni(111). CO2* can subsequently form through either direct oxidation of CO* by O* or dissociation of COOH* via O–H bond cleavage. On Ni(111), the CO* + O* → CO2* pathway is endothermic by 0.66 eV and has an activation energy of 1.09 eV, in agreement with previous calculations [Blaylock et al., 2009]. In striking contrast, CO oxidation on Pd1–Cu(111) is exothermic by 1.04 eV and requires only 0.45 eV of activation energy. Although COOH* dissociation to CO2* is also exothermic on Pd_1–Cu(111) by 0.46 eV, the direct CO* oxidation pathway remains kinetically preferred because it proceeds with the lower activation barrier. These results highlight a pronounced mechanistic difference between the two surfaces: Ni(111) relies more strongly on sequential COOH*-mediated oxidation, whereas Pd_1–Cu(111) promotes direct CO oxidation to CO2*. This altered reaction landscape illustrates how isolated Pd atoms can modify both the thermodynamics and kinetics of oxygen-assisted carbon oxidation on Cu-based SAA surfaces.

4. CONCLUSION

Periodic density functional theory calculations were employed to elucidate and compare the elementary reaction network of methane steam reforming on Ni(111) and Pd_1–Cu(111) single-atom alloy surfaces. The results identify a key mechanistic advantage of Pd_1–Cu(111) as it lowers the CH_4* activation barrier to 0.97 eV, 0.32 eV below that of Ni(111), while increasing the barrier for the coke-precursor-forming CH* → C* step to 1.77 eV. This combination facilitates methane activation while kinetically suppressing surface carbon formation. Pd_1–Cu(111) nevertheless exhibits a clear water-activation penalty, with higher barriers for both H_2O* → OH* and OH* → O* formation, potentially limiting the availability of oxygen-derived intermediates. Importantly, once generated, these species promote a low-barrier CH* → HCO* pathway, redirecting reactive carbon away from C* accumulation and toward CO formation. However, because water dissociation is itself less favorable on Pd_1–Cu(111), the supply of OH*/O* needed to sustain this carbon-oxidation route may itself become rate-limiting under working conditions, so the coke-suppression advantage identified here should be regarded as a mechanistic, elementary-step result rather than a demonstrated gain in overall turnover frequency; a full microkinetic treatment would be required to establish the net effect on catalytic performance. Overall, Pd_1–Cu(111) emerges as a mechanistically promising, potentially carbon-tolerant alternative to conventional Ni catalysts. These findings provide a molecular basis for designing SAA catalysts that balance methane activation, water dissociation, and coke resistance under realistic MSR conditions.

ABSTRACT

Filtration control is an essential activity during drilling because excessive fluid loss to permeable formation causes wellbore instability, acute drilling performance, differential pipe sticking and formation damage. In this study, Low-Temperature Low-Pressure (LTLP) Filtration Properties of Drilling Mud Formulated from Nigerian Arawa Bentonite Clay was investigated. Filtrate loss, spurt loss and leak-off coefficients for API base, API Standard, raw Arawa, Arawa base, Arawa standard and Arawa standard treated with sub-micron calcium carbonate formulation was evaluated using API low temperature filter press at 100 psi at room temperature. Filtrate volume was measured as a function of time up to 30 minutes while spurt loss (Vs) and leak-off coefficient (K) were determined by fitting the experimental data into Carter filtration model. The results have shown that API base, API Standard, raw Arawa, Arawa base, Arawa standard formulation and Arawa standard formulation treated with sub-micron calcium carbonate formulation have LTLP fluid loss of 8ml, 7.6ml, 14ml, 12ml, 8.6ml, and 7.8ml respectively making the fluid loss within API standard requirement of ≤15ml. The formulations have shown spurt loss of 6.7423x10^{-16}ml, 4.86 x10^{-16}ml, 9.9449 x10^{-16}ml, 1.0337 x10^{-16}ml, 3.7923 x10^{-17}ml and 5.7679 x10^{-17}ml respectively, and leak-off coefficient of 1.46ml.min$^{-1/2}$, 1.37ml.min$^{-1/2}$, 2.49ml.min$^{-1/2}$, 2.12ml.min$^{-1/2}$, 1.49ml.min$^{-1/2}$ and 1.34ml.min$^{-1/2}$ respectively. The model performance statistics have shown good correlation between Experimental and model parameters with average R-square, adjusted R-square and Sum of Square Error (SSE) of 0.97697, 0.97121and 0.5 respectively. The study demonstrates the potential of beneficiated and standardized Nigerian Arawa bentonite clay as locally sourced constituents of drilling mud for Oil and Gas drilling application.

Keywords: *Drilling mud; LTLP; bentonite; Carter model; API; spurt loss (Vs); leak-off coefficient and R-square*

1. INTRODUCTION

Drilling mud is critical to drilling operations. It performs essential functions such as cuttings transport, protection of oil and gas production zone, cooling and lubrication drill bit, ensuring wellbore stability, filtration control, and controlling formation pressure. Among these, filtration control is particularly important because excessive filtrate invasion into the formation can cause formation damage especially in water-sensitive shales, cause wellbore instability, and differential sticking and ultimately affecting drilling efficiency (Agwu *et al.*, 2021). Filtration performance of drilling mud is commonly evaluated under low-temperature low-pressure (LTLP) and high-temperature high-pressure (HTHP) conditions to mimic surface and downhole environments, respectively (Sun *et al.*,2026).

For low-temperature low-pressure, filtrate loss, spurt loss and leak-off coefficient are important parameters in LTLP filtration. While filtrate loss is the cumulative amount of filtrate lost to the formation during specific time of filtration, spurt loss is the filtrate loss to the formation before an effective filter cake formation. Leak-off coefficient which is a function of filter cake permeability is the rate or ease with which the filtrate is lost to the formation during cake-controlled filtration (Fu and Liu, 2019). It is proportional to the square root of time (Shad *et al.*, 2021).

For LTLP oil and gas drilling application, water-based drilling muds (WBMs) are widely used due to their environmental compatibility and lower cost compared to oil-based muds (OBMs) and synthetic-based muds (SBM); however, their performance strongly depends on the properties of the bentonite clay used, reservoir characteristics and formation temperature and pressure (Singh *et al.*,2026).

Bentonite clay which is primarily composed of montmorillonite as major clay mineral, is the most common viscosifier and filtration control component of drilling mud due to its swelling and colloidal characteristics. Nevertheless, bentonite clay deposits in Nigeria are predominantly calcium-based (Igwilo *et al.*,2020), which exhibit lower swelling capacity and inferior filtration performance compared to sodium-based bentonite (Bilal *et al.*,2016; Okorie *et al.*, 2021). Consequently, beneficiation and activated may be required to meet the standard of a sodium-based bentonite. Hence, use of locally sourced clay could potentially reduce dependence of imported drilling-grade bentonite for oil and gas drilling in Nigeria.

Many research works have focused on rheological and physiochemical properties of Nigerian bentonite; limited attention has been given to filtration properties of locally sourced bentonite. Therefore, this study investigates LTLP filtration properties of drilling mud formulated from indigenous Nigerian bentonite. Experimental filtration tests conducted under LTLP conditions would be used to evaluate the fluid loss, spurt loss and fluid leak-off coefficient. The findings also aim to support the development of cost-effective, locally sourced drilling mud as viable alternatives to imported bentonite.

2. METHODOLOGY

2.1 Sample Collection and Preparation

Samples of the raw bentonite clay were collected by removing the overburden material from Arawa bentonite clay location in Arawa, Gombe state. The collected clay sample were brought to laboratory, dried, crushed and pulverized using jaw crusher and ball mill machine respectively. The ball milled sample is sieved using 200 mesh size to give 63 µm based on API 13A specification for drilling mud materials

2.2 Determination of Cation Exchange Capacity (CEC) of Clay

Methylene blue test was used to determine the clay cation exchange capacity based on Equation 1. This procedure was adopted from Bilal *et al.,* 2016.

$$CEC\left(\frac{meq}{100}\right) = \frac{V * N * 100}{W} * 100 \quad (1)$$

V=Volume of methylene solution used (mL)

N= Normality of methylene blue solution used in titration (mol/L)

W= Weight of dry clay sample (g)

2.3 Clay Beneficiation and Activation

The bentonite clay after wet beneficiation was allowed to settle, and the supernant water layer was discarded after leaving it to stand for 48 hours. Then finally the solid clay was dried in oven at 60 ^{o}C for 48 hours to completely dry the samples ready for soda activation.

Soda activation was done by adding an equivalent quantity of NaOH based on the cation exchange capacity (CEC) of the clay. The cation exchange capacity of the raw clay is 34 meq/100g of clay and was found to increase to 74 meq/100g of clay after activation. This method is a noble approach in which the property of the clay compares closely with that of an optimum quantity of soda in an iterative method. The calculation of amount of soda based on x meq/100g of clay CEC is shown below.

Therefore, for a clay with CEC of y meq/100 g of clay, it has been established that x mol of Na^{+} is needed to activate w g of the clay sample as shown in Equation 2. Therefore, for 11.58g of clay, 0.156g of NaOH is needed to activate the clay.

$$x\ mol = y*w*10^{-5} \quad (2)$$

2.4 Drilling mud formulation

One laboratory barrel (350 ml) of drilling mud was formulated using API grade and Arawa bentonite clay according to the formulation in Table 1. The samples are; API base formulation, API standard formulation, Raw formulation, base formulation (formulation with soda activated clay only), standard formulation with micro size reduced calcium carbonate, standard formulation with sub micro size calcium carbonate. The sub micro size calcium carbonate was formed by mechanically reducing the micro size calcium carbonate to particle size less than 1µm in size. Table 1 shows adopted mud formulation based on the nomenclature. The mud components where mixed by measuring the required water volume and adding the NaOH to ensure pH is between 8.5-10 because Xanthan gum and PAC mix well in the pH range. This is then followed by addition of bentonite and polymer (PAC and Xanthan). This order is to avoid 'fisheyes' formation in the mud mixer cup as explained by Agwu *et al.*,2021 and other components were then added. The formulation was then mixed using a Hamilton Beach mixer for 10 min and aged for 24 hours as done by Ruosh *et al.*,2025.

Table 1: Mud formulation

Additive	**Wt. %**	**Mass (g)**
Water	69.48	243.16
Bentonite	3.31	11.58
NaOH	0.02	0.06
XG	0.22	0.77
PAC	0.51	1.79
Barite	22.06	77.19
$CaCO_3$	4.41	15.44
Total	**100**	**350**

2.5 Determination of Low Temperature Low Pressure Filtration Properties

After drilling mud formulation, the next thing is to characterise the mud by determining its filtration properties.

2.5.1 Determination of low temperature low pressure (LTLP) fluid loss (FL)

Low temperature low pressure API filter press was used for fluid loss measurement in accordance with API RP 13B-1 procedure. The sample drilling mud was poured into the API filter press cell to 350 ml of the O-ring ledge mark while ensuring that all spilled fluid was cleaned along the gasket edge. The filter press cell was assembled ensuring that the filter paper on the gasket was properly seated to prevent leakage, and the top cap was securely fixed. A graduated cylinder placed under the drain tube to collect the filtrate. Differential pressure of 100 psi supplied by hand pump to the filter cell through a regulator and the filtrate collected over a period of 30 minutes at 5 minutes interval.

2.5.2 Determination of spurt loss and leak-off coefficient

The spurt loss (Vs) and K were determined by fitting the experimental data generated in Section 3.1 into Carter filtration model (Modified Darcy filtration model) as shown in Table 2. The data was fitted into Equation 3 (Carter filtration model). The data was fitted using a generated MATLAB code. R-square, adjusted R-square and Sum of square error were used to determine goodness of fit for the data.

$$V(t)=Vs+K\sqrt{t} \tag{3}$$

V(t)=Filtrate loss after time t
Vs=Spurt loss
K= Leak-off coefficient.

3. RESULTS AND DISCUSSION

3.1 Filtrate Loss

The fluid loss for API base, API standard (API STD), Arawa raw, Arawa base and Arawa standard (Arawa STD) and Arawa standard formulation (Arawa STD+X) is shown in Table 2

It can be seen from the table that API base has higher fluid loss than API standard across all time step due to enhancement of the mud formulation. Similar trend was observed for Arawa bentonite formulation as the raw sample is enhanced by soda activation and ultimately treated with sub-micron calcium carbonate.

Table 2: Fluid loss (FL) for API and Arawa bentonite formulation

Time(min)	$\sqrt{t}$ (min$^{1/2}$)	API Base FL (ml)	API STD FL (ml)	Arawa Raw FL (ml)	Arawa Base FL (ml)	Arawa STD FL (ml)	Arawa STD+X FL (ml)
5	2.236	3	2.8	5.5	4.5	2.8	2.5
10	3.162	4	3.8	7.5	6.5	4.5	4
15	3.873	6	5.7	9.5	8	5.5	5
20	4.472	6.5	6.2	11	9.5	6.5	5.8
25	5	7.5	7	12.5	10.5	7.6	6.8
30	5.477	8	7.6	14	12	8.6	7.8

Comparison of Low Temperature-Low Pressure filtrate loss for API base formulation, API standard (API STD) formulation, raw Arawa formulation, standard Arawa formulation (Arawa STD), standard formulation treated with sub-micron $CaCO_3$ (Arawa STD+X). The result is presented in Figure1 .

From Figure 1, if can deduced that API base formulation has LTLP fluid loss of 8 ml after a cumulative filtration of 30min. The fluid loss is within API requirement of ≤15 ml for drilling grade bentonite. The value is in comparison with finding of Ruosh *et al.,*2025 who reported for water-based mud low temperature fluid loss of 5.9 ml and 5.6 ml at optimum concentration of 0.9% for polyanionic cellulose and Xanthan gum respectively. However, after standardization, API standard (API STD) formulation was found to have a fluid loss of 7.6 ml. The reduction was because of plugging of pore spaces by micro calcium carbonate that was used in the formulation.

Raw Arawa formulation has shown filtrate loss of 14ml indicating poor filtration control. This is due to untreated nature of the Arawa bentonite clay sample making it have low hydration. The higher fluid loss for the raw Arawa bentonite is an indication of that filter cake formed is highly permeable. Hence, high leak-off coefficient is expected.

After soda activation, Arawa base formulation was found to have fluid loss of 12 ml. This reduction could be as result of improved clay hydration caused by soda activation. This value did not completely match that of API base and API standard formulation. The higher value demonstrated by Arawa base formulation when compared to API base and API standard formulation indicates that more of the continuous phase was lost through the filter cake of the Arawa base formulation.

Furthermore, standardization of soda activated Arawa bentonite (Arawa STD) and treatment with sub micron calcium carbonate (Arawa STD+X), fluid loss of 8.6 ml and 7.8 ml. The fluid loss of after treatment with sub micron calcium carbonate matches that API standard formulation. The decrease demonstrate the plugging capacity of the smaller particles of calcium carbonate as explained by Karakosta *et al.,*2021. When compared to raw Arawa bentonite formulation, the fluid loss decreased by approximately 38.6% and 44.3% Arawa standard and Arawa Standard formulation treated with sub-micron calcium carbonate which tallies with the finding of Al-Shargabi *et al.,* 2022.

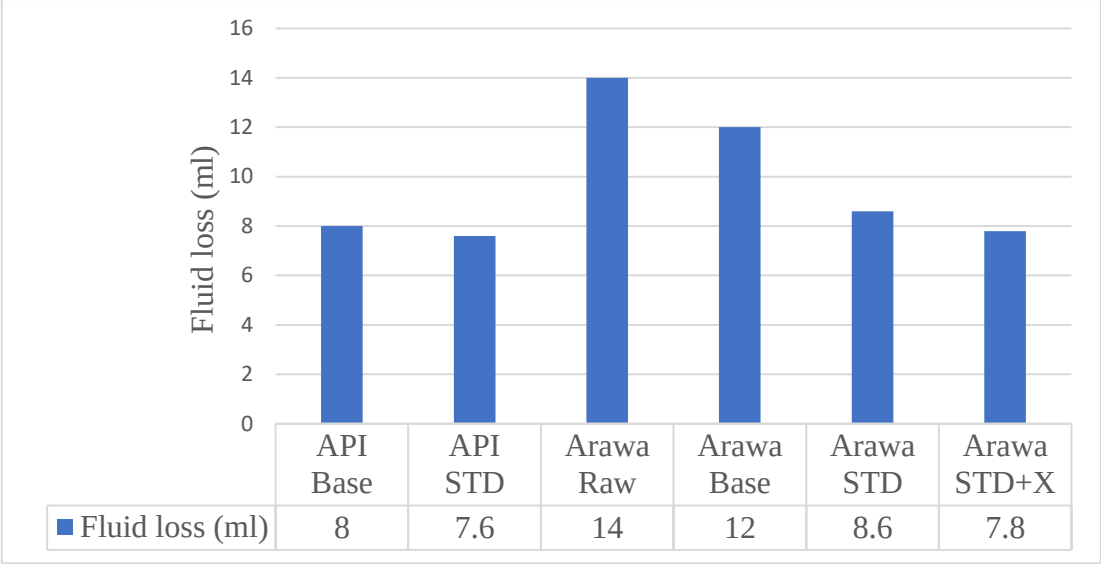

Figure 1: Low Temperature-Low Pressure filtrate loss for API and Arawa formulation

Spurt loss, leak-off coefficient and correlation coefficients for fitted fluid loss data is shown in Table 3 as deduced from Table 2. It was observed that API base and API STD formulation has spurt loss of $6.74x10^{-16}$ ml which reduced to $4.86x10^{-16}$ml for API standard formulation with corresponding decrease in leak-off coefficient from 1.46 $mlmin^{-1/2}$ to 1.38 $mlmin^{-1/2}$ due to formation of lower permeability filter cake standardization.

For Arawa bentonite formulation, the spurt loss was found to be $9.94x10^{-16}$ ml for raw formulation and decreased to $1.03x10^{-16}$ ml, $3.79x10^{-17}$ ml and to $5.77x10^{-17}$ ml for base, standard and sub-micron calcium carbonate treated formulation respectively. The decrease in leak of coefficient from 2.49 $mlmin^{-1/2}$ to 2.12 $mlmin^{-1/2}$, 1.49 $mlmin^{-1/2}$ and 1.34 $mlmin^{-1/2}$ for raw Arawa, Arawa base, Arawa standard and sub-micron calcium carbonate treated (Arawa STD+X) formulation respectively is an indication of decreases in ease with which the continuous phase passes through the formed filter cake. Hence, a reduction in fluid loss was observed.

The data was fitted into Carter filtration model using lsqcurvefit in MATLAB and strong correlation between model and experimental data was observed as shown in Table 3 bellow.

The fitted model gave average values of 0.97697, 0.97121, 0.50085 for R-square (R^2), Adjusted_R^2 and Sum of Square Error (SSE) respectively.

It can also be deduced from Table 3 that relative to raw Arawa bentonite formulation that the leak-off coefficient has decreased by 14.9% for Arawa base to 40.2% for Arawa standard to 46.2 % for Arawa standard formulation treated with submicron calcium carbonate indicating continuous decrease in in ease with which the mud passes through the filter cake.

Table 3: Spurt loss, leak-off coefficient and correlation coefficients for fitted fluid loss data

Formulation	**Vs(ml)**	**K($mlmin^{-1/2}$)**	**R^2**	**Adjusted_R^2**	**SSE**
API Base	$6.74x10^{-16}$	1.46	0.96845	0.96057	0.6099
API STD	$4.86x10^{-16}$	1.37	0.96902	0.96127	0.5381
Arawa Raw	$9.94x10^{-16}$	2.49	0.99368	0.99209	0.3162
Arawa Base	$1.03x10^{-16}$	2.12	0.99189	0.98986	0.3042
Arawa STD	$3.79x10^{-17}$	1.49	0.97123	0.96404	0.6406
Arawa STD+X	$5.77x10^{-17}$	1.34	0.96755	0.95943	0.5961

4. CONCLUSION

This paper investigated the low-temperature low-pressure (LTLP) filtration properties of drilling mud formulated from indigenous Arawa bentonite clay, soda activation, standardization, and drilling mud treatment with sub-micron calcium carbonate.

It was found that

I. Raw Arawa formulation exhibited the highest filtrate loss of 14.0 mL after 30 min, while soda activation reduced the filtrate loss to 12.0 mL. The standardized formulation reduced the filtrate loss to 8.6 mL, and treatment of standardized formulation with sub-micron calcium carbonate produced a further reduction to 7.8 mL, which is comparable to the 7.6 mL obtained for the API standard formulation.

II. All tested formulations recorded filtrate losses within the stated API requirement of ≤15 mL.

III. The fitted filtration model provided a good representation of the experimental data, with R-square, adjusted R-square, and SSE values of 0.97697, 0.97121, 0.5 respectively.

IV. The leak-off coefficient decreased progressively from 2.49 mL $min^{-1/2}$ for raw Arawa to 1.49 $mlmin^{-1/2}$ for Arawa STD and 1.34 $mlmin^{-1/2}$ for Arawa STD+X, indicating improved filtration resistance after treatment with sub-micron calcium carbonate.

V. The leak-off coefficients for Arawa STD and Arawa STD+X formulation compare closely with leak-off coefficients for API base and API standard formulation respectively with leak-off coefficients of 1.46 $mlmin^{-1/2}$ and 1.37 $mlmin^{-1/2}$ respectively.

VI. The results demonstrate the potential of soda activated and standardized Arawa bentonite as a locally sourced material for drilling mud applications. Further studies should evaluate its filtration performance under high-temperature high-pressure (HPHT) conditions and investigate the long-term stability of the formulated mud systems. Additionally, the experiment only addresses three key filtration parameters. Others like filter cake thickness, cake permeability and mud rheology were not investigated.

ACKNOWLEDGEMENTS

I wish to acknowledge the support of the Tertiary Education Trust Fund (TETFund) for funding this research through the National Research Fund (NRF). I also sincerely appreciate the contributions and support of my supervisors and laboratory assistants, whose guidance, assistance, and commitment contributed significantly to the successful completion of this research.

ABSTRACT

The increasing demand for lightweight, high-performance materials in engineering applications necessitates the development of cost-effective aluminium matrix composites (AMCs) using locally sourced reinforcement. This study focuses on the development and characterization of Al-Si-Mg alloy reinforced with Giro clay nanoparticles (GCNP). The Giro clay was beneficiated and processed into nanoparticles, followed by chemical and phase characterization using X-Ray Fluorescence (XRF) and X-Ray Diffraction (XRD). The analyses revealed that the Giro clay is predominantly composed of sulfate-bearing phases (SO_3 at 51.14 wt.%) with significant silica content (SiO_2 at 25.07 wt.%), along with minor ceramic phases including CaO (4.76 wt.%), Al_2O_3 (1.78 wt.%), and Fe_2O_3 (0.54 wt.%), confirming its viability as a reinforcing agent. The composites were developed via the stir casting route, with reinforcement concentrations systematically varied from 0 to 10 wt.% at 2 wt.% intervals. The as-cast alloy (0 wt.%) and the optimal composite formulation (4 wt.%), were characterized using Scanning Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (SEM/EDS) to evaluate the dispersion of nanoparticles, grain refinement, and elemental distribution within the aluminum matrix. Microstructural analysis confirmed a relatively uniform dispersion of the Giro clay nanoparticles at lower weight fractions, with evidence of grain boundary pinning and reduced dendrite arm spacing. The stir-casting parameters were optimized to minimize porosity and achieve acceptable wettability between the ceramic phases and the Al-Si-Mg matrix. The fabricated composites demonstrated structural integrity, with the 4 wt.% reinforcement formulations exhibiting the most refined microstructure and optimal phase distribution. This study successfully establishes a processing-structure-property linkage for Giro clay-reinforced AMCs, demonstrating that locally sourced nanoparticles can be effectively utilized to develop advanced engineering materials, positioning this research as a significant step toward self-reliance in materials technology.

1. INTRODUCTION

Aluminium and its alloys rank among the most versatile metallic materials for engineering applications due to their favourable strength-to-weight ratio, corrosion resistance, and formability (Kaufman, 2023; Polmear et al., 2024; Mondolfo, 2025). This widespread usage, particularly in marine, automotive, and aerospace applications, makes the continued development of aluminium-based materials critically important (Gebrehiwet et al., 2023). Pure aluminium exhibits deficiencies in mechanical strength and elastic modulus, driving alloy development through the addition of elements such as silicon, which improves fluidity and castability, and magnesium, which enhances strength-to-weight ratio and corrosion resistance in chloride environments (Li et al., 2023; Zhao et al., 2024). The Al-Si-Mg system produces medium-strength alloys that are among the most corrosion-resistant of all aging alloys, making them attractive for marine and coastal applications (Kahlenberg et al., 2023; Bartawi et al., 2025).

Modern technology increasingly demands property combinations unattainable by conventional metals, ceramics, or polymers, necessitating composite material development (Ashby, Shercliff, & Cebon, 2023; Miracle & Donaldson, 2020). Particulate-reinforced aluminium matrix composites (AMCs) have attracted considerable research interest due to their isotropic nature, low production cost, and enhanced properties (Chifu et al., 2025; Kumari et al., 2016). More recently, nanocomposites—where at least one constituent phase has dimensions in the nanometre range—have emerged as advanced alternatives offering superior performance characteristics (Huang & Xu, 2025; Suroń et al., 2024).

Giro clay, a locally sourced natural material from Kebbi State, Nigeria, has demonstrated potential as a cost-effective reinforcement for aluminium matrix composites (Balogun, 2022a; 2022b). Studies on Nigerian clay deposits have shown that they belong to the alumino-silicate group with high silica and alumina contents suitable for refractory and engineering applications (Omoruyi et al., 2022; Odiboh, 2026; Ogunleye & Bada, 2021; Shuaib-Babata & Mudiare, 2017). The clay contains beneficial ceramic phases including Al_2O_3, SiO_2, CaO, and Fe_2O_3, which can contribute to passive film stability and microstructural refinement. While Giro clay has shown promise for enhancing microstructural and physical characteristics of Al-Si-Mg composites (Balogun, 2022b), limited research exists on the systematic characterization of this Nigerian clay for nanocomposite development and the fabrication parameters required for successful composite processing via stir casting.

This study addresses this gap by investigating the development and characterization of Al-Si-Mg composites reinforced with Giro clay nanoparticles (GCNP). The specific objectives are to: (i) characterize the Giro clay used as nano-particle reinforcement using X-Ray Fluorescence (XRF) and X-Ray Diffraction (XRD); (ii) fabricate the Al-Si-Mg / Giro clay nanoparticles composite (GCNPC) using the stir casting method with reinforcement concentrations from 0 to 10 wt.% at 2 wt.% intervals; and (iii) characterize the as-cast alloy and composite samples using XRD, XRF, and Scanning Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (SEM/EDS).

The research contributes to advancing locally sourced materials for engineering applications, enhancing the economic value of Giro clay deposits in Nigeria as an alternative reinforcement in aluminium composites (Shuaib-Babata & Mudiare, 2017; Odiboh, 2026). The findings provide essential baseline data for subsequent studies and potential engineering applications.

2. METHODOLOGY

2.1 Materials

The primary materials used for this research were commercially pure aluminium wires obtained from Northern Cable Company (NOCACO), Kaduna, processed Giro clay nanoparticles sourced from the Giro clay deposit in Kebbi State, Nigeria, and alloying elements including silicon and magnesium obtained from Sunlab Chemicals, Jos. Sodium chloride (NaCl) and distilled water were used for the preparation of artificial seawater (3.5 wt.% NaCl solution). Grinding papers of 80 to 800 grits, polishing paste, and Keller's reagent were used for metallographic sample preparation.

2.2 Production of Giro Clay Nanoparticles

The Giro clay obtained from Kebbi State, Nigeria, was beneficiated and processed into nanoparticles. The processing involved crushing, milling, and sieving to achieve particle sizes in the nanometre range. The processed nanoparticles were characterized using X-Ray Fluorescence (XRF) and X-Ray Diffraction (XRD) to determine their chemical composition and phase identification.

2.3 Composite Fabrication via Stir Casting

The Al-Si-Mg alloy was produced by melting the commercially pure aluminium wires with the addition of silicon (7 wt.%) and magnesium (0.3 wt.%) in the required proportions. The Giro clay nanoparticles were pre-heated in an electric furnace for one hour to remove moisture. The melt temperature was allowed to fall to 15°C below the liquidus temperature (600°C) to achieve a semi-solid state before incorporating the pre-heated reinforcement. The reinforcement was added at concentrations of 2%, 4%, 6%, 8%, and 10 wt.%. A mechanical stirrer was employed to ensure

homogeneous distribution of the reinforcement within the melt. The melt was then reheated to 700°C and cast into cylindrical sand moulds of dimensions 300 mm × 20 mm to produce test samples in rod form.

Additionally, control sample of matrix alloy with no reinforcement addition was also cast according to composition provided in Table 1. While six formulations were fabricated (0 - 10 wt.%) this paper presents detailed characterization of the control (Sample A) and the optimal formulation (Sample C, 4 wt.%)

Table 1: *Composition of Aluminium Matrix*

Element	Weight (%)	Weight (g)
Aluminium (Al)	92.7	305.91
Silicon (Si)	7.0	23.10
Magnesium (Mg)	0.3	0.99

2.4 Characterization of As-Cast Alloy and Composites

2.4.1 X-Ray Fluorescence (XRF)

The chemical composition of the Giro clay nanoparticles and the as-cast alloy/composites was determined using X-Ray Fluorescence (XRF) analysis. The samples were prepared according to standard procedures and analyzed to identify the elemental and oxide compositions present in the materials.

2.4.2 X-Ray Diffractometry (XRD)

Phase identification of the Giro clay nanoparticles and the developed composites was conducted using a Rigaku Miniflex 300 X-Ray Diffractometer. The samples were scanned over a 2θ range to identify the crystalline phases present, including the ceramic phases contributed by the reinforcement.

2.4.3 Scanning Electron Microscopy / Energy-Dispersive X-ray Spectroscopy (SEM/EDS)

Microstructural characterization of the as-cast alloy and optimal composite sample with 4 wt.% reinforcement was performed using Scanning Electron Microscopy coupled with Energy-Dispersive X-ray Spectroscopy (SEM/EDS). The samples were prepared according to ASTM E3 standards, mounted, ground using emery papers of 80–800 grits, and polished using silicon paste. The SEM was operated with a field emission gun at an accelerating voltage of 15 kV (within the specified range 5 – 30 kV) to examine the surface morphology, nanoparticle dispersion, grain refinement, and elemental distribution within the aluminium matrix.

2.4.4 Optical Microscopy (OM)

Metallographic samples were prepared and etched with Keller's reagent for 10–30 seconds at room temperature according to ASTM E7, E340, and E407 standards. The microstructures were viewed and captured using an Optical Microscope (OM) with an in-built camera to evaluate the grain structure and phase distribution.

3. RESULTS AND DISCUSSION

3.1 Characterization of Giro Clay Nanoparticles (Reinforcement)

3.1.1 X-Ray Fluorescence (XRF) Analysis

The chemical composition of the Giro clay nanoparticles (GCNP) reinforcement was determined using X-Ray Fluorescence (XRF) analysis. The results are presented in Table 2.

Table 2: *XRF Analysis of Giro Clay Nanoparticles (Reinforcement)*

Oxide / Element	SiO_2	SO_3	CaO	Al_2O_3	Fe_2O_3	Cl (Element)
Wt%	25.065	51.143	4.761	1.780	0.538	15.514

The XRF analysis reveals that the Giro clay is predominantly composed of silicon dioxide (SiO_2, 25.07 wt.%) and sulfur trioxide (SO_3, 51.14 wt.%), with significant calcium oxide (CaO, 4.76 wt.%), aluminium oxide (Al_2O_3, 1.78 wt.%), and iron oxide (Fe_2O_3, 0.54 wt.%). The presence of chlorine (Cl, 15.51 wt.%) suggests chloride-bearing phases, consistent with the clay's depositional

environment. The complete composition sums to approximately 98.8 wt.%, with the remaining fraction attributed to trace elements not reported in this analysis.

The ceramic phases identified (SiO_2, Al_2O_3, CaO, Fe_2O_3) are beneficial for aluminium matrix composites, as they can contribute to passive film stability and microstructural refinement (Xu & Zhang, 2025). The high SO_3 content indicates the presence of sulfate-bearing minerals, which was later confirmed by XRD analysis. The composition is consistent with Nigerian alumino-silicate clays reported in literature (Omoruyi et al., 2022; Ogunleye & Bada, 2021).

The high SO_3 (51.14 wt.%) and Cl (15.51 wt.%) content in the Giro clay suggests the presence of soluble sulfate and chloride phases. While these phases could potentially influence the corrosion behavior of the composite in marine environments (e.g., promoting pitting or sulfate attack). The present study focuses strictly on the development and characterization of the composite. Detailed corrosion testing is recommended as future work to fully assess these implications.

3.1.2 X-Ray Diffractometry (XRD) Analysis

The XRD analysis of the Giro clay nanoparticles (GCNP) reinforcement was conducted to identify the crystalline phases present. The results are presented in Figure 1 and summarized in Table 3.

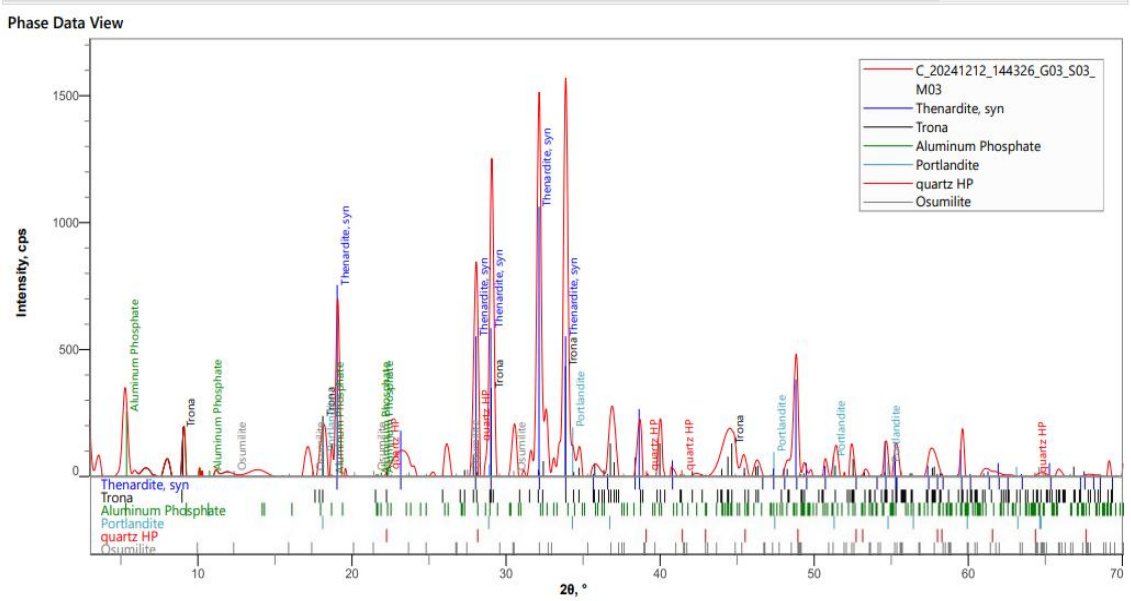

Figure 1: XRD Spectrum of Giro Clay Nanoparticles (GCNP) Reinforcement

Table 3: *Phase Composition of Giro Clay Nanoparticles from XRD Analysis*

Phase	Chemical Formula	Weight (%)	Crystal System
Thenardite	Na_2SO_4	37	Orthorhombic Fddd
Trona	$Na_3H(CO_3)_2 \cdot 2H_2O$	28	Monoclinic
Portlandite	$Ca(OH)_2$	18	Hexagonal
Quartz HP	SiO_2	16	Hexagonal
Aluminium Phosphate	$AlPO_4$	1.2	Trace

The XRD analysis reveals a complex multi-phase system with thenardite (Na_2SO_4, 37 wt.%) as the dominant phase, followed by trona ($Na_3H(CO_3)_2 \cdot 2H_2O$, 28 wt.%), portlandite ($Ca(OH)_2$, 18 wt.%), quartz (SiO_2, 16 wt.%), and aluminium phosphate ($AlPO_4$, 1.2 wt.%) as a trace phase. Multiple overlapping peaks are observed (28.05°: thenardite + trona; 32.10°: thenardite dominant), with low-intensity peaks (5.29°: $AlPO_4$) indicating minor phases. Crystallite sizes are highly variable: thenardite (~250–400 Å) and trona (~608 Å).

The dominance of thenardite and trona correlates with the high SO_3 content (51.14 wt.%) from XRF analysis, while portlandite corresponds to CaO (4.76 wt.%), and quartz corresponds to SiO_2 (25.07 wt.%) in Table 2. This mineral assemblage is typical of evaporite deposits and alkaline lake sediments, suggesting that the Giro clay originated from such a geological environment (Omoruyi et

al., 2022). The presence of quartz (SiO_2) and calcium-bearing phases (portlandite) indicates that the Giro clay can contribute to passive film stability in the aluminium matrix (Xu & Zhang, 2025).

The high crystallinity of the thenardite and trona phases, as indicated by their sharp diffraction peaks, suggests that the Giro clay has undergone significant diagenetic alteration. Shuaib-Babata and Mudiare (2017) reported that Nigerian clays exhibit varied crystallinity depending on their depositional environment, with some showing high quartz content and others showing kaolinite dominance. The Giro clay's distinct mineralogy, dominated by sodium sulfate and carbonate phases, distinguishes it from typical kaolinitic or montmorillonitic clays, making it a unique reinforcement material for aluminium matrix composites.

3.1.3 Scanning Electron Microscopy / Energy-Dispersive X-ray Spectroscopy (SEM/EDS) Analysis

The SEM micrograph and EDS spectrum of the Giro clay nanoparticles are presented in Plate 1, with the chemical composition summarized in Table 4.

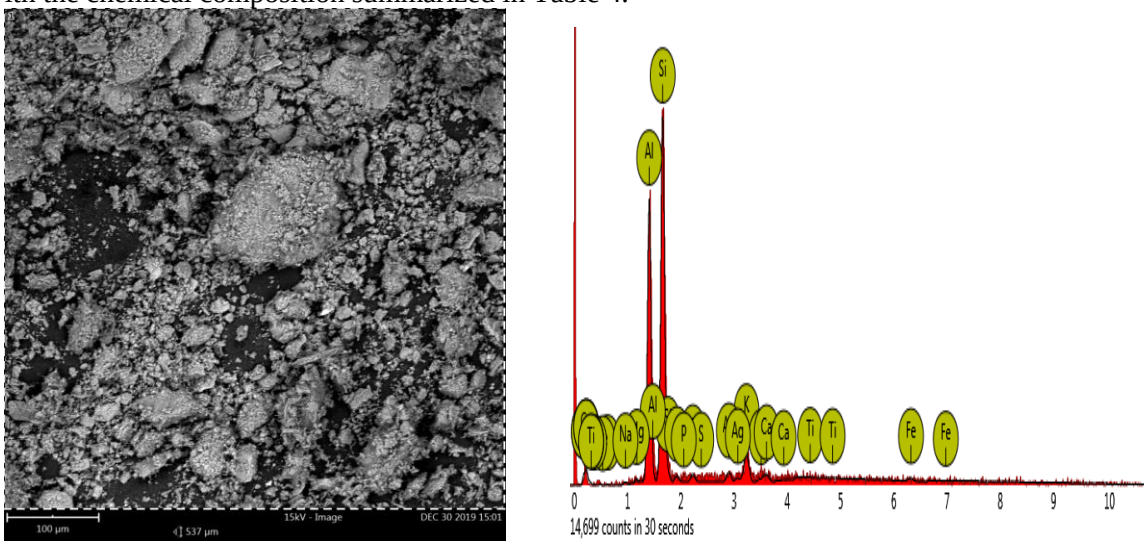

Plate 1: SEM micrograph and EDX Spectrum of Giro Clay Particles

Table 4: *Chemical Composition of Giro Clay Nanoparticles by SEM/EDS*

Element Number	Element Symbol	Element Name	Atomic Conc.	Weight Conc.
14	Si	Silicon	53.81	49.62
13	Al	Aluminium	32.46	28.75
47	Ag	Silver*	1.96	6.94
19	K	Potassium	5.38	6.90
20	Ca	Calcium	1.63	2.15
26	Fe	Iron	1.14	2.08
16	S	Sulfur	1.45	1.53
15	P	Phosphorus	1.36	1.38
12	Mg	Magnesium	0.52	0.41
11	Na	Sodium	0.30	0.22

The EDS analysis shows that silicon is the major constituent with the highest weight concentration of 49.62 wt.%, followed by aluminium with 28.75 wt.%. Other elements present include potassium (6.90 wt.%), calcium (2.15 wt.%), iron (2.08 wt.%), sulfur (1.53 wt.%), phosphorus (1.38 wt.%), and minor quantities of magnesium (0.41 wt.%), sodium (0.22 wt.%), and silver (6.94 wt.%).

The predominance of silicon and aluminium confirms that the Giro clay is primarily an alumino-silicate material, consistent with the XRF findings. The presence of potassium, calcium, and iron as minor elements is typical of natural clay deposits and suggests the presence of feldspathic minerals or iron-bearing impurities (Odiboh, 2026). The silver content (6.94 wt.%) is an artefact from sputter coating applied to the sample during SEM sample preparation to enhance conductivity and is not part of the clay composition (Rawal & Sidpara, 2025). However, oxygen is not reported in the EDS analysis despite XRF and XRD confirming the oxide/silicate nature of the Giro clay. This is due

to the inherent limitation of standard EDS detectors for light elements (Z < 11). The EDS data were quantified using a standardless ZAF correction method, which normalizes spectra to 100% excluding oxygen. The presence of oxygen is confirmed by XRF (SiO_2, Al_2O_3, CaO, Fe_2O_3, SO_3) and XRD (thenardite, trona, portlandite, quartz, $AlPO_4$). Therefore, EDS results are semi-quantitative for elements Z ≥ 11, with oxide analysis reserved for XRF and XRD.

The SEM micrograph of the Giro clay nanoparticles reveals the morphology and particle size distribution of the reinforcement material. The particles appear to be irregular in shape with varying sizes, indicating that further processing may be required to achieve uniform nanoparticle dispersion in the aluminium matrix. Rawal and Sidpara (2025) reported that uniform nanoparticle dispersion is critical for achieving optimal properties in aluminium nanocomposites, and that processing parameters such as stirring speed and temperature significantly influence particle distribution.

3.2 Characterization of As-Cast Al-Si-Mg Alloy (Control)

3.2.1 X-Ray Fluorescence (XRF) Analysis

The XRF analysis of the Al-Si-Mg alloy (control sample) is presented in Table 5.

Table 5: *XRF Analysis of Al-Si-Mg Alloy (Control)*

Element	**Al**	**Si**	**Mg**	**Mn**	**S**	**Fe**	**Ca**	**K**	**Cl**
Wt%	96.7	0.9	0.03	0.004	0.126	0.129	0.304	0.066	1.52

The XRF analysis confirms the composition of the Al-Si-Mg alloy, with aluminium as the dominant element at 96.72 wt.%. Silicon is present at 0.990 wt.%, which is slightly lower than the target composition of 7 wt.%. This discrepancy may be attributed to the limitations of XRF in detecting light elements such as silicon accurately, or it may indicate that the alloy composition deviated from the target due to processing conditions. Magnesium is present at 0.033 wt.%, which is significantly lower than the target of 0.3 wt.%, suggesting possible magnesium loss during melting due to its high vapour pressure and tendency to oxidize (Abishkenov et al., 2025).

The presence of impurities such as iron (0.129 wt.%), calcium (0.304 wt.%), sulfur (0.126 wt.%), and chlorine (1.515 wt.%) may originate from the raw materials or from contamination during processing. Abishkenov et al. (2025) reported that impurities in aluminium alloys, particularly iron and silicon, can form intermetallic phases that influence the corrosion behaviour of the material.

3.2.2 X-Ray Diffractometry (XRD) Analysis

The XRD analysis of the as-cast Al-Si-Mg alloy (control sample) was conducted to identify the crystalline phases present. The results are presented in Figure 2 and summarized in Table 6.

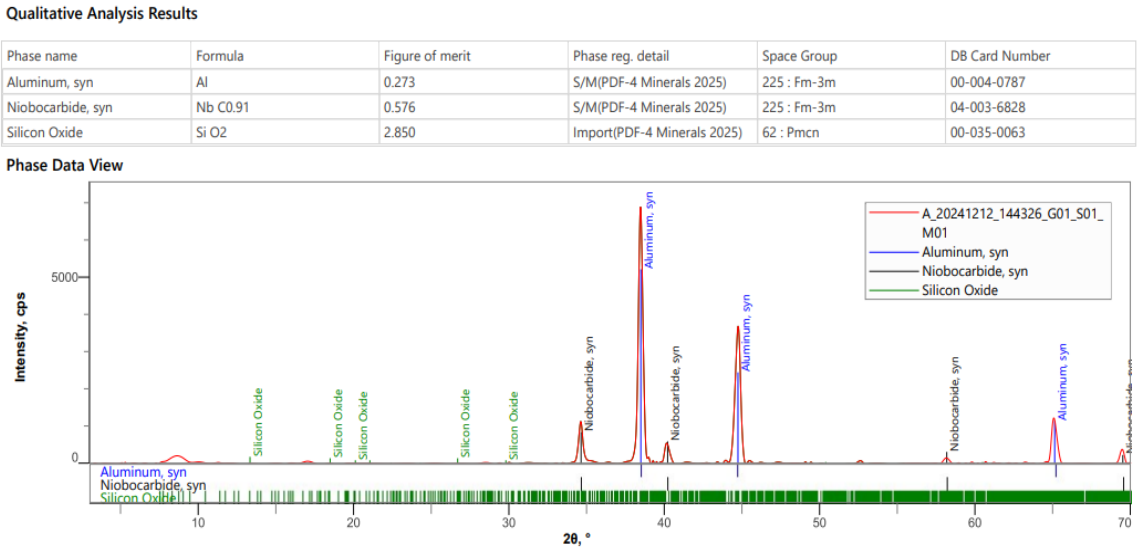

Figure 2: XRD Spectrum of As-Cast Al-Si-Mg Alloy (Control)

Table 6: *Phase Composition of As-Cast Al-Si-Mg Alloy (Control) from XRD Analysis*

Phase	Chemical Formula	Weight (%)	Crystal System
Aluminium	Al	93.2	Cubic Fm-3m
Niobocarbide	$NbC_{0.91}$	3.3	Cubic Fm-3m
Silicon Dioxide	SiO_2	3.4	-

The XRD analysis reveals aluminium (93.2 wt.%) as the dominant phase, with strong peaks at 38.43° (111), 44.66° (200), and 65.00° (220). Niobocarbide ($NbC_{0.91}$, 3.3 wt.%) is present as a minor phase, with peaks at 34.59° (111) and 40.12° (200). Silicon dioxide (SiO_2, 3.4 wt.%) is identified as a trace impurity. A low-intensity peak at 8.72° suggests potential amorphous content or a minor impurity phase.

The crystallite size of aluminium is approximately 287–317 Å (from Scherrer analysis), while niobocarbide exhibits a crystallite size of approximately 267–364 Å, indicating a broader size distribution. The dominance of aluminium peaks confirms the successful production of the Al-Si-Mg alloy.

The presence of niobocarbide ($NbC_{0.91}$) is attributed to contamination from the stainless steel stirrer or crucible, which likely contained niobium-bearing alloying additions. The SiO_2 phase likely originates from surface oxidation or contamination from the Giro clay reinforcement, as silica is a major component of the clay (25.07 wt.% from XRF analysis). This is consistent with the findings of Abishkenov et al. (2025), who reported that impurities in aluminium alloys, particularly iron and silicon, can form intermetallic phases that influence the material's properties.

The high aluminium purity (93.2 wt.%) is consistent with the XRF analysis (96.72 wt.% Al), although the minor phases identified by XRD ($NbC_{0.91}$ and SiO_2) were not fully captured by XRF, highlighting the complementary nature of these two characterization techniques. The crystallite size analysis indicates that the aluminium grains are relatively fine, which is beneficial for mechanical properties and corrosion resistance (Xu & Zhang, 2025).

3.2.3 Scanning Electron Microscopy / Energy-Dispersive X-ray Spectroscopy (SEM/EDS) Analysis

The SEM micrograph and EDS spectrum of the Al-Si-Mg alloy (control sample) are presented in Plate 2, with the chemical composition summarized in Table 7.

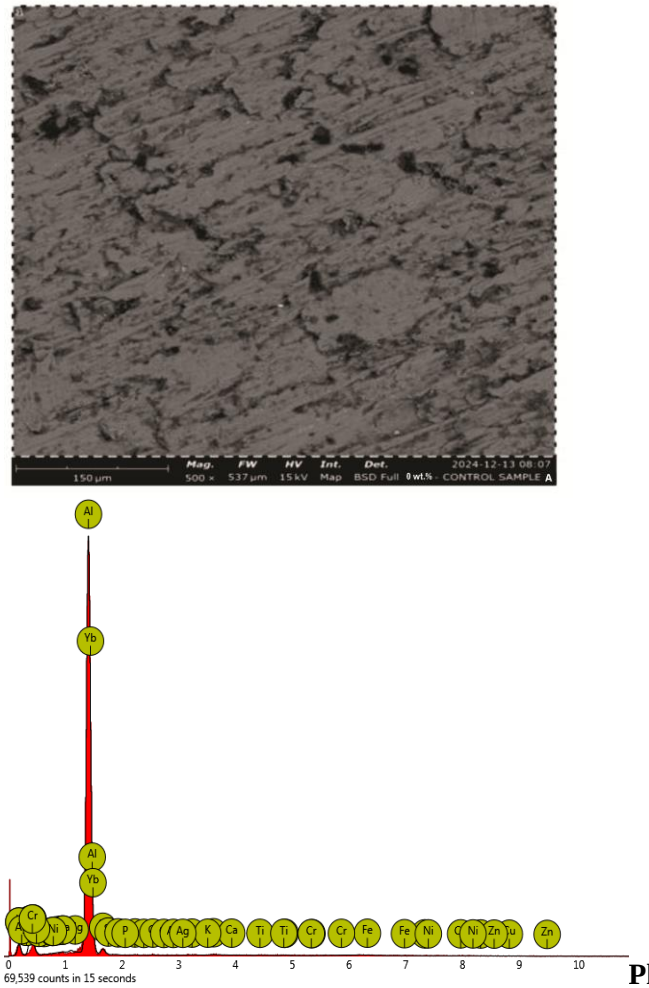

Plate 2: SEM Micrograph and EDS Spectrum of Al-Si-Mg Alloy (Control)

Table 7: *Chemical Composition of Al-Si-Mg Alloy (Control) by SEM/EDS*

Element Number	Element Symbol	Element Name	Atomic Conc.	Weight Conc.
13	Al	Aluminium	87.84	92.05
6	C	Carbon	9.03	4.21
14	Si	Silicon	2.44	2.66
23	V	Vanadium	0.15	0.29
20	Ca	Calcium	0.13	0.20
16	S	Sulfur	0.15	0.19
17	Cl	Chlorine	0.13	0.18
22	Ti	Titanium	0.07	0.12
19	K	Potassium	0.06	0.09

The EDS analysis confirms aluminium as the dominant element (92.05 wt.%), with silicon at 2.66 wt.%. The carbon content (4.21 wt.%) is relatively high and may result from contamination during sample preparation or from carbide formation, consistent with the XRD identification of niobocarbide ($NbC_{0.91}$). The presence of vanadium, calcium, sulfur, chlorine, titanium, and potassium as trace elements confirms the minor impurities identified in the XRF analysis. The peak appearing in the EDS spectrum in the vicinity of the Al Kα peak may be attributed to peak overlap with Yb Mα (1.52 keV). However, quantification using the standardless ZAF correction method did not resolve Yb at detectable levels; the peak is predominantly Al (Kα at 1.486 keV). Yb is therefore not reported in Table 7, as its presence, if any, is below the detection limit of the EDS system or is an artefact of peak overlap (Goldstein et al., 2018).

The SEM micrograph shows the grain structure of the as-cast Al-Si-Mg alloy, revealing a typical dendritic structure characteristic of cast aluminium alloys. The presence of intermetallic phases and minor porosity is visible, which may influence the corrosion resistance of the material. The microstructural features observed are consistent with those reported by Abishkenov et al. (2025) for Al-Si-Mg alloys processed by stir casting, who observed that the dendritic structure and porosity levels are influenced by processing parameters such as cooling rate and stirring conditions.

3.3 Characterization of Al-Si-Mg Alloy/ Giro Clay Nanoparticle Composites

3.3.1 *Scanning Electron Microscopy (SEM) Analysis*

The SEM micrograph of the Al-Si-Mg /4 wt.% GCNP composite sample is presented in Plate 3.

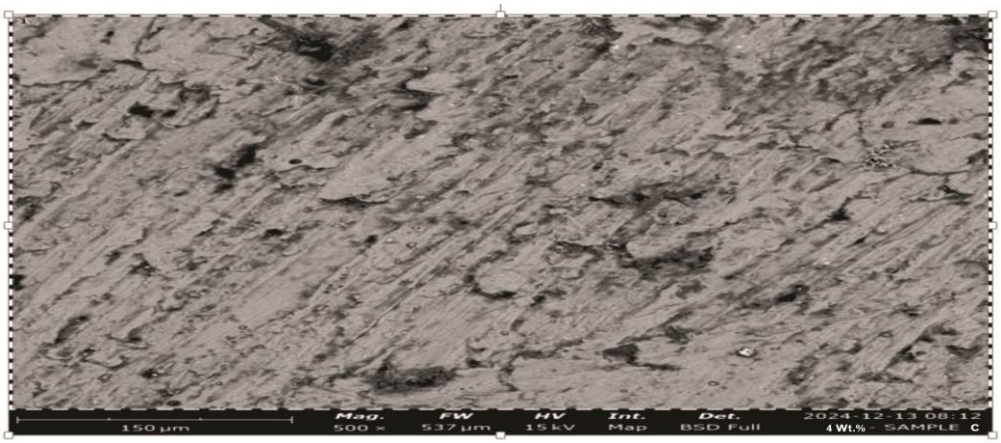

Plate 3: SEM Micrograph of the 4wt% Giro Clay Nanoparticle Composite

The SEM micrograph reveals the microstructure of the 4 wt.% GCNP composites, showing the distribution of reinforcement particles within the aluminium matrix. The Giro clay nanoparticles appear to be relatively well-dispersed, with some clustering observed at grain boundaries. The presence of fine particles at the grain boundaries suggests that the reinforcement particles act as nucleation sites for grain refinement during solidification, which is consistent with the findings of Rawal and Sidpara (2025).

The improved dispersion at 4 wt.% reinforcement indicates that the stir casting parameters (350 rpm stirring speed, 600°C semi-solid processing, and argon protection) were optimal for this concentration. This is consistent with the findings of Xu and Zhang (2025), who reported that effective particle dispersion is achieved when the melt is in the semi-solid state, as the viscosity is sufficient to prevent particle segregation but low enough to allow for uniform distribution.

3.3.2 X-Ray Diffractometry (XRD) Analysis

The XRD analysis of the Al-Si-Mg / GCNP composite sample is presented in Figure 3.

Qualitative Analysis Results

Phase name	Formula	Figure of merit	Phase reg. detail	Space Group	DB Card Number
Aluminum, syn	Al	0.212	S/M(PDF-4 Minerals 2025)	225 : Fm-3m	00-004-0787
Silicon Oxide	Si O2	0.659	S/M(PDF-4 Minerals 2025)	12 : I12/m1	04-012-0465
Tantalcarbide, syn	Ta C	0.524	S/M(PDF-4 Minerals 2025)	225 : Fm-3m	01-075-3086

Phase Data View

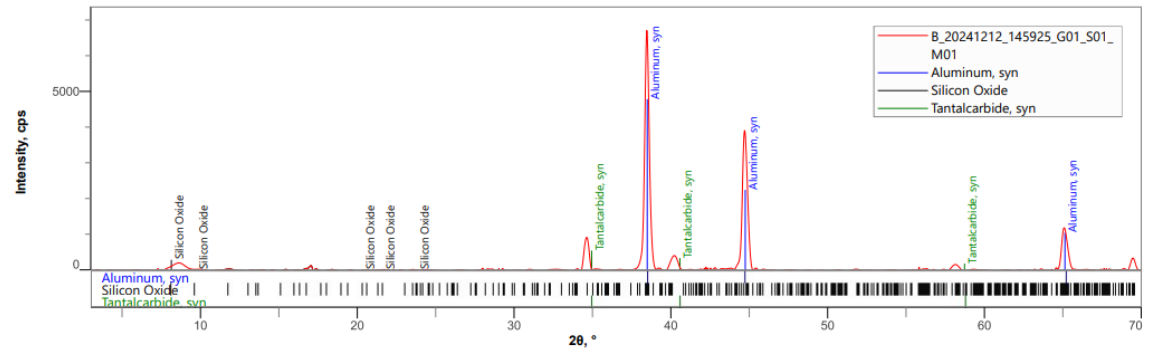

Figure 3: XRD Spectrum of the Al-Si-Mg / GCNP Composite (4 wt.%)

The XRD analysis reveals aluminium (95.3 wt.%) as the dominant phase, with SiO_2 (2.8 wt.%) confirming successful incorporation of the Giro clay reinforcement. The identification of TaC (1.9 wt.%) as a minor phase in the composite, and NbC in the control, is noteworthy. One possible explanation is contamination from the stainless steel stirrer or crucible**,** as these are common sources of carbide-forming elements in high-temperature processing. However, given that TaC is known to be stable in molten aluminum while NbC tends to decompose, the presence of NbC in the control sample is unusual and may indicate a different source**,** such as residual elements in the raw materials or a master alloy addition (Kobashi et al., 1993). Further investigation, including EDS point analysis of the carbide particles, would be required to confirm their origin. The composite shows higher Al purity (95.3 wt.%) compared to the control sample (93.2 wt.%), suggesting cleaner processing for the composite. The Al crystallite size is approximately 283–291 Å, slightly smaller than the control (287–317 Å), indicating grain refinement from the Giro clay nanoparticles (Rawal & Sidpara, 2025). The presence of SiO_2 is expected to contribute to passive film stability (Xu & Zhang, 2025).

3.4 Optical Microscopy (OM) of As-Cast Sample (Control)

The OM micrograph of the as-cast Al-Si-Mg alloy is presented in Plate 4.

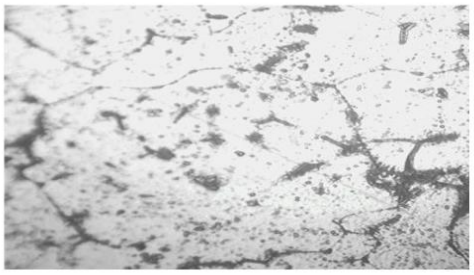

Plate 4: OM Micrograph of As-Cast Al-Si-Mg Alloy (Control)

The OM micrograph shows the grain structure of the as-cast Al-Si-Mg alloy. The aluminium grains appear gray in colour and are uniformly distributed within the microstructure. The dendritic structure typical of cast aluminium alloys is visible, with fine intermetallic phases distributed between the dendrite arms.

The grain structure observed is typical of Al-Si-Mg alloys cast in sand moulds, where the relatively slow cooling rate allows for the development of dendritic structures. The presence of intermetallic phases at grain boundaries is expected to influence the corrosion behaviour of the alloy, as these phases can act as cathodic or anodic sites in localized corrosion processes.

4. CONCLUSION

The development and characterization of Al-Si-Mg / Giro clay nanoparticle composites fabricated via stir casting have been successfully achieved. The following conclusions are drawn:

i. **Giro Clay Characterization:** XRF and XRD analyses confirmed that Giro clay contains beneficial ceramic phases including SiO_2 (25.07 wt%), CaO (4.76 wt%), Al_2O_3 (1.78 wt%), and Fe_2O_3 (0.54 wt%), with dominant mineral phases of thenardite (37 wt%), trona (28 wt%), portlandite (18 wt%), and quartz (16 wt%). The high SO_3 content (51.14 wt.%) confirms the presence of sulfate-bearing minerals.

ii. **Composite Fabrication:** Al-Si-Mg / GCNP composites were successfully fabricated via stir casting with reinforcement concentrations of 0–10 wt.% at 2 wt.% intervals. The 4 wt.% reinforcement formulations exhibited the most refined microstructure and optimal particle dispersion.

iii. **Characterization:** XRD confirmed successful incorporation of SiO_2 from the Giro clay into the aluminium matrix. The optimally reinforced sample (4 wt.% reinforcement) showed Al purity of 95.3 wt.% with SiO_2 content of 2.8 wt.%, confirming successful composite development. SEM/EDS analysis confirmed relatively uniform dispersion at lower reinforcement levels.

iv. **Optimal Formulation:** The sample with 4 wt.% Giro clay nanoparticle reinforcement demonstrated the best combination of microstructural refinement, particle dispersion, and phase distribution among all developed composites.

v. **Local Content Significance:** This study successfully demonstrates that locally sourced Giro clay from Kebbi State, Nigeria, can be processed into nanoparticles and utilized as a cost-effective reinforcement for aluminium matrix composites, supporting local content inclusion in material development.

Recommendations

i. Optimize stir casting parameters (stirring speed, holding time, cooling rate) for improved particle dispersion at higher reinforcement concentrations ($\geq$6 wt%).

ii. Conduct heat treatment studies to investigate ageing effects on microstructure and material properties.

iii. Evaluate mechanical properties (tensile, hardness, wear) for complete structure-property relationships.

ABSTRACT

This study investigates the effect of double pressing and double sintering (DPDS) on the mechanical and tribological properties of aluminum matrix composites reinforced with rice husk ash (RHA). Aluminum–RHA composites containing 0 –15 wt.% RHA were fabricated using powder metallurgy through three processing routes: single pressing–single sintering (SP–SS), single pressing–high-pressure sintering (SP–HPS), and double pressing–double sintering (DPDS). Hardness, wear rate, and coefficient of friction (COF) were evaluated, with representative values obtained under stable sliding conditions used to establish physically meaningful correlations. The DPDS route produced higher hardness values for both pure aluminum (69.9 HV) and the 5 wt.% RHA composite (78.0 HV), with the corresponding lowest specific wear rates of (8.33 × 10^{-7} $mm^3/N{\cdot}m$) and reduced coefficients of friction (COF) of 0.195 and 0.203, respectively. A clear inverse relationship between hardness and specific wear rate was observed for pure aluminum and the 5 wt.% RHA composites, consistent with classical tribological principles. However, composites containing 10–15 wt.% RHA exhibited increased wear and friction despite their relatively higher hardness, which was attributed to particle agglomeration, weak interfacial bonding, and abrasive wear associated with the silica-rich RHA particles. These findings demonstrate that DPDS is an effective processing route for improving the tribological performance of aluminum–RHA composites, with 5 wt.% RHA providing the best combination of hardness, wear resistance and coefficient of friction under the investigated conditions. The use of locally sourced RHA in this study promotes agricultural waste valorization and sustainable materials development, supporting the global goal of advancing environmentally responsible engineering solutions.

1. INTRODUCTION

The incorporation of hard ceramic reinforcements can further enhance the hardness, load-bearing capacity, and wear resistance Aluminum matrix composites (AMCs) have attracted significant research attention due to its lightweight and superior mechanical properties compared to conventional aluminum alloys (Chak et al., 2020; Kumar et al., 2024). Aluminum's low density (approximately 2.7 g/cm^3), combined with its high specific strength, makes it an attractive matrix material for lightweight structural applications (Singhal, Shelly, Rawat, et al., 2025; Singhal, Shelly, Saxena, et al., 2025). of aluminum matrix composites, thereby improving their performance under sliding wear conditions (Singhal, Shelly, Saxena, et al., 2025). Recently, agro-waste materials particularly rice husk ash

(RHA) have attracted increased interests due to their high silica content, abundance, and environmental benefits (Islam et al., 2024; Taiye et al., 2024). Incorporating RHA into aluminum matrices not only enhances mechanical properties like hardness and wear resistance but also supports eco-friendly material development from agricultural waste (Singh Karam et al., 2022).

Rice husk is unusually high in ash compared to other biomass fuels in the range of 10-20%. Rice husk ash typically contains more than 80% silica, highly porous and light-weight, with high external surface area when properly calcined. Flach et al. (2022) highlighted that RHA enhances hardness, reduce density, and promotes wear resistance in composite. However, the effectiveness of RHA as a reinforcement is strongly dependent on processing conditions. Challenges such as particle agglomeration, poor interfacial bonding, and residual porosity often limit the mechanical and tribological performance of aluminum– Rice husk ash (Al-RHA) composites fabricated using conventional powder metallurgy routes (Akgümüş Gök et al., 2024; Shaikh, Arif, et al., 2019).

Conventional SP–SS often result in high porosity, weak interfacial bonding, incomplete densification, leading to increased wear and unstable friction behavior (Shaikh, Raja, et al., 2019). DPDS involve an initial pressing and pre-sintering, followed by re-pressing and a final sintering cycle, thereby promoting better particle rearrangement, enhanced neck growth, and reduced porosity. Literature shows that DPDS significantly improves hardness and tensile strength (Mechanical properties), while enhancing tribological performance (Alem et al., 2020; Hammes et al., 2014; Liu et al., 2023). Although double pressing and double sintering (DPDS) has been investigated for aluminum-based composites reinforced with synthetic and carbon-based reinforcements, its application to rice husk ash (RHA)-reinforced aluminum remains comparatively less explored. Previous studies have demonstrated the potential of DPDS to improve the consolidation and mechanical performance of aluminum composites; however, limited attention has been given to the combined influence of RHA content and the DPDS processing sequence on the hardness and tribological response of Al–RHA composites (Alaneme & Sanusi, 2015). In particular, the present study compares conventional single pressing–single sintering routes with a DPDS route involving initial compaction, pre-sintering, re-pressing and final sintering using the same Al–RHA compositions. The single press and single sinter process suffers from limited green density due to work hardening and friction, leaving high residual porosity after sintering. This porosity severely weakens mechanical properties and corrosion resistance**.** Double pressing and double sintering use a second high-pressure press on a sintered part to crush pores that the first press couldn't eliminate, resulting in a much denser and stronger final component (Alem et al., 2020).

Therefore, this study evaluates the DPDS route for the fabrication of Al–RHA composites containing 0, 5, 10, and 15 wt.% RHA, with particular emphasis on the influence of the additional pressing–sintering cycle on their hardness and tribological performance. The findings provide insight into the processing–property relationships of Al–RHA composites and contribute to the development of sustainable aluminium-based composites with improved mechanical and tribological performance.

2. METHODOLOGY

2.1 Materials

The materials and reagents used in this study included commercially pure aluminium powder (99.99% purity), which served as the matrix material. Rice husk ash (RHA), derived from the calcination of rice husk particles obtained from a rice mill in MTD, Zaria, Kaduna State, Nigeria, was used as the reinforcement. Ethanol was employed as the mixing medium during powder blending, while zinc stearate powder was used as a die lubricant during compaction to reduce friction between the powder compact and die wall and facilitate the ejection of the green compact.

2.2.1 Sample Preparation

The rice husk obtained from the rice mill was initially purified by removing impurities such as sand, dust and organic residues through winnowing. The rice husk was subsequently washed thoroughly with water to remove adhering dirt and dried under sunlight to facilitate moisture removal. The dried rice husk was then placed in a furnace and calcined at 700 °C for 6 hours. After calcination, the resultant rice husk ash (RHA) was removed from the furnace and allowed to cool to room

temperature in air. The cooled ash was subsequently pulverized using a ball mill to reduce its particle size and passed through a 75 μm sieve. The sieved RHA was collected and stored in sealed polyethylene bags to minimize moisture absorption and contamination prior to further processing and characterization.

2.3 Composite Fabrication

The experimental variables investigated in this study were the RHA content and powder-metallurgy processing route. The mixing conditions were kept constant for all compositions. Aluminum powder and RHA were blended at RHA contents of 0, 5, 10 and 15 wt.%, as presented in Table 1. For each composition, the experiment was performed using the three processing routes described in Table 2. The powder mixtures were ball-milled at a constant rotational speed of 200 rpm for 1 hour using a ball-to-powder ratio of 10:1

Table 1: *Percentage composition of samples*

Al	**RHA**
100	0
95	5
90	10
85	15

2.3.1 Powder Mixing

Aluminum powder and varying weight percentages of rice husk ash (5%, 10%, and 15%) were measured using a digital weighing balance. The powders were mixed using a ball mill at 200 rpm for 1 hour to ensure uniform distribution of rice husk ash within the aluminum matrix. Homogeneous dispersion was achieved through wet ball milling using a ball-to-powder ratio (BPR) of 10:1. A total of 0.5 mL of ethanol, which served as a process control agent (PCA), was added to the mixture and subsequently evaporated in a furnace.

2.3.2 Powder Compaction and Sintering

The 1 g powder mixtures were compacted into cylindrical billets using a uniaxial hydraulic press. Two processing routes were employed: SP–SS, representing the conventional powder metallurgy route, and DPDS, the novel processing route. For the SP–SS route, the powders were compacted once at either 3 MPa (Route 1) or 5 MPa (Route 2), followed by sintering at 594 °C for 2 hours in an electric muffle furnace. The sintered samples were then cooled outside the furnace to room temperature. For the DPDS route, the powder mixture was initially compacted at 3 MPa, followed by pre-sintering at 300 °C for 1 hour to promote preliminary diffusion and particle bonding. The pre-sintered compact was subsequently repressed at 5 MPa to improve particle rearrangement and reduce porosity, followed by final sintering at 594 °C for 2 hours. The sintering temperature was selected based on the melting point of aluminum (approximately 660 °C), corresponding to about 90% of its melting temperature, and was maintained across all RHA contents to provide consistent processing conditions. Similar sintering temperatures have been employed in previous powder-metallurgy studies of Al–RHA composites, supporting their suitability for promoting solid-state diffusion and interparticle bonding while remaining below the melting temperature of aluminum (Mohamed Ariff et al., 2022).

However, the addition of RHA may influence the thermal and interfacial behavior of the composites. Therefore, the use of a fixed temperature of 594 °C across the 0–15 wt.% RHA range represents a controlled processing condition rather than an assumption that it is the optimum sintering temperature for every composition. After sintering, the specimens were allowed to cool outside the furnace to room temperature. The DPDS route was adopted to enhance densification, reduce porosity, and improve the mechanical properties of the fabricated Al–RHA composites. Samples were labeled according to their RHA content and processing route. Table 2 provides details of the powder metallurgy routes adopted for the fabrication of the samples.

Table 2: *Description of the powder metallurgy routes adopted for the sample fabrication*

Route	Processing Description	Abbreviation
Route 1	Single pressing at 3 MPa → sintering at 594 °C	SP–SS (Single Pressing and Single Sintering)
Route 2	Single pressing at 5 MPa → sintering at 594 °C	SP–HPS (Single Pressing–Higher Pressure Sintering)
Route 3	Double pressing and double sintering: 3MPa pressing → pre-sintering at 300 °C → re-pressing at 5 MPa → final sintering at 594 °C	DPDS (Double Pressing and Double Sintering)

2.4 Hardness

The hardness tests were performed using a Vickers micro hardness testing machine, ASTM E384. A diamond indenter was used with an applied load of 0.3kgf, and a dwell time of 8 seconds. To account for sample inconsistencies, three readings were taken at different spots. The average hardness value was then determined from these readings.

2.5 Wear and Coefficient of Friction

The wear test was conducted on the samples according to ASTM 99-95a test standard for wear testing of materials. Using ball-on-disk tribometer machine (model version R0.01), an 8N load was applied over a 30 m sliding distance, with the test duration of 30 minutes for all the samples. The corresponding average sliding speed was 1.0 m/min (0.0167 m/s). The counter-body has a ball diameter of 6mm. The wear track radius was 3mm, and the specimen mass is 1g. The tests were conducted under dry ambient laboratory conditions at 27 °C and 55% relative humidity. The coefficient of friction (COF) was automatically recorded by the ball-on-disk tribometer during the wear tests, while the specific wear rate was calculated using Equation (1).

$$\text{Specific wear rate} = \frac{\text{Wear Volume}}{\text{Load X Sliding Distance}} \quad (1)$$

3. RESULTS AND DISCUSSION

Table 3: *Properties Al-RHA composite processed via different powder metallurgy route*

Composition	Processing Route	Hardness (HV)	Wear Rate ($mm^3/N.m$)	Coefficient of Friction
100% Al	SP–SS (3 MPa)	48.9	2.50×10^{-5}	0.273
100% Al	SP–HPS (5 MPa)	57.1	5.00×10^{-6}	0.217
100% Al	DPDS	69.9	8.33×10^{-7}	0.195
95% Al + 5% RHA	SP–SS (3 MPa)	63.1	3.33×10^{-6}	0.239
95% Al + 5% RHA	SP–HPS (5 MPa)	65.5	8.33×10^{-7}	0.228
95% Al + 5% RHA	DPDS	78	8.33×10^{-7}	0.203
90% Al + 10% RHA	SP–SS (3 MPa)	69.4	1.89×10^{-3}	0.277
90% Al + 10% RHA	SP–HPS (5 MPa)	73.7	1.24×10^{-3}	0.414
90% Al + 10% RHA	DPDS	77.4	5.96×10^{-4}	0.319
85% Al + 15% RHA	SP–SS (3 MPa)	84.6	9.76×10^{-4}	0.281
85% Al + 15% RHA	SP–HPS (5 MPa)	91.5	1.66×10^{-3}	0.42
85% Al + 15% RHA	DPDS	75.9	8.53×10^{-4}	0.41

3.1 Hardness

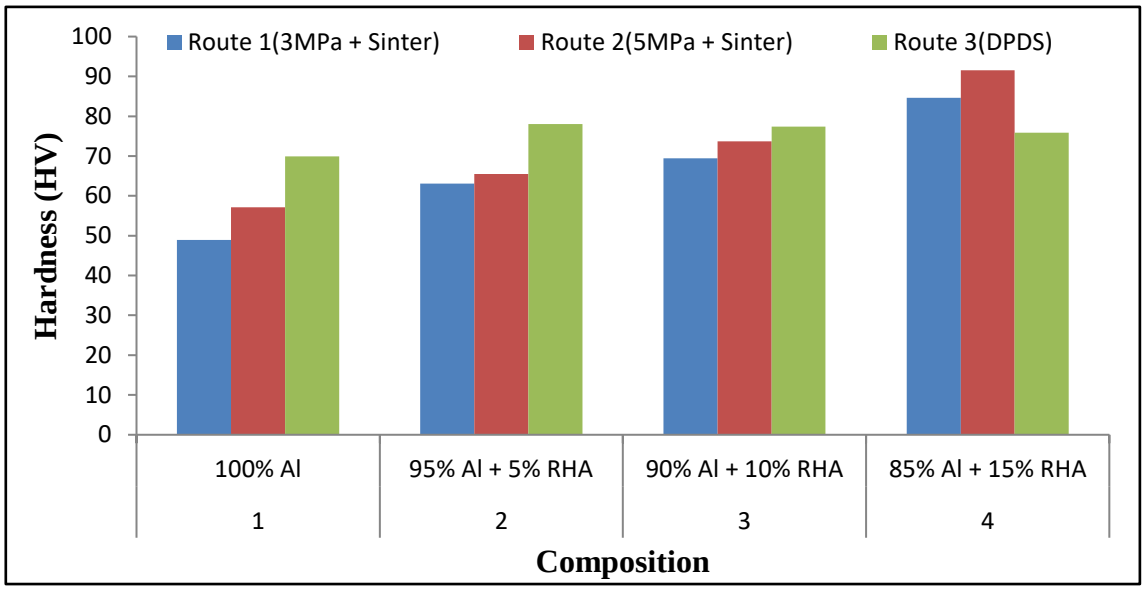

Figure 1: Hardness characteristics of AL- RHA Content under Different Processing Routes

As shown in Table 3 and Figure 1, hardness was influenced by the compaction pressure and sintering conditions. For pure aluminum, hardness increased from 48.9 HV for SP–SS to 69.9 HV for DPDS. A similar improvement was observed for the 5 wt.% RHA composites, where DPDS produced the highest hardness of 78.0 HV. For the DPDS route, hardness increased from pure aluminum to 5 wt.% RHA, reaching a maximum of 78.0 HV, and subsequently decreased slightly at 10 wt.% (77.4 HV) and 15 wt.% RHA (75.9 HV). The reduction at higher RHA contents may be associated with less effective particle packing, possible particle agglomeration, and weaker matrix–particle interaction. These mechanisms are proposed as possible explanations rather than confirmed microstructural effects, since detailed microstructural characterization was not performed in the present study. Overall, the hardness trend followed the order DPDS > SP–HPS > SP–SS for pure aluminum, 5 wt.% RHA composites. However, at 15 wt.% RHA, this trend was reversed, with SP–HPS producing the highest hardness (91.5 HV), while DPDS exhibited the lowest hardness (75.9 HV). This result suggests that the beneficial effect of multiple pressing and sintering cycles on hardness was not maintained at the highest RHA content. Nevertheless, hardness alone was insufficient to guarantee improved tribological performance at higher reinforcement levels.

3.2 Wear Behaviour

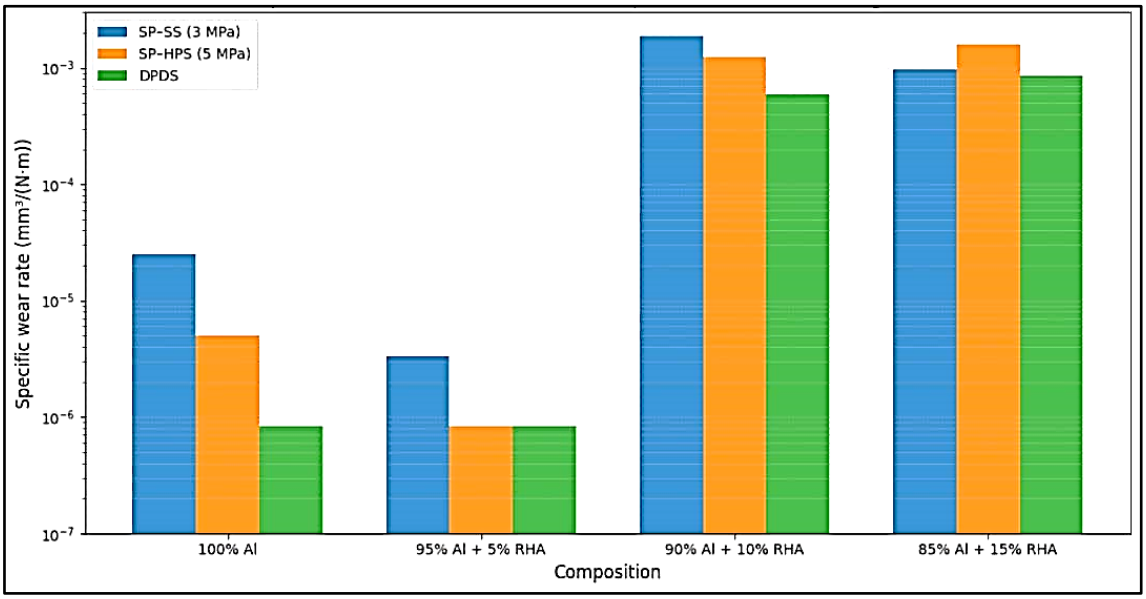

Figure 2: Effect of rice husk ash content and processing route on the wear rate of Aluminum-RHA composites

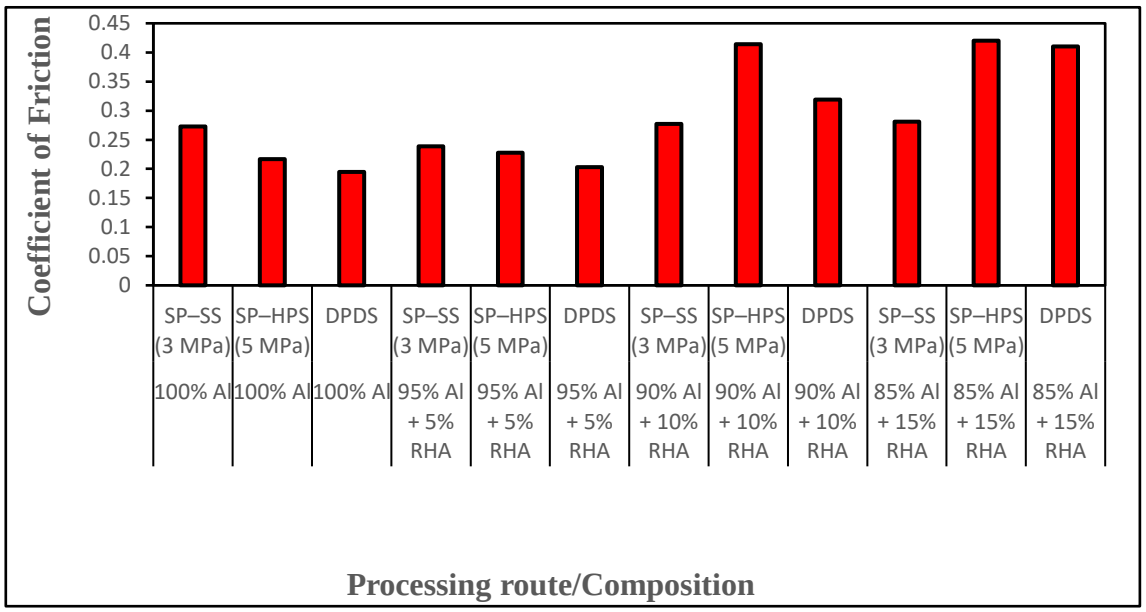
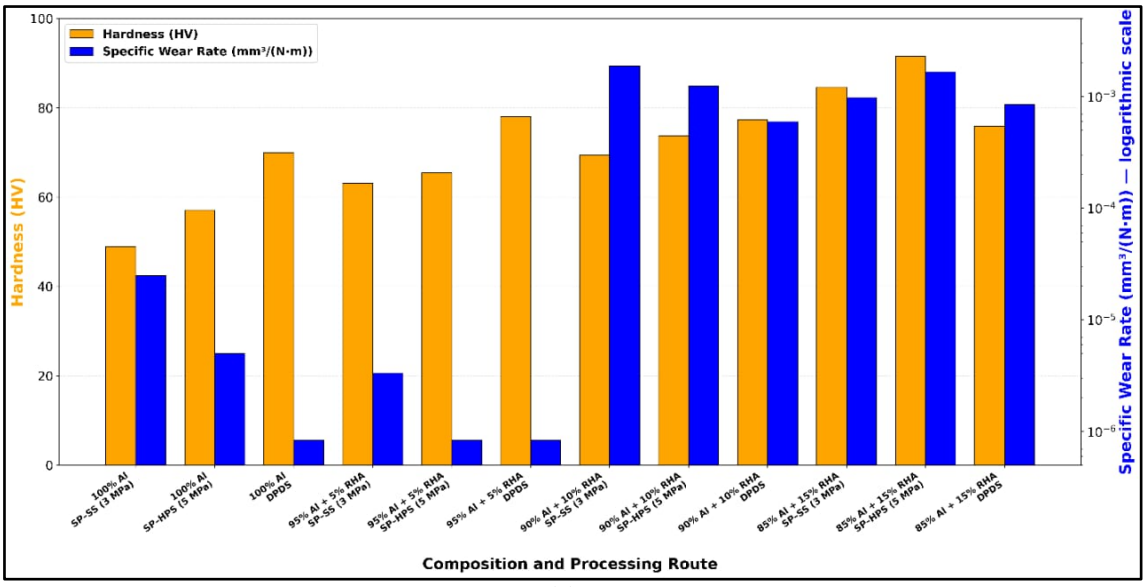
Figure 2 illustrates the influence of reinforcement content and processing route on wear behavior, showing a significant reduction in wear rate for DPDS- processed pure aluminum and 5wt. % RHA. A clear inverse relationship between hardness and wear rate was observed. The DPDS-processed pure aluminum sample exhibited the lowest wear rate of 8.33×10^{-7} mm³/N·m, compared with 2.50×10^{-5} mm³/N·m for the SP–SS condition. Similarly, the 5 wt. % RHA composites processed via DPDS showed a wear rate of 8.33×10^{-7} mm³/N·m, indicating excellent wear resistance. In contrast, composites containing 10 and 15 wt. % RHA displayed significantly higher wear rates despite increased hardness. For example, the 10 wt. % RHA composites processed via SP–SS recorded a wear rate of 1.89×10^{-3} mm³/N·m, while the DPDS condition reduced wear to 5.96×10^{-4} mm³/N·m but did not eliminate severe wear behavior. These results suggest that excessive RHA content promotes particle agglomeration, interfacial decohesion, and abrasive particle pull-out, leading to accelerated material loss. However, these mechanisms are proposed as possible explanations rather than confirmed effects, as detailed microstructural and worn-surface characterization was not performed in the present study.

3.3 Coefficient of Friction





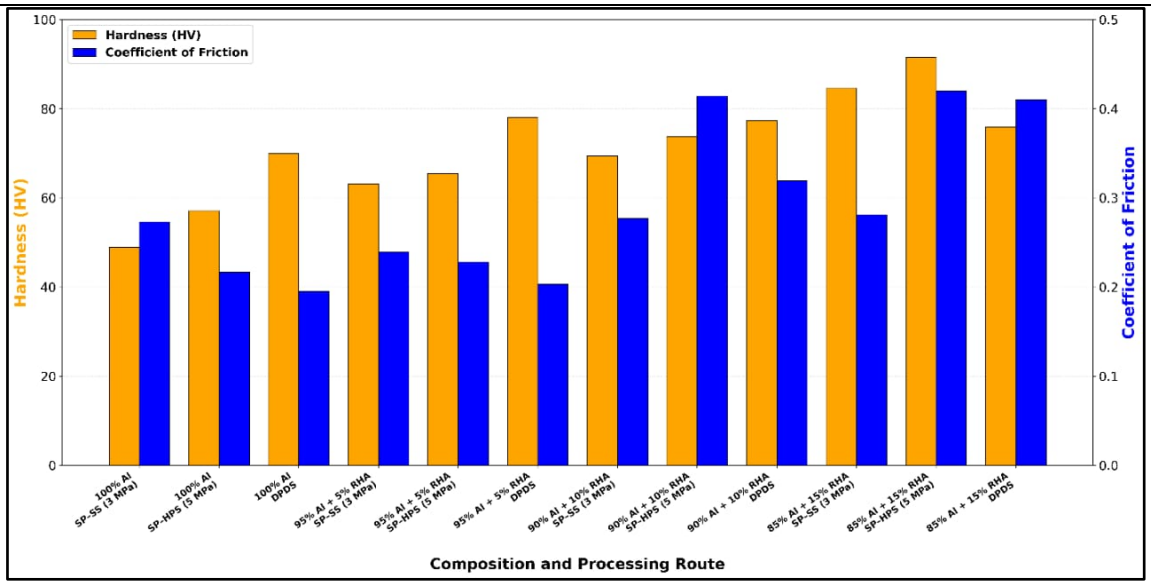


Figure 3: Effect of rice husk ash content on Aluminum-RHA composites processed via different routes

The coefficient of friction followed trends similar to the wear rate (see Figure 3). Lower wear rates were associated with reduced friction values, particularly for DPDS-processed samples. Pure aluminum processed via DPDS exhibited a COF of 0.195, while the 5 wt. % RHA composites showed a COF of 0.203. These values indicate stable sliding conditions with reduced adhesive and abrasive interactions. Higher COF values were recorded for 10–15 wt. % RHA composites, reaching 0.414–0.420 for some SP–HPS samples. The higher friction values observed at some of the higher RHA contents may be associated with the presence of hard silica-rich particles, which can act as third-body abrasives and promote ploughing and micro-cutting at the sliding interface. However, these interpretations are proposed as speculative mechanisms because the particle distribution and worn-surface morphology require further confirmation through surface and microstructural characterization.

3.4 Correlation between Hardness and Tribological Performance

(a)

(b)

Figure 4: Comparison of hardness with (a) wear rate and (b) coefficient of friction

Figure 4a and b show the relationships between hardness and wear rate, and between hardness and COF for the fabricated Al–RHA composites, respectively. The results show an inverse relationship between hardness and specific wear rate, particularly for pure aluminum and the 5 wt.% RHA composites (See Figure 4a). For these compositions, the DPDS route produced higher hardness values accompanied by lower wear rates. This behavior can be attributed to the improved resistance of the harder material to plastic deformation and surface material removal during sliding. The observed trend is consistent with Archard's wear law, which identifies material hardness as an important factor influencing wear resistance. However, at higher RHA contents of 10 and 15 wt.%, the relationship between hardness and wear rate becomes less consistent. This suggests that the wear behavior is influenced not only by hardness but also by microstructural characteristics such as porosity, particle agglomeration, weak matrix–RHA interfacial bonding, and particle pull-out. These defects can promote crack initiation, surface damage, and third-body abrasion, thereby increasing the wear rate despite the presence of a relatively hard reinforcement phase. Figure 4b compares hardness and COF, showing that the DPDS-processed pure aluminum and 5 wt.% RHA composites exhibit higher hardness alongside lower COF values. The reduction in COF with increasing hardness suggests that the improved surface resistance reduces asperity deformation and severe adhesive interactions during sliding, resulting in more stable sliding contact. Nevertheless, the relationship is not strictly linear across all RHA contents as earlier discussed in Section 3.4.

Figure 4 demonstrates that increased hardness generally contributes to improved tribological performance, as reflected by lower wear rate and COF. However, this relationship depends on the reinforcement content, as observed in this study. The consistent improvement observed for the DPDS-processed pure aluminum and 5 wt.% RHA composite indicates that the DPDS route effectively enhanced hardness while simultaneously reducing wear rate and COF. In contrast, the improvements in hardness at higher RHA contents did not consistently translate into reduced wear rate and COF, suggesting that other factors associated with increasing reinforcement content may influence the tribological behavior. These results therefore indicate that an optimum reinforcement content and appropriate processing route are essential for achieving a balanced combination of high hardness, low wear rate, and low COF in Al–RHA composites.

4. CONCLUSION

The effects of DPDS on the hardness and tribological performance of Al–RHA composites were investigated. Both RHA content and processing route influenced the material properties, with 5 wt.% RHA processed by DPDS providing the best overall balance of hardness, wear resistance, and

coefficient of friction. At 15 wt.% RHA, SP–HPS produced the highest hardness (91.5 HV) but also the highest COF (0.420), whereas DPDS produced the lowest wear rate (8.53×10^{-4} mm³/N·m) at the same composition. This confirms that higher hardness does not necessarily result in improved tribological performance. The lack of microstructural characterization limits verification of the mechanisms underlying these trends; future studies should therefore incorporate SEM/EDS and surface roughness analyses. The use of locally sourced RHA in this study promotes agricultural waste valorization and sustainable materials development, supporting locally driven and environmentally responsible engineering solutions in Nigeria. Overall, DPDS shows potential for sustainable Al–RHA composite development, with 5 wt.% RHA providing the most favorable overall performance under the investigated conditions.

ABSTRACT

The effect of heat treatment and different quenching media on the mechanical, tribological, and microstructural behaviour of A6082–SNSA/MWCNT hybrid composites were studied. The fabricated composites were subjected to heat treatment and quenched in tap water (TW), ice block (IB), and SAE40 engine oil (SEO), and their properties were compared with untreated hybrid composites and the base matrix alloy. The result of the mechanical properties revealed that all heat-treated samples exhibited significant improvements in hardness, compressive strength, and impact strength relative to the untreated composite. The IB quenched sample recorded the highest hardness of 155.33 Hv, representing 15% increment, while the TW quenched sample exhibited superior compressive and impact strengths of 1567.1 MPa representing 64.30% and 3.0J respectively. Tribological analysis showed that the SEO quenched composite possessed the lowest coefficient of friction of 0.166, which represents 16.27% improvement, whereas the TW quenched composite demonstrated the most favourable wear performance among the treated samples. Optical microstructural analysis revealed that rapid quenching (IB) produced the finest and most compact dendritic network, while oil quenching resulted in coarse, elongated dendrites with increased segregation and micro-voids. Scanning electron microscope (SEM) analysis of the worn surfaces confirmed dominance of abrasive and delamination wear mechanisms, with reduced surface damage observed in heat-treated samples. The results demonstrate that quenching medium significantly influences the mechanical, tribological, and microstructural behaviour of the hybrid composites.

1. INTRODUCTION

Aluminium matrix composites (AMCs) have attracted considerable interest for lightweight engineering applications because of their high strength-to-weight ratio, wear resistance, and thermal stability. A6082 aluminium alloy is particularly attractive as a matrix material, while the incorporation of suitable reinforcements can further improve its mechanical and tribological performance (Jiang *et al*., 2021; Ononiwu *et al*., 2021; Kumar *et al*., 2025).

MWCNTs are attractive reinforcements because of their high strength, stiffness, and nanoscale load-transfer capability, while shea nutshell ash (SNSA) provides a low-cost and environmentally sustainable agro-waste reinforcement. Previous studies have demonstrated the potential of SNSA and carbon-based reinforcements for improving the properties of polymeric and aluminium composites (Haruna *et al*., 2019; Zubairu *et al*., 2021; Abdullahi *et al*., 2025).

Heat treatment can modify precipitation behaviour, grain structure, matrix–reinforcement interaction, and consequently the mechanical and tribological properties of aluminium composites. Previous studies have reported improvements in hardness, strength and wear resistance following appropriate heat-treatment schedules, although the response depends strongly on alloy composition, reinforcement characteristics and quenching conditions (Gandhi *et al*., 2019; Huang *et al*., 2024; Kuczek *et al*., 2025; Ravikumar *et al*., 2021).

Despite the substantial progress reported in the literature, most existing studies have focused on single or conventional reinforcement systems, with relatively few investigations considering hybrid reinforcement combinations. Furthermore, majority of the reported works evaluated only selected mechanical or tribological properties, while limited attention has been given to understanding the combined effects of heat treatment on the microstructure, mechanical properties, and wear behaviour of hybrid AMCs reinforced simultaneously with agro-waste and carbon nanotubes. Addressing this gap is essential for developing lightweight, high-performance, and sustainable AMCs for advanced engineering applications. Therefore, the present study investigates the effect of heat treatment on the mechanical and wear behaviour of A6082–SNSA/MWCNT hybrid composites.

2. METHODOLOGY

In this study, A6082 metal matrix with length x width x thickness of 350 mm x 25 mm x 25 mm was used. The content of the components of the A6082 alloy is presented in Table 1. Shea nut shell ash (SNSA) particles and Multiwalled carbon nanotubes, comprising 6wt% and 2 wt% particles were used as reinforcements. Stir casting method was employed to fabricate the hybrid composites. The details of the synthesis and characterization of the reinforcements could be found in our previous studies (Abdullahi *et al*., 2025). While A6082 provides excellent strength-to-weight ratio, corrosion resistance, and good castability, SNSA offers a sustainable and low-cost reinforcement source, whereas MWCNTs contribute exceptional strength, stiffness, and load-transfer capability at the nanoscale. The combination of these reinforcement materials is therefore expected to produce hybrid composites with improved mechanical and tribological performance while promoting sustainable utilization of agricultural waste (Abdullahi *et al.*, 2025).

Table 1: Compositions of AA6082 Alloy

Element	Al	Si	Ti	Fe	Mn	Zn	Mg	Cu	Cr	Ni
Wt.%	96.22	1.26	0.07	0.47	0.11	0.28	1.30	0.18	0.09	0.02

2.1 Hybrid Composites Fabrication

The hybrid composite was produced by heating about 550g of AA6082 to 680 °C using a graphite crucible in a charcoal fired furnace. Coated MWCNT (Abdullahi *et al*., 2025) and the SNSA were introduced into the molten AA6082 alloy and stirred using a mechanical stirrer equipped with a stainless-steel tip, operating at 450 rpm for 4.5 min. To ensure effective wetting of the reinforcement phase by the matrix, the reinforcements were heated to 250 ^{0}C and introduced into the molten AA6082. The molten mixture was poured into a square pre-heated steel mould of 350 mm in length 25 mm height and 25 mm thickness. The fabrication parameters were adopted from the optimized procedure reported by Abdullahi *et al*. (2025).

2.2 Heat Treatment

Heat treatment was performed on the cast samples using a Box-Resistance Furnace Model No 2392. Samples were solution-treated at 540 °C for 4 h, quenched separately in tap water (TW), ice block (IB) and SAE 40 engine oil (SEO), aged at 160 °C for 8 h, and subsequently cooled at room temperature (Rotella *et al*., 2018).

2.3 Mechanical Properties Tests

Hardness test was performed according to ASTM E384. The compressive strength of the hybrid composites was tested using a computerized universal testing machine. The specimens were prepared as per the ASTM E-8. The tensile strength specimen was machined as per ASTM E8 with 10 mm diameter and 15 mm length specimens. Impact test of the samples was conducted as per ASTM Standard E 602. V-notches of 0.5mm depth was made on the samples and the impact strength was carried out using Charpy Impact testing machine, serial no. 412-07-152619 with capacity of 155-300J. Table 2 show samples designations and the heat treatment carried out.

Table 2: Samples Nomenclature and Heat Treatment Process carried out

S/N	Heat treatment sample	Designation
1	A6082	Matrix
2	Un-treated hybrid composite	HBC
3	Water quenched	TW
4	Ice block quenched	IB
5	SAE 40 oil quenched	SEO

2.4 Tribological Test

A standard Tribometer/Version 6.1.19 (ball-on-disc) apparatus was employed to conduct the wear tests in accordance with ASTM G99. Test was conducted by applying 10N load at 10 cm/s speed for 30 m sliding distance. Hardened steel (65 HRC) counter disc of 10 mm track diameter and 8 mm thick was used. Specimens of 20 mm diameter and 40 mm height were prepared and the ball surface was polished by emery paper. The tests were conducted at 29 °C room temperature and 55 % relative humidity for 30 minutes (Ahmer *et al*., 2016). The variation of friction coefficient with time and sliding distance was recorded continuously during the tests. Wear rate and coefficient of friction for samples were measured using Equations 1 and 2 as earlier used by Bhaumik and Kamaraj, (2021).

$$Wear\ rate,\ WR = \Delta W/s \quad (1)$$

$$\Delta W = W_1 - W_2 \quad (2a)$$

$$s = 2\pi Ndt \quad (2b)$$

Where WR is the wear rate (mg/min), ΔW is the weight loss, W_1 and W_2 is the weight before and after abrasion (mg), S is the sliding distance (m), N is the machine speed, d is the disc diameter, and t is the time for each sample to undergo abrasion.

2.5 Scanning Electron Microscope (SEM) and Metallography

The microstructures and worn surfaces were examined by optical microscopy and SEM/EDS following standard metallographic preparation and Kroll's etching (Shuvo *et al*., 2025; Jaber *et al*., 2023; Motyka *et al*., 2014.

3. RESULTS AND DISCUSSION

3.1 Mechanical Properties

Figure 1a-c shows average variation of mechanical properties of the samples after different heat treatment processes. It can be seen from Figure 1a that all heat-treated composite samples exhibited superior hardness compared to the untreated samples. The IB block quenched sample recorded the highest hardness of 155.33 HV (a 15% increase relative to the untreated control), followed by the sample quenched in SEO at 134 HV (an 8.45% increase). This enhancement in hardness is attributed to precipitation hardening, grain refinement, a more homogeneous microstructure, and the stabilization of hard intermetallic phases during solution treatment and artificial aging (Rmadan *et al.*, 2024). The variation across quenching media underlines the critical role of cooling rate in dictating precipitation kinetics, with ice-block quenching yielding the most favourable hardening response. Heat treatment proved more effective in enhancing the hardness of the composite specimens than that of the unreinforced matrix alloy (Ravikumar *et al*., 2021; Abishkenov *et al*., 2024; Rmadan *et al*., 2024).

Figure 1b shows average compressive strength of the treated hybrid composite samples. It can be seen that heat treatment significantly enhanced the compressive strength across all samples compared to the HBC. The sample quenched in TW achieved the highest compressive strength of 1567.1 MPa (a 64.30% increase), followed by the IB-quenched sample at 828.8 MPa (a 36.25%

increase). These strength improvements stem from matrix-reinforcement diffusion mechanisms, composition of the reinforcements, grain refinement, and strengthened matrix–reinforcement interfacial bonding (Nagaraja *et al*., 2021). The variation in compressive strength among the quenching media also demonstrates that cooling rate significantly influences distribution of strengthening precipitates required for maximum load-bearing capability. (Şenel and Mahmutoğlu, 2022; Nagaraja *et al*., 2021).

Figure 1c shows the mean effect of heat treatment on Impact strength of the hybrid composite of all samples. Both treated and untreated hybrid composites demonstrated higher impact energy absorption than the unreinforced matrix sample. The TW-quenched sample exhibited the highest impact strength at 3.0 J, demonstrating superior toughness and resistance to dynamic load deformation. Conversely, the IB-quenched sample recorded lower impact energy values. The improved impact resistance in TW quenching suggests that a balanced cooling rate promoted a uniform distribution of fine precipitates, achieving an optimal trade-off between strength and toughness without inducing excessive brittleness. Improved impact resistance could be due to an increased number of fine precipitates that were uniformly distributed after the heat treatment of the composite samples (Mahan *et al*., 2023). This finding demonstrates that the choice of quenching medium has a significant influence on the dynamic mechanical behaviour of the hybrid composites (Mahan *et al*., 2023; Zubairu *et al*., 2021).

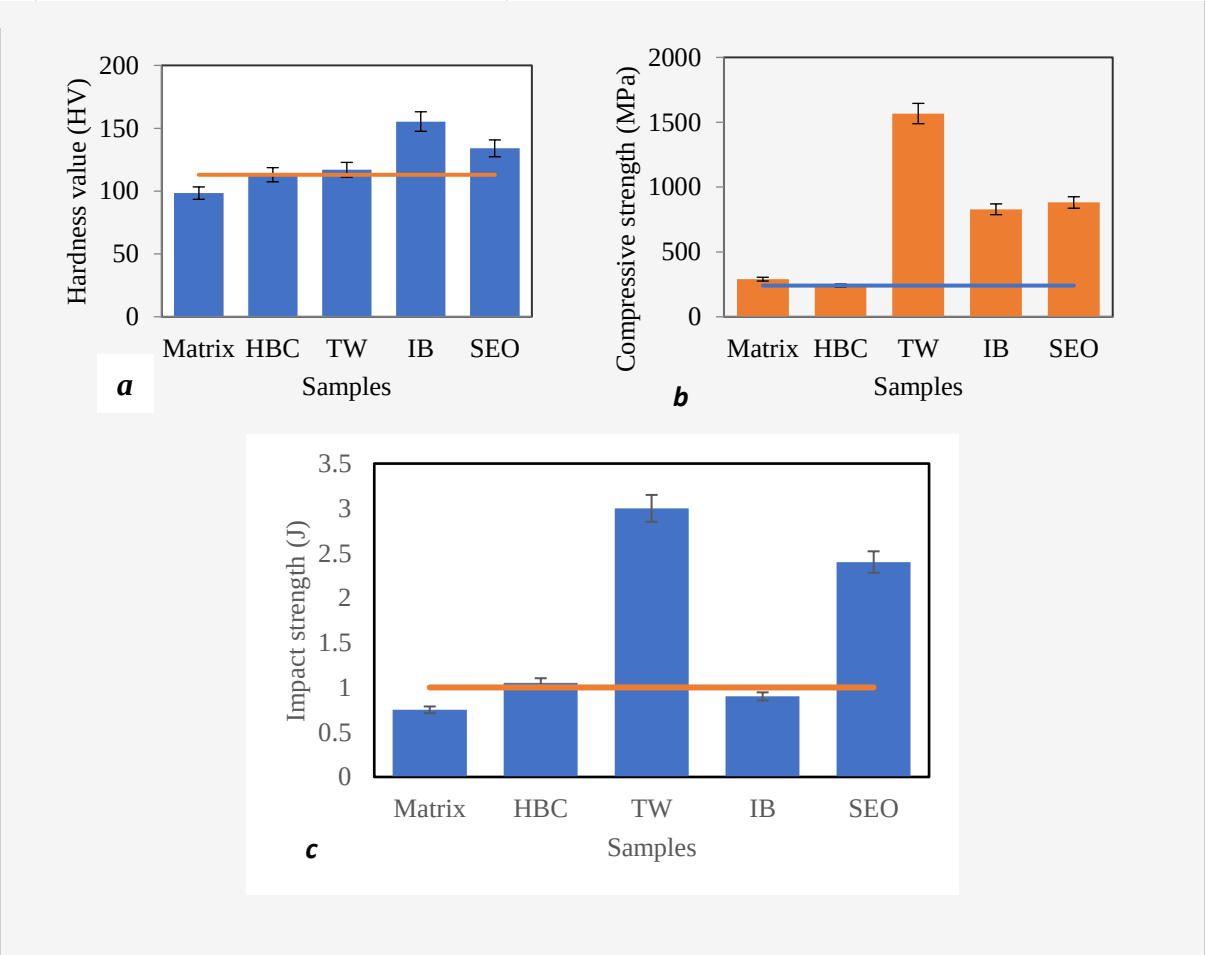

Figure 1: Variation Mechanical properties of A6082-SNSA/MWCNT composites after different heat-treatment conditions: (a) hardness, (b) compressive strength, and (c) impact strength

3.2 Tribological Properties

Tribological properties, including the coefficient of friction (CoF) and specific wear rate (SWR), were determined for the samples, and the results are presented in Figure 2a–b. Figure 2a shows the mean variation in CoF under the different heat-treatment conditions. The sample quenched

in SEO exhibited the lowest CoF of 0.166, representing a 16.6% reduction relative to the untreated HBC, which recorded a CoF of 0.199. In comparison, higher CoF values were obtained for the untreated AA6082 matrix (0.221), TW-quenched sample (0.217), and IB-quenched sample (0.211). The lower friction exhibited by the SEO-quenched sample may be attributed to the relatively mild cooling rate associated with oil quenching, which can promote a more favourable microstructural condition and enhance the stability of the surface tribo layer during sliding contact. This behaviour suggests that heat treatment influences not only the bulk mechanical properties of the composite but also the surface characteristics and interfacial interactions that govern its frictional response (Paladugu *et al*., 2022; Baghel and Krishna, 2023).

Figure 2b presents the mean specific wear rate (SWR) of the AA6082 hybrid composite samples subjected to different heat-treatment conditions. The untreated HBC exhibited the lowest specific wear rate, whereas heat treatment resulted in increased material loss for the samples quenched in TW, IB, and SEO. The increase in wear rate following heat treatment may be associated with changes in matrix hardness, precipitate distribution, residual stresses, and matrix–reinforcement interfacial integrity. Such microstructural modifications can increase the susceptibility of the matrix to plastic deformation and facilitate the detachment of wear debris during sliding. Similar observations have been associated with thermal treatment and ageing-induced changes in aluminium alloys (Anuar *et al*., 2023). Although severe quenching, such as ice quenching, has been reported to promote favourable precipitation and dislocation-pinning effects in alloys such as AA7075, thereby improving wear resistance (Ravikumar *et al*., 2021), the present results demonstrate that the tribological response is strongly dependent on alloy composition, reinforcement characteristics, heat-treatment condition, and cooling rate. Therefore, the higher wear rates observed after quenching in the present AA6082-SNSA/MWCNT hybrid composite indicate that the applied heat-treatment conditions did not produce sufficient strengthening to offset the microstructural changes that promoted material removal during sliding.

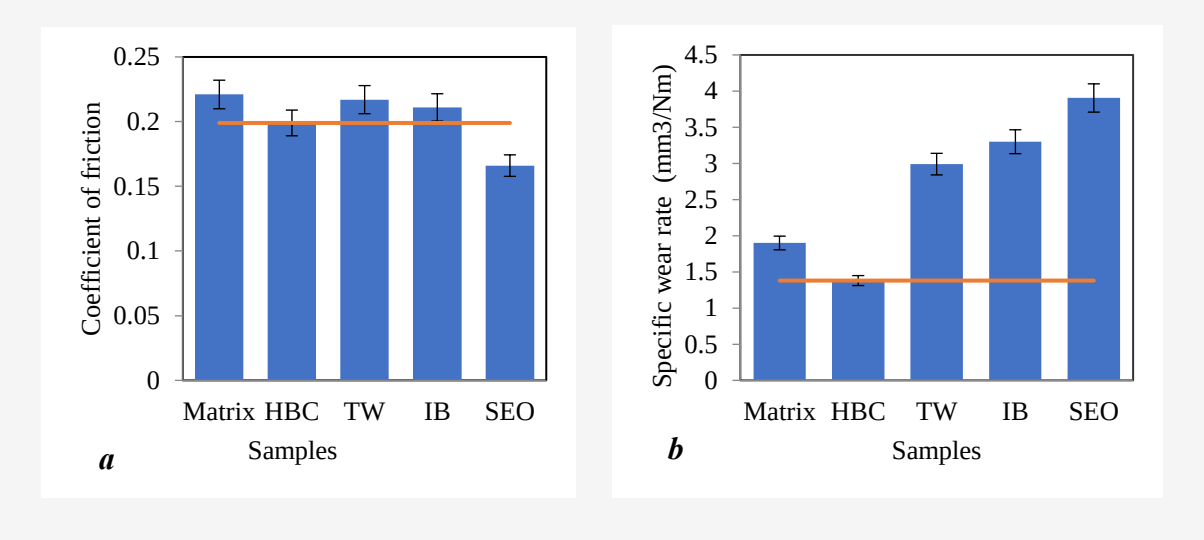

Figure 2: Variation of Tribological behaviour of A6082-SNSA/MWCNT composites: (a) coefficient of friction and (b) specific wear rate

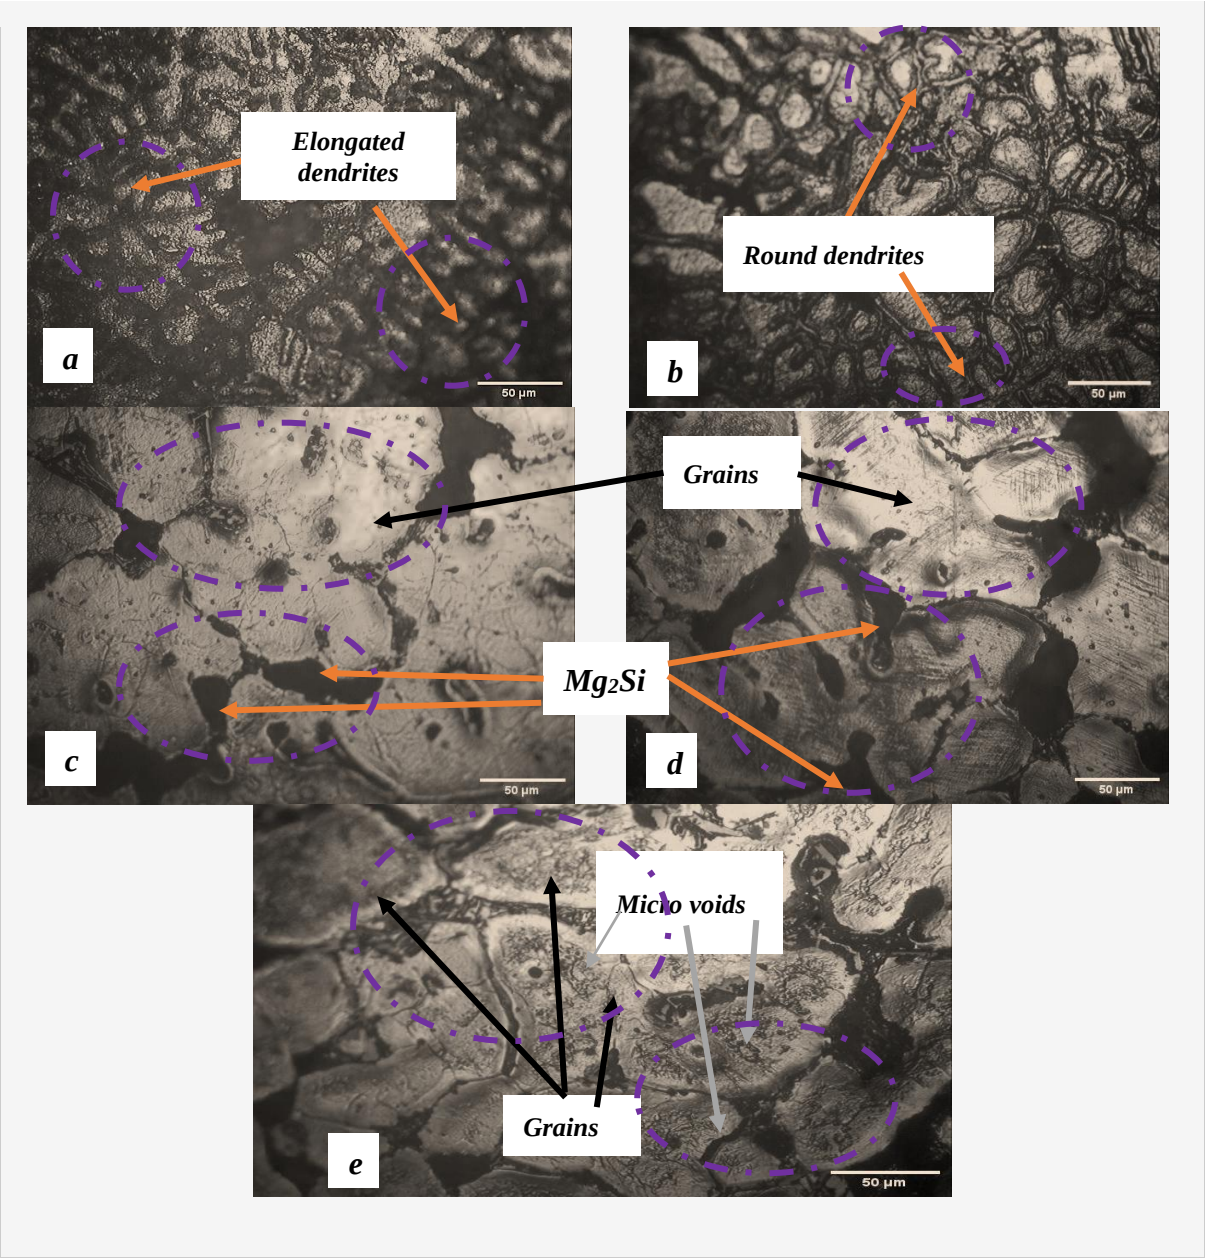
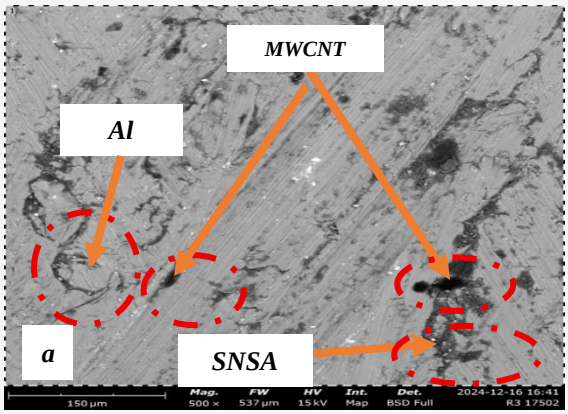
3.3 Microstructure and wear surface characterization

3.3.1 Optical microstructure

The microstructure of the as-cast AA6082 matrix shown in Figure 6a reveals elongated dendritic structures of primary α-Al grains (bright regions) and Al–Mg_2Si eutectic phases (dark regions), which are characteristic of cast aluminium alloys (Yuan *et al*., 2021; Brodova *et al*., 2022). Figure 6b presents the microstructure of the untreated HBC, characterized by relatively coarse dendrites and localized clustering of reinforcement particles within the matrix. Figures 6c–e shows the microstructures of the composite subjected to different quenching media. The TW-quenched sample (Figure 6c) exhibits moderately refined and more equiaxed grains, with shorter dendritic arms and

narrower inter dendritic regions compared with the untreated HBC. The IB-quenched sample (Figure 6d) displays the finest and most compact dendritic structure, with relatively uniform grain morphology and reduced inter dendritic regions. This refinement can be attributed to the higher cooling rate of ice-block quenching, which restricts dendritic growth and limits coarsening. Ramirez-Vidaurri *et al.* (2022) similarly reported that increasing cooling rate reduces secondary dendrite arm spacing and suppresses dendritic coarsening. In contrast, the SEO-quenched sample (Figure 6e) exhibits comparatively coarser dendritic features, suggesting that the slower cooling rate of SEO permits greater dendritic growth and localized segregation. The micrographs demonstrate that the quenching medium significantly influences the grain morphology and dendritic structure of the A6082–SNSA/MWCNT hybrid composites. Rapid cooling in the IB medium produced greater grain refinement, whereas slower cooling in SEO promoted relatively coarser structures. These microstructural differences are consistent with the observed mechanical behaviour, as grain refinement and a more compact microstructure can restrict dislocation movement and improve matrix–reinforcement interaction, thereby contributing to increased hardness and compressive strength (Ramirez-Vidaurri *et al*., 2022; Odinachi *et al*., 2017).





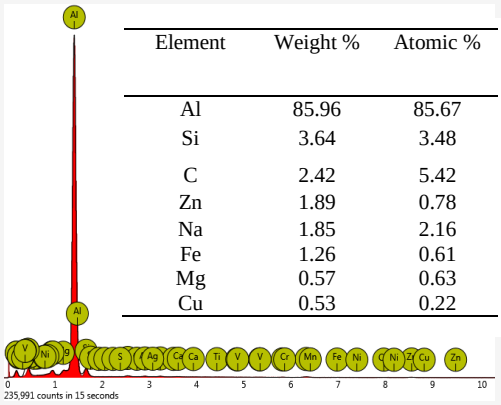


Figure 6: Optical Micrograph of: (a) Matrix (b) HBC, (c) TW treated, (d) IB treated, and (e) SEO treated A6082-SNSA/MWCNT Hybrid Composites at Magnifications of X100

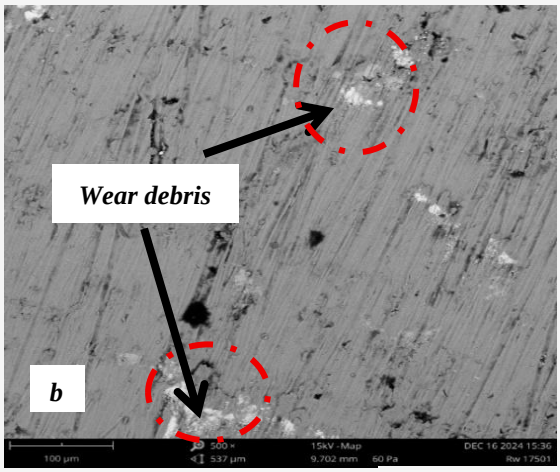
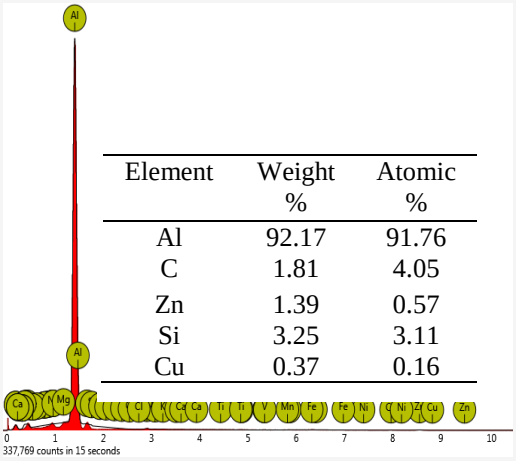
3.3.1 SEM/EDS analysis



The microstructure studies of worn surfaces of the samples were studied using SEM/EDS and the micrographs are presented in Figure 7a-d. The worn surfaces of the A6082–SNSA/MWCNT hybrid composites were examined using SEM/EDS, and the resulting micrographs are presented in Figure 7a–d. The worn surfaces exhibited characteristic features associated with abrasion, delamination, adhesion, and, in some cases, reinforcement particle pull-out. The untreated HBC (Figure 7a) showed pronounced grooves parallel to the sliding direction, together with delaminated regions. These features indicate that abrasive and delamination wear were the dominant mechanisms. The formation of grooves along the wear track is commonly associated with the ploughing action of hard reinforcement particles or detached wear debris (Erappa Rajj *et al*., 2024; Turan *et al*., 2020). The TW-quenched sample (Figure 7b) exhibited fewer and shallower grooves, reduced delamination, and a comparatively uniform worn surface, suggesting less severe surface damage. This observation is consistent with the findings of Suchendra *et al.* (2023), who associated smoother worn surfaces with improved resistance to material removal. The IB-quenched sample (Figure 7c) contained a small amount of scattered wear debris, which may have resulted from micro-fracture, delamination, or reinforcement particle pull-out during sliding. Similar wear debris and micro-fracture features have been reported for reinforced aluminium composites (Ramadoss *et al*., 2020). In contrast, the SEO-quenched sample (Figure 7d) displayed relatively large delaminated or particle pull-out regions and prominent grooves, but comparatively little loose wear debris. The limited accumulation of debris suggests that detached material was readily removed from the contact surface, consistent with its relatively low coefficient of friction. Similar combinations of grooves, delamination, ploughing, and particle pull-out have been identified as characteristic wear features in aluminium-based composites under sliding conditions (Radhika *et al*., 2024; Yadav *et al*., 2024).



The EDS results presented alongside the SEM micrographs in Figure 7 further confirm the elemental composition of the worn surfaces. Aluminium was the dominant element in all samples, ranging from 85.96 to 94.29 wt.%, while Si and C were detected in the ranges of 0.41–3.64 wt.% and 1.81–2.98 wt.%, respectively. The presence of these elements indicates the involvement of both the AA6082 matrix and reinforcement-containing regions during sliding. The TW-quenched sample recorded the highest Al content (94.29 wt.%) and exhibited a relatively uniform worn morphology, whereas the untreated HBC showed more pronounced grooves and delamination. The SEM/EDS observations demonstrate that heat treatment altered the severity and dominant modes of surface damage, with the nature of the wear response being dependent on the quenching medium and the resulting microstructural condition.

Element	Weight %	Atomic %

4. CONCLUSION

This study investigated the effects of heat treatment and quenching media on the mechanical, tribological, and microstructural behaviour of A6082–SNSA/MWCNT hybrid composites. The results demonstrate that the heat-treatment significantly influenced the overall performance of the composites, with the response varying according to the quenching medium.

Among the investigated conditions, ice-block (IB) quenching produced the highest hardness of 155.33 HV, representing an improvement of approximately 15% over the untreated HBC. Tap-water (TW) quenching resulted in the highest compressive strength of 1567.1 MPa, corresponding to a 64.30% improvement, as well as the highest impact strength of 3.0 J. The SEO-quenched sample exhibited the lowest coefficient of friction (CoF) of 0.166, while the untreated HBC recorded the lowest specific wear rate (SWR) of 1.38 mm^3/Nm.

Microstructural examination further revealed that IB quenching produced the finest and most compact dendritic structure, whereas SEO quenching resulted in relatively coarser dendrites accompanied by micro voids. SEM/EDS analysis of the worn surfaces identified abrasion and delamination as the predominant wear mechanisms. The dominance of aluminium, together with the detection of Si and C, confirmed the involvement of the A6082 matrix and reinforcement-containing phases during sliding. Overall, the findings establish that appropriate selection of the quenching medium can be used to tailor the mechanical, tribological, and microstructural characteristics of A6082–SNSA/MWCNT hybrid composites for potential engineering applications.

ABSTRACT
*This study presents a geospatial analysis of soil textural classes for Kaduna, Kano and Katsina States in the North-western region of Nigeria. Soil classification maps were digitized from the FAO Digital Soil Map of the World using ArcGIS 10.3.1. Results revealed that Sandy Loam is the dominant class in Kano and Katsina States, covering approximately 68% and 61% of the land area respectively. Kaduna State revealed a greater variation in soil textural classes, with Loam as the dominant class in the southern Guinea Savanna area, followed by Sandy Clay Loam and Sandy Loam in the northern Sudan Savanna zone. The spatial distribution of these classes has direct implications for agricultural management in the Sudan Savanna agro-ecological zone. The extensive Sandy Loam areas in Kano and Katsina are prone to rapid infiltration, low water retention and nutrient leaching. Therefore, these zones require soil-water conservation measures such as mulching, tied ridging, and micro-catchments and precision irrigation scheduling using drip or deficit irrigation to improve water use efficiency for drought-tolerant crops like millet, sorghum and cowpea. Furthermore, the Loam and Sandy Clay Loam areas in central and southern Kaduna, with higher water and nutrient holding capacity, are more suitable for crop-soil matching with maize, soybean and irrigated rice under controlled irrigation. The digitized maps provide a spatial decision-support framework for targeted erosion control structures in coarse-textured zones and for variable-rate fertilizer application under precision agriculture. This contributes to SDG 2: Zero Hunger by enabling site-specific input management and yield optimization. The study recommends ground-truthing through physico-chemical analysis of soil samples across representative map units in the three States to validate and refine the map for policy, engineering and extension purposes.***Keywords:*** *ArcGIS; FAO; Northwest; SDG 2; Soil; Soil Texture*

1. INTRODUCTION

Soil is the uppermost part of the earth surface on which plants grow (Stephen et al., 2017). It is a mixture of mineral matter, organic matter, water and air. Soil quality is a major determinant of agricultural productivity Bichi & Khalil, (2025) and Ologunde & Nunes, (2026) and, thus, understanding the soil quality dynamics remains paramount in achieving food security in any region . Soil texture is the relative proportions of sand, silt, and clay in the soil. The optimization of a farming season can be greatly influenced by the soil textural classes. As this influences engineering properties, water movement, rooting depth of plants of a soil, Erosion resistance, nutrient retention, water infiltration and most importantly crop production Ahmed et al., (2020) and Sharu, M. B. et al., (2025). These soil properties often vary from time to time (Gambo et al., 2025), soil quality assessment is therefore an unending process. The Northwestern region of Nigeria is known as a hub of production of crops such as groundnut, millet sorghum and maize etc. However, an optimized production of these major crops is often limited by climatic variability and unsustainable local farming practices. Muhammad et al., (2026) highlighted the suitability of sandy loam and loamy soils for optimum productivity of maize plant which is a major crop in attaining SGD2- Food Security and Zero Hunger, in Northwestern Nigeria. A geospatial interpretation of soil types in this region is therefore, an important information required for an effective land use and land cover (Farming) planning as wells as soil conservation strategies. Despite the availability of global soil database by the FAO, the localized application and interpretation of soil textural classes in this region is lacking. The study

therefore, aimed to analyze and classify the spatial distribution of soil textural classes of Kano, Kaduna and Katsina States all located in the Northwestern region of Nigeria.

2. METHODOLOGY

2.1 Description of Study Area

The study area include Kano, Kaduna Katsina, State located in the northwestern region of Nigeria. These are located between a latitude of 12.99ºN to 10.52ºN and a longitude of 7.44ºE to 8.52ºE (Muhammad et al., 2026). The states falls under the Sudan Savanna ecological Zones and are classified as a semi-arid climate. The zone experiences two distinct seasons known as dry season from October to May and a wet season from May to September. The annual average rainfall range between 500 mm to 1000 mm. The States are characterized by an average temperature ranging between 28^{O}C to 40º C.

2.2 Data Source

The soil data was obtained from the Digital Soil Map of the World (DSMW)(FAO,2007).

2.3 Data Processing and Interpretation

This involves a preliminary desk-based study pending ground-truthing. This soil data was processed and digitized in ArcGIS 10.3.1 through the following steps;

a. **Projection**: The administrative boundary shapefiles of the States were projected to WGS 1984, UTM.ZONE-32N

b. **Extraction of Study Areas**: This was achieved by importing the DSMW soil polygon of Nigeria and Kano, Kaduna and Katsina states shapefiles into ArcGIS 10.3.1

c. **Clipping Raster Data:** The extraction by Mask tool in Spatial Analyst tool of ArcGIS 10.3.1 was used to extract the polygon layers of each States from the DSMW raster file.

d. Soil Textural Interpretation and Classification: The soil textural classes were interpreted based on Harmonized World Soil Database (FAO, 2012). The textural classes were defined by the USDA classification system into Loam, Sandy Loam, Sandy-Clay Loam etc. A suitable color range were chosen for cartographic and Legend representation for each state.

3. RESULTS AND DISCUSSION

The digitized soil classification maps for Kaduna, Kano and Katsina states are presented in Figures 3.1, 3.2 and 3.3. Table 3.1 also shows the distribution per square kilometre of soil textural classes for each state. Generally, the States were dominated with sand soils with some variations (sandy-clay, sand-loam etc). The occurrence of sandy soils and sandy loams soils is an expected classification due to the geological and climatic conditions of Sudan Savanna (Northwest) which supports the formation and accumulation of sand particles. This is in line with study findings by Ahmed & Yusuf, (2020); Danjuma, (2023); and Garba et al., (2023). The warm climate also increases the rate of organic matter decomposition which is required to improve the soil structure and fertility of sandy soils.

The dominance of high sand content in the states accounts for why soils have a high leaching loses and lower water holding capacity. A study by Bichi & Khalil (2025) conducted in Dutsin-Ma Local Government Area Katsina State similarly found out that all samples appear to fall under same soil type of Sandy Loam. This means that the variation in texture may not be significant and because of that same type of irrigation technique can be employed in Dutsin-Ma LGA the study area.

Note: The maps below show multiple colors for same textural class due to different soil components with similar texture but different parent material and drainage properties. This explains why same textural classes with different FAO/SWAT serial numbers.

Table 3.1: FAO/SWAT Soil Textural Distribution per Area

Kaduna FAO/SWAT S/N	Area (sqkm)	FAO/SWAT S/N	Katsina Area (sqkm)	FAO/SWAT S/N	Kano Area (sqkm)

1528	0.016405	1470	0.054202		

3.1 Kaduna State

Kaduna State displayed the most heterogeneous soil profile .The most dominant soil types identified in Kaduna State were Loam, Sandy Clay Loam, and Sandy Loam. These were hy same distributed in significant, contiguous patches. This is an indication that the state is of relatively favorable soil conditions. This correlates with the study findings by Garba et al., (2023) conducted in Birnin Yero Kaduna State that concluded soils in the study area were predominantly sandy loam and loamy. Smaller patches of Loamy Sand were also identified in some areas of the state. The presence of Loam and Sandy clay loam in most areas of Kaduna State indicates a possibility of growing a wider range of crop varieties due to favorable soil properties.

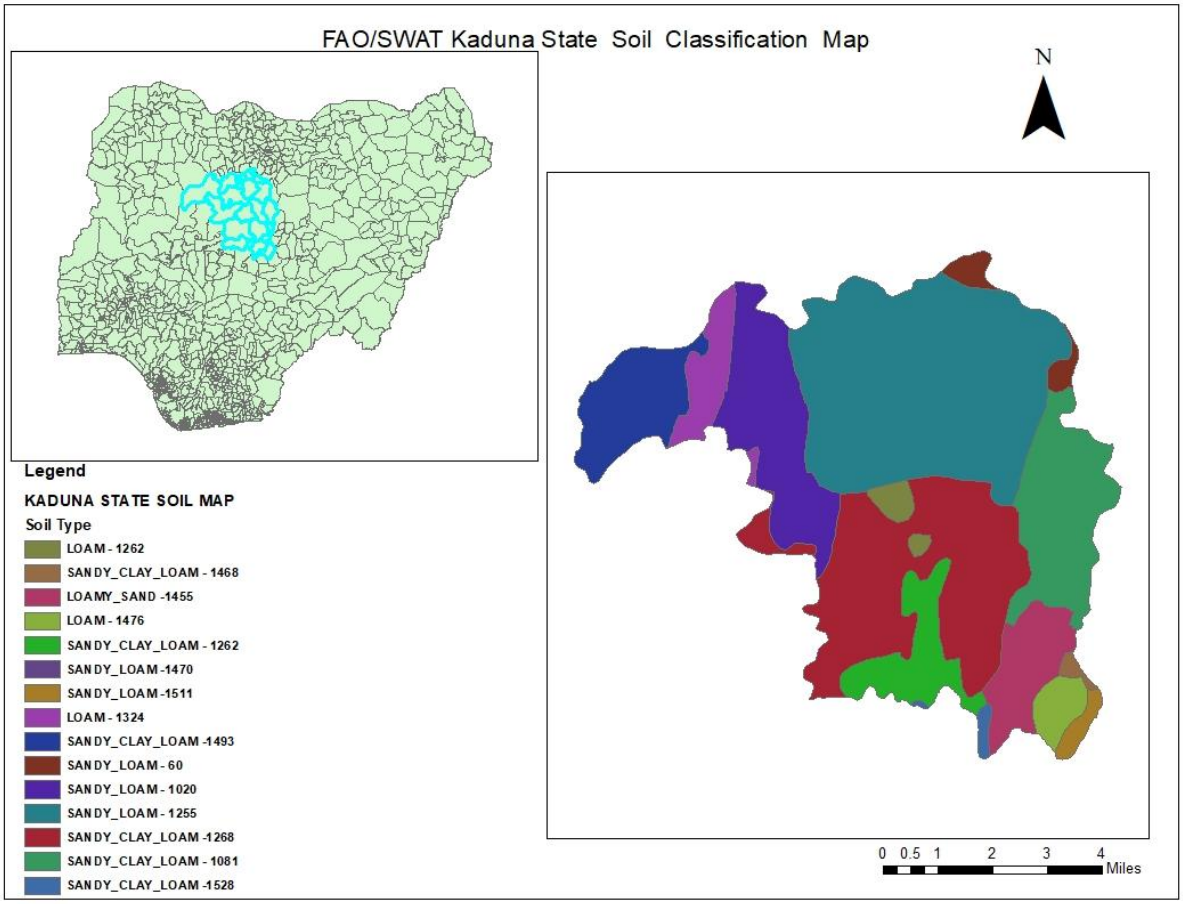

Figure 3.1: Kaduna State Soil Textural Classification Map

3.2 Kano State

Kano state was generally dominated by coarse-textured soils. Sandy Loam was the major soil class, covering 65% of the land area of the state. This was followed by Sandy Clay Loam. Muhammad et al., (2026) conducted a similar study in Kano State and found out that Six distinct soil textural classes were identified within the River Watari basin: loam, sandy loam, sandy clay loam, silty clay loam, clay loam, and clay. A very low water and nutrient-holding capacity soil known as Sand was identified at the central region of the state.

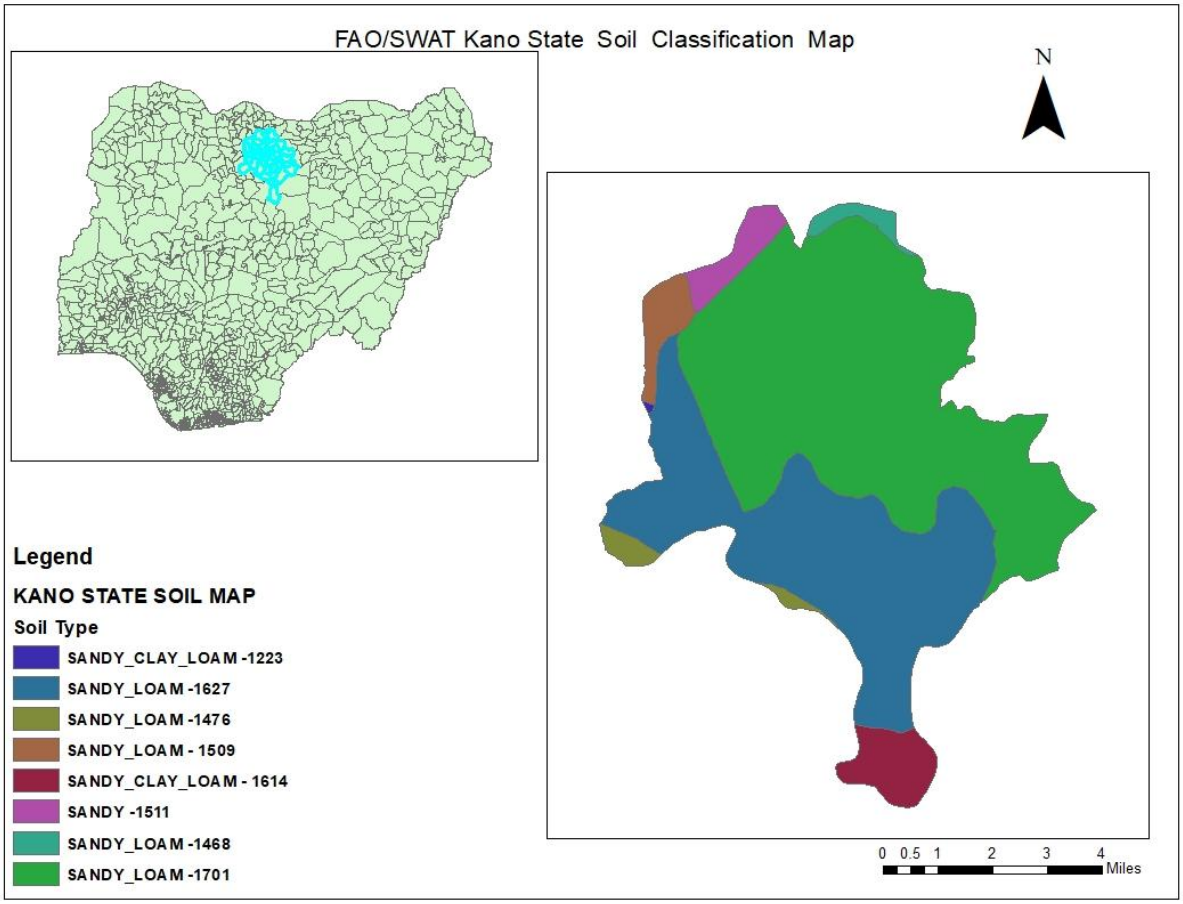

Figure 3.2: Kano State Soil Textural Classification Map

3.3 Katsina State

Katsina State also shows a predominant soil type of Sandy Loam in most parts of the State. However, the state showed a more varied composition than Kano, due to occurrences of larger areas with Sandy Clay Loam, Loam and Clay Loam. A study by Ahmed & Yusuf, (2020) presented similar results. This also correlates with the findings by Danjuma, (2023). The presence of Clay Loam soils is an indication that there are localized areas with higher water retention potential. For Clay soils are generally known to have higher porosity and lower permeability.

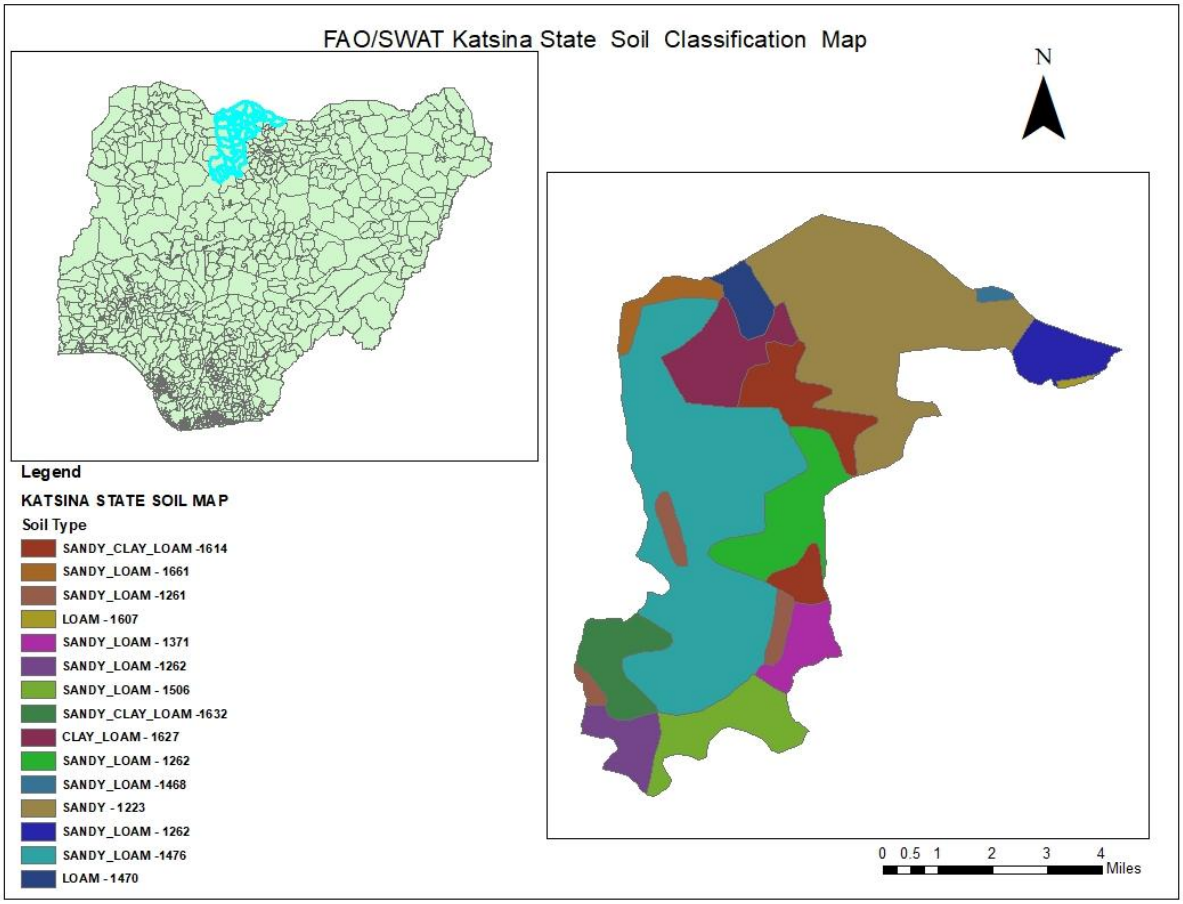

Figure 3.3: Katsina State Soil Textural Classification Map

4. CONCLUSION

The dominance of Sandy Loam in Kano and Katsina States indicates inherent constraints of low organic matter, poor water retention, and high susceptibility to wind and water erosion. For these areas, the maps directly support SDG 2 by guiding the adoption of specific soil-water conservation measures : contour stone bunds and zai pits to reduce runoff, and organic mulching to conserve soil moisture for rainfed cereals. In Kaduna State , the mosaic of Loam and Sandy Clay Loam provides opportunity for crop-soil matching . The Loam zones are recommended for high-value, water-responsive crops such as maize and irrigated vegetables, while Sandy Clay Loam areas are suitable for sorghum and groundnut with supplemental irrigation. For precision agriculture technologies , the digitized layers can be integrated into farm management systems to enable variable rate application of NPK fertilizer — lower rates on coarse Sandy Loam to prevent leaching, and higher rates on Loam areas to maximize yield. Irrigation scheduling can also be spatially optimized: more frequent, low-volume applications for Sandy Loam in Kano/Katsina, and less frequent applications for Loam in Kaduna. To operationalize these recommendations, future work should prioritize ground-truthing through physical-chemical analysis of soil samples across the mapped textural classes. This will be useful in validating the FAO-derived units and provide the fertility data needed for state-level agricultural policies on fertilizer subsidy targeting and erosion control planning.

ABSTRACT

Investment casting produces high-quality, dimensionally accurate parts with complex geometries that forging and machining cannot easily achieve, but imported refractories and binders make the process expensive to adopt. This study investigated locally available moulding plaster, cassava flakes, kaolin, Portland cement, and fine sand as substitutes, using beeswax as the pattern material. Particle size, viscosity, flexural strength, and refractoriness were determined. Viscosity reached 710 mPa·s for moulding plaster, 650 mPa·s for cassava flakes, and 613 mPa·s for kaolin, while flexural strength reached 105.60 MPa for moulding plaster, 80.00 MPa for Portland cement, and 52.13 MPa for kaolin. Six trial compositions were evaluated and an optimum blend containing 82% moulding plaster, 5% cassava flakes, 5% cement, 4% kaolin, and 4% fine sand was selected. The fired mould achieved flexural strengths of 159.25, 139.00, and 154.75 MPa for three samples, with an average permeability of 92 AFS. A brass jewellery piece was successfully cast in the finished mould. The findings demonstrate the feasibility of combining locally available materials into a functional investment casting system without imported refractories.

Keywords: *investment casting; locally sourced refractories and binders; ceramic shell mould; beeswax; brass casting*

1. INTRODUCTION

Investment casting, commonly known as the lost-wax process, is widely used where complex geometry, dimensional accuracy, and surface finish are important. The process has applications in aerospace, defence, power generation, automotive, medical devices, construction, and other manufacturing sectors (Diamond, 1980; Groover, 2010; Soemardi et al., 2016). A global market review has noted that investment casting continues to expand into new sectors precisely because of this combination of accuracy and geometric freedom (Ronald & Richard, 2012). The process depends heavily on the quality and cost of its refractory mould system. Conventional investment casting commonly uses alumina, silica, zircon, mullite, and related refractory materials with binders such as colloidal silica, ethyl silicate, sodium silicate, or fireclay (Beeley & Smart, 1995; Ibhadode, 2014; Prasad, 2012). In Nigeria, many of these materials are imported in usable forms, increasing cost and supply-chain constraints for small and medium-scale foundries.

Previous investigations have demonstrated that slurry viscosity, particle size, suspension behaviour, shell strength, permeability, and refractoriness strongly influence investment casting performance (Kline et al., 2010; Shukla & Juneja, 2011; Singh et al., 2012; Zhao et al., 2011). Parallel work on the pattern side of the process has shown that wax type, blending, and injection conditions govern the dimensional stability and surface quality of the pattern that the shell is built around (Bembalge & Karunakar, 2011; Kamboj, 2017; Rezavand & Behravesh, 2007; Sandhu & Sharma, 2012; Yadav et al., 2011); the beeswax pattern route adopted here draws on this body of work while relying on a single, low-cost, locally available pattern material rather than blended commercial waxes. On the shell side, alternative refractory systems and additives have been explored to reduce cost or improve high-temperature performance, including graphite-modified permeability control (Kline et al., 2010), fly-ash-modified ceramic shells (Shukla & Juneja, 2011), calcium zirconate systems for reactive alloys

(Klotz et al., 2019), locally sourced shell materials for steel casting in South East Asia (Purwadi et al., 2012), optimized ceramic shell formulations (Dave & Kaila, 2014), high-temperature strength characterization of shell moulds (Kolczyk & Zych, 2011), camphor-based intensification of shell mechanical properties (Tamta & Karunakar, 2014), and statistically rigorous bend-testing protocols for shell characterization (Richards et al., 2016). However, most published systems still rely on imported refractory and binder systems, or on additives that are themselves imported. This creates a practical research gap: whether locally available materials can be characterized, formulated, and combined into a complete working investment casting mould system.

The aim of this study was to investigate the use of locally available materials for producing an investment casting mould. Specifically, the study sought to identify suitable local materials; characterize their relevant physical and mechanical properties; develop a stable slurry; evaluate viscosity, bulk density, suspension percentage, and thixotropy; produce and fire a ceramic shell mould; determine strength, permeability, and refractoriness; and demonstrate the mould by casting a brass component.

2. METHODOLOGY

Materials and Equipment

Moulding plaster, Portland cement (grade 42.5), and kaolin were used as refractory constituents, while fine sand and cassava flakes served as binder-related constituents. Beeswax was used as the pattern material. All materials were sourced commercially within Nigeria. Equipment included a standard sieve set, digital balance, slurry stirrer, Fann Model 35SA viscometer, Ridsdale permeability testing device, vernier caliper, graduated flask, Universal Materials Testing Machine (100 kN capacity), laboratory thermometers, and a flash-fire oven.

Material Characterization

Particle size distribution was determined by sieve analysis using 1000 g samples in accordance with BS 1377: Part 1: 1990. Flexural strength was measured on 100 × 10 × 4 mm specimens by three-point bending at a crosshead speed of 2 mm/min, using three replicates for each material. Flexural stress was calculated as $\sigma_3 pt = 3PL/(2bd^2)$, where P is the applied load, L is the support span, b is the specimen width, and d is the specimen thickness. Flexural modulus was determined from the same three-point bending test as $E = L^3m/(4bd^3)$, where m is the slope of the initial linear (elastic) region of the load–deflection curve, following the approach outlined for ceramic shell bend testing by Richards et al. (2016); the linear region was fitted over the first 10–20% of the load range before any visible non-linearity or crack initiation.

Viscosity was measured with a Fann rotational viscometer at 100 rpm. Refractoriness was evaluated by heating specimens from room temperature to 800°C at a controlled rate of 10°C/min in a muffle furnace, holding for 30 min at 200°C intervals, and inspecting each specimen for sintering, cracking, spalling, or grain breakdown at each hold point; a specimen was classified as resistant to thermal shock if it showed no visible cracking or spalling up to 600°C and no gross structural breakdown up to 800°C.

Slurry Formulation and Mould Production

Six trial slurry compositions were prepared by varying cement, cassava flakes, fine sand, kaolin, and moulding plaster (Table 1). The sixth composition—82% moulding plaster, 5% cassava flakes, 5% cement, 4% kaolin, and 4% fine sand—was selected because it produced a stable and workable slurry. Bulk density, suspension percentage, thixotropy, and viscosity were monitored. Beeswax patterns were assembled on a central sprue and repeatedly dipped into the slurry with 3–4 h of drying between coats. After the required shell thickness was achieved, the mould was dried for 2–3 days, dewaxed, and fired at approximately 500°C. The mould was then used for brass casting.

Table 1: Trial Slurry Compositions Investigated (wt%)

Material	Exp.1 (%)	Exp.2 (%)	Exp.3 (%)	Exp.4 (%)	Exp.5 (%)	Exp.6 (%)
Cement	20	25	30	40	40	5
Cassava flakes	20	20	30	40	30	5
Fine sand	10	20	30	11	10	4
Kaolin	20	15	2.5	2	5	4
Moulding plaster	30	20	7.5	7	15	82
Total	100	100	100	100	100	100

Note. The moulding-plaster values for Exp.1 and Exp.5 have been corrected from the originally recorded 40% and 10% (which produced totals of 110% and 95%, respectively) to 30% and 15%, so that every trial composition sums to 100 wt%.

Figure 1: Beeswax Pattern Tree and Completed Investment Casting Mould Prior to Firing.

3. RESULTS AND DISCUSSION

Particle Size Distribution

Table 2 summarizes the sieve retention of the four raw materials on a 1000 g sample basis. Almost all of the kaolin and moulding plaster passed through to the pan, confirming that both were very fine powders, with 986.64 g and 999.54 g respectively retained in the pan fraction. Cassava flakes and fine sand were retained mainly on the coarser sieves from 600 µm to 2.0 mm. Figure 2 presents the same data as the percentage of each material's mass retained at each sieve size, and is directly consistent with Table 2: the plaster and kaolin bars are concentrated almost entirely in the pan fraction, while the cassava-flake and sand bars are distributed across the coarser sieve sizes. The finer and more evenly graded plaster and kaolin particles favour stable packing and suspension in the slurry, whereas the broader particle-size distributions of cassava flakes and fine sand contribute different flow and packing characteristics.

Table 2: Sieve Analysis of the Raw Mould Materials (1000 g Samples)

Sieve Size	Cassava Flakes (g)	Fine Sand (g)	Kaolin (g)	Moulding Plaster (g)
2.0 mm	64.00	38.60	0.27	0
1.18 mm	169.70	520.50	0.58	0
600 µm	481.60	230.02	0.83	0
425 µm	212.02	97.80	0.92	0
212 µm	54.60	41.40	1.04	0
150 µm	9.03	25.70	1.87	0.1
63 µm	0	20.60	2.80	0.13
Pan	0	16.90	986.64	999.54

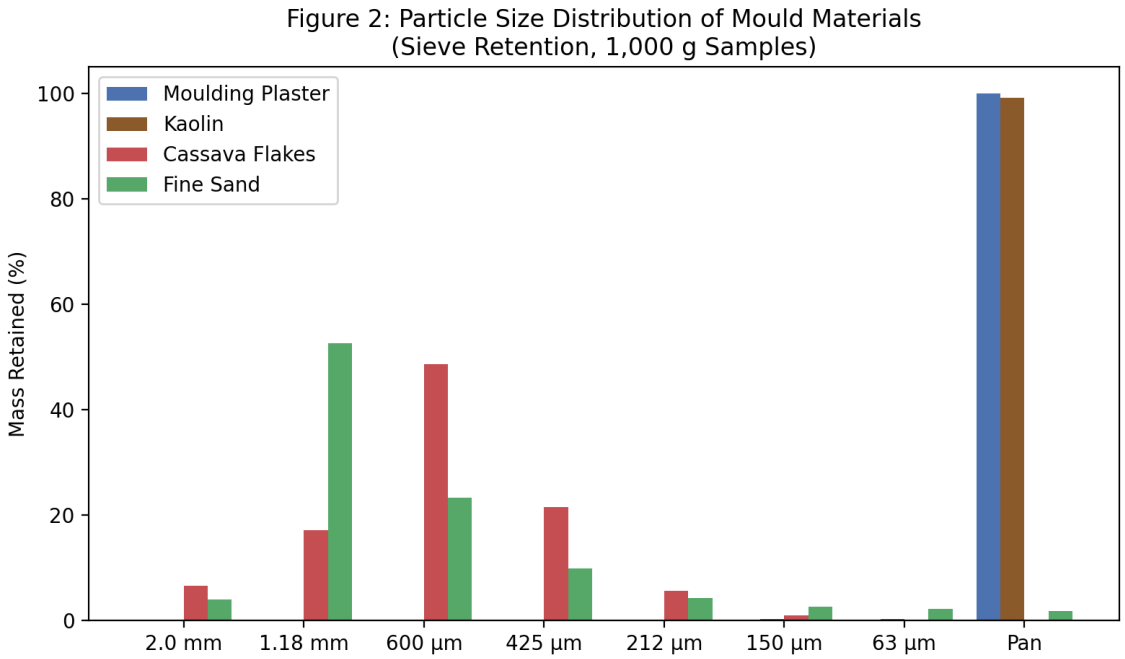

Figure 2: Particle Size Distribution of Mould Materials (regenerated from Table 2 sieve-retention data).

Flexural Strength of Raw Mould Materials

Moulding plaster had the highest average flexural strength, 105.60 MPa, based on replicate values of 100.80, 120.60, and 96.00 MPa. Portland cement averaged 80.00 MPa, with replicate values of 96.00, 96.00, and 48.00 MPa, while kaolin averaged 52.13 MPa from 48.00, 52.80, and 57.60 MPa. The higher strength of moulding plaster supported its dominant proportion in the final slurry.

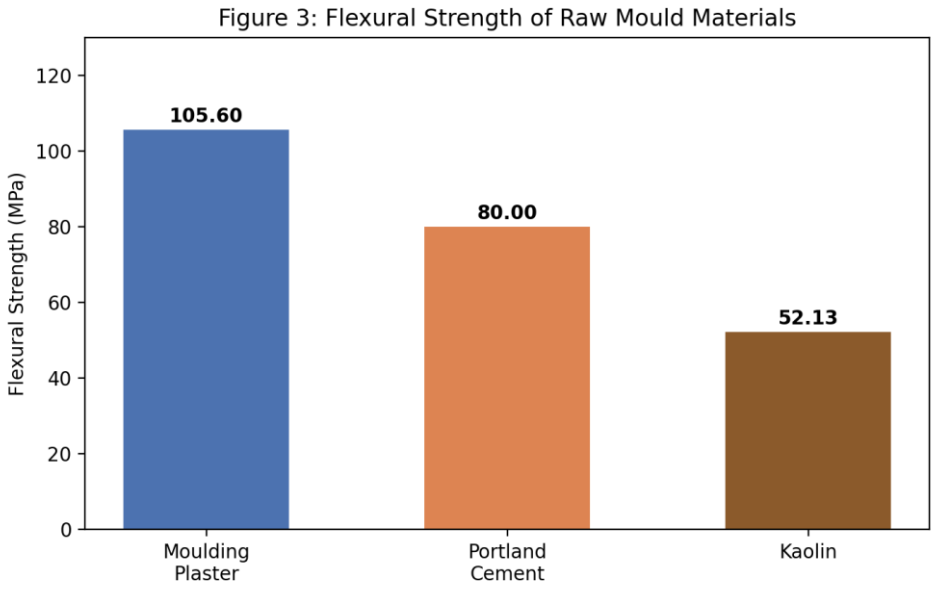

Figure 3: Flexural Strength of Raw Mould Materials.

Slurry Viscosity

Viscosity increased with refractory-to-binder ratio. At the highest ratio tested, moulding plaster reached 710 mPa·s, cassava flakes 650 mPa·s, and kaolin 613 mPa·s. The final combined slurry reached 890 mPa·s, which was within the workable range used for shell building. The combined-slurry curve tracks the moulding-plaster curve closely up to a ratio of 2.4 because plaster is the dominant constituent (82% of the final blend) and therefore governs the rheology of the mixture through most of the tested range; the sharper rise to 890 mPa·s at a ratio of 2.6 reflects the onset of particle-packing saturation, where the finer plaster and kaolin particles begin to interlock and restrict flow once the refractory fraction approaches its maximum practical loading. The relatively high viscosity of the final blend was favourable for maintaining a coherent coating on the beeswax pattern during repeated dipping.

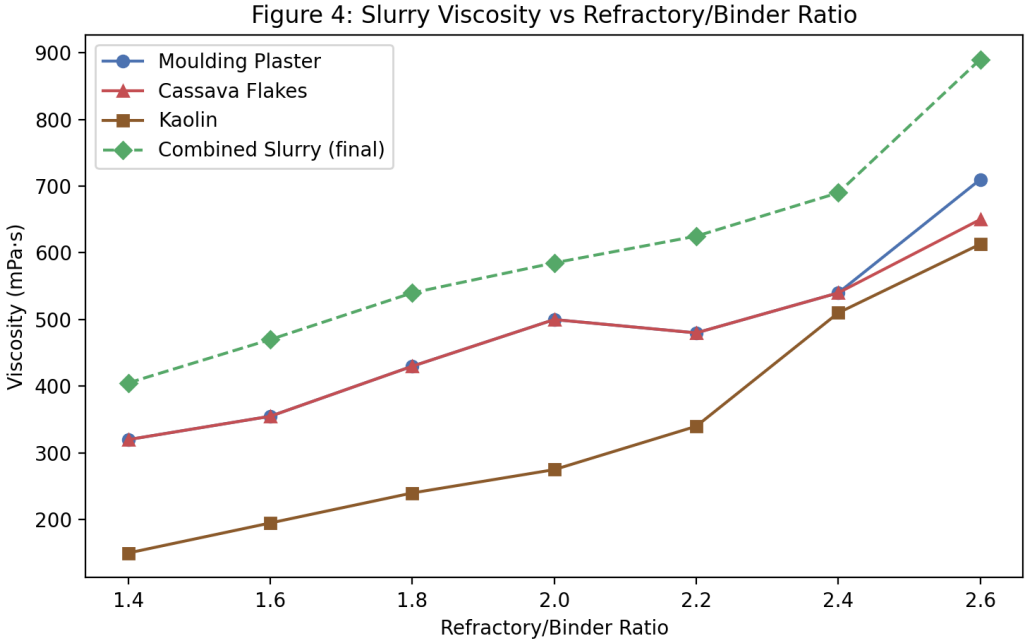

Figure 4: Slurry Viscosity versus Refractory/Binder Ratio and Final Combined Slurry.

Bulk Density, Suspension and Thixotropy

The individual slurry densities were 3.17 g/cm³ for moulding plaster, 3.02 g/cm³ for cassava flakes, and 2.52 g/cm³ for kaolin (Table 3). After 14 hours, moulding plaster retained approximately 43% of its solids in suspension compared with 15% for cassava flakes and 3% for kaolin. All three slurries exhibited viscosity decay under continued shearing, indicating thixotropic behaviour. Moulding plaster had the highest reported thixotropic rate of 4.0, followed by cassava flakes at 3.0 and kaolin at 0.5.

Table 3: Bulk Density of Individual Material Slurries

Material	Slurry Density (g/cm³)
Moulding Plaster	3.17
Cassava Flakes	3.02
Kaolin	2.52

Figure 5: Thixotropic Behaviour of the Slurries

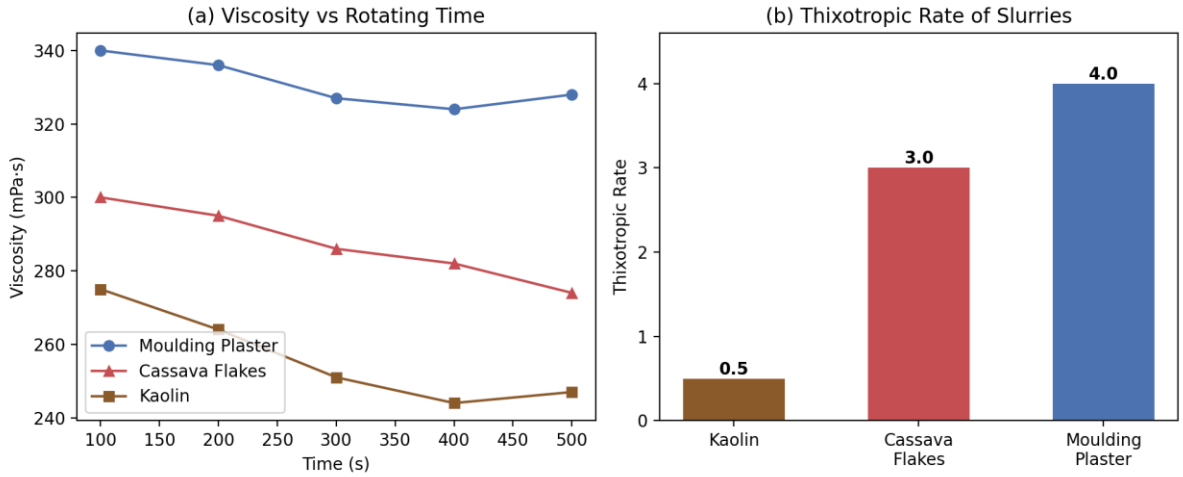

Figure 5: Thixotropic Behaviour of the Slurries: (a) Viscosity vs Rotating Time; (b) Thixotropic Rate.

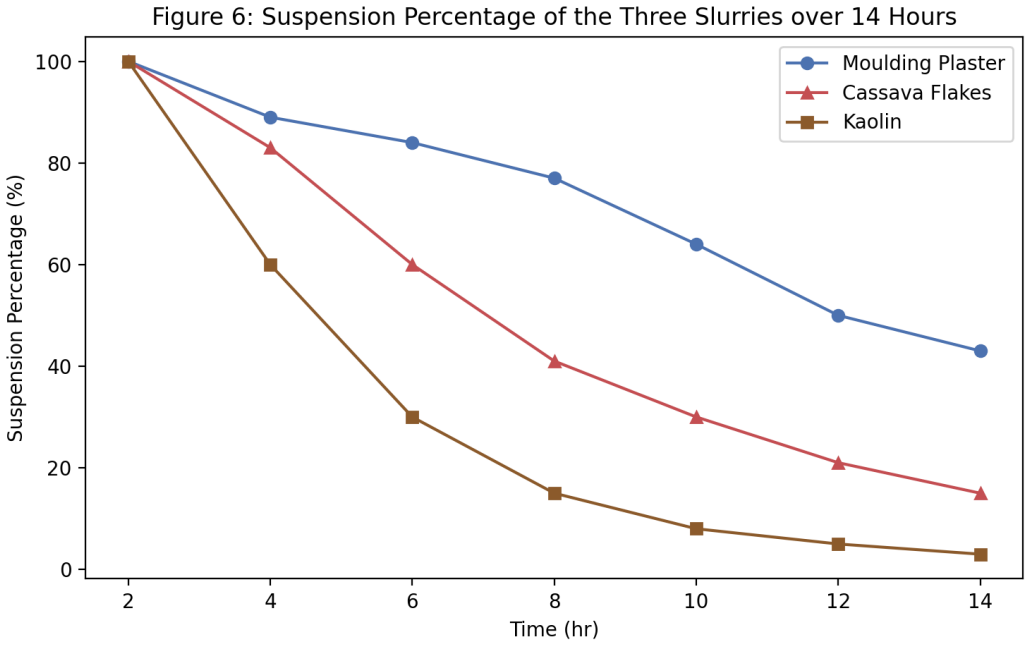

Figure 6: Suspension Percentage of the Three Slurries over 14 Hours.

Refractoriness

Moulding plaster showed the best resistance to sudden temperature change among the three refractories tested, showing no visible cracking or spalling up to 600°C and no gross structural breakdown up to 800°C, and also resisted molten metal and hot gases satisfactorily. Portland cement was mechanically robust but less resistant to thermal shock, developing visible surface cracking at the 400–600°C hold. This complementary behaviour supported the use of plaster as the major refractory with a smaller cement addition to provide mechanical robustness.

Fired Mould Strength, Permeability and Casting Trial

The fired mould produced flexural strengths of 159.25 MPa for sample X, 139.00 MPa for sample Y, and 154.75 MPa for sample Z (Table 4). The corresponding flexural moduli, calculated from the slope of the elastic region of each load–deflection curve (Section 2.2), were 4.37, 4.92, and 6.80 GPa. Permeability was measured on samples taken after each dip coat rather than on the finished shell alone; Figure 8 shows that permeability rose progressively from approximately 70 AFS at the first coat to 112 AFS at the seventh and final coat, giving an overall average of 92 AFS across the build. The mould was successfully used to produce a brass jewellery casting without cracking or gross defects (Figure 9).

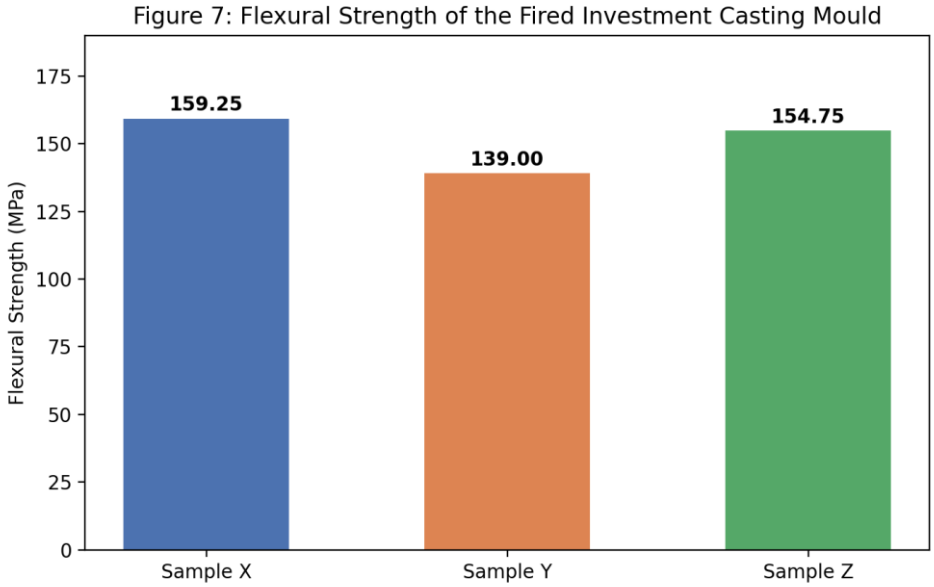

Figure 7: Flexural Strength of the Fired Investment Casting Mould.

Table 4: Flexural Strength and Flexural Modulus of the Fired Investment Casting Mould

Sample	Average Flexural Strength (MPa)	Average Flexural Modulus (GPa)
X	159.25	4.37
Y	139.00	4.92
Z	154.75	6.80

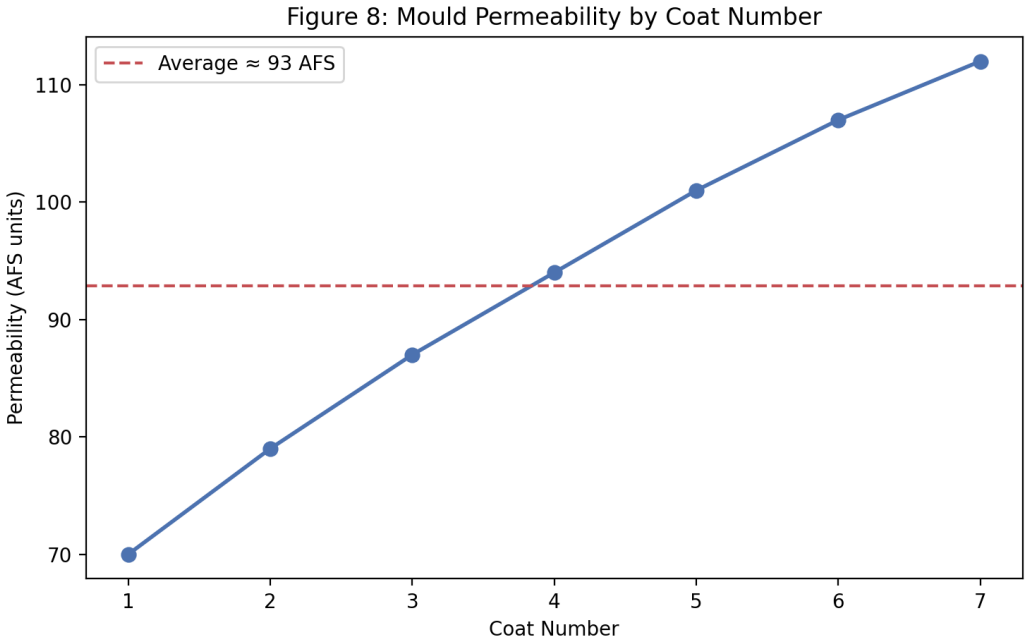

Figure 8: Mould Permeability by Coat Number, Increasing from ~70 AFS (Coat 1) to 112 AFS (Coat 7); Average ≈ 92 AFS.

Figure 9: Brass Jewellery Casting Produced from the Investment Casting Mould.

Discussion

The results indicate that moulding plaster was the most influential constituent in achieving a workable local slurry. Its high flexural strength, strong suspension stability, high thixotropic response, fine particle size, and resistance to thermal shock explain why it constituted 82% of the optimum composition. Cassava flakes provided a locally available starch-based constituent whose viscosity and suspension behaviour were intermediate between plaster and kaolin. The fired shell substantially exceeded the strength of the individual raw materials: the strongest fired sample (159.25 MPa, Sample X) represents an increase of approximately 51% over the strongest raw constituent, moulding plaster alone (105.60 MPa), suggesting that layered construction and firing promoted a stronger integrated mould structure than any single raw material could achieve on its own.

The permeability result is important because investment moulds must allow gases generated during pouring and decomposition of the wax pattern to escape. The measured average of 92 AFS, rising from approximately 70 AFS in the earliest coats to 112 AFS in the fully built shell (Figure 8), indicates adequate and progressively improving gas passage through the build. These observations are broadly consistent with previous studies showing that shell permeability and strength depend on material type, particle characteristics, binder behaviour, and number of coats (Kline et al., 2010; Sarek et al., 2009), and align with the statistically grounded bend-testing approach recommended by Richards et al. (2016) for characterizing ceramic shell moulds. The finding also parallels earlier demonstrations that locally available materials can substitute for imported shell systems in other contexts, including local steel-casting shell development (Purwadi et al., 2012) and camphor-modified shell strength improvement (Tamta & Karunakar, 2014), reinforcing that the present approach is consistent with a broader trend toward locally adapted investment casting systems. The principal contribution of the study is the demonstration that a complete investment casting route from material selection and slurry formulation through mould production and actual casting can be implemented using locally available materials.

4. CONCLUSION

The study demonstrated the feasibility of producing an investment casting mould from locally available materials. Moulding plaster, cassava flakes, kaolin, Portland cement, and fine sand were characterized and combined using beeswax as the pattern material. Moulding plaster recorded the highest flexural strength among the raw refractories at 105.60 MPa and showed the best suspension stability and resistance to sudden temperature change. Six trial compositions led to a workable blend containing 82% moulding plaster, 5% cassava flakes, 5% cement, 4% kaolin, and 4% fine sand. The fired shell achieved flexural strengths between 139.00 and 159.25 MPa, with corresponding flexural moduli between 4.37 and 6.80 GPa, and an average permeability of 92 AFS, and successfully produced a brass jewellery casting without major defects. The results support local material substitution for non-ferrous, jewellery-scale investment casting. Further work should investigate repeated casting cycles,

other alloys, larger and more complex patterns, alternative local refractory combinations, and production-scale economic performance.

ABSTRACT

The increasing demand for safer, lightweight, and corrosion-resistant liquefied petroleum gas (LPG) cylinders has created the need for alternative materials that overcome the limitations of conventional steel cylinders. This study presents the conceptual design and material evaluation of a translucent composite LPG cylinder based on polypropylene (PP)/fiberglass (FG) composites. The conceptual design integrates a lightweight polymer composite shell capable of withstanding service loads while providing sufficient light transmittance to enable direct visual monitoring of LPG level without auxiliary gauges. Five PP/FG formulations (40/60, 45/55, 50/50, 55/45, and 60/40 wt%) were developed through melt compounding and compression moulding to identify the optimum material for the proposed cylinder. Mechanical performance was assessed through tensile, flexural, impact, and hardness testing, while optical suitability was evaluated using indoor and outdoor light transmittance measurements. The results showed that composite composition significantly influenced both structural and optical properties. The 55/45 PP/FG formulation exhibited the highest tensile strength (33.17 MPa) and the greatest light transmittance (9.50% indoors and 24.30% outdoors), demonstrating the best balance between strength and translucency. Flexural testing showed a different trend, the 60/40 PP/FG composite exhibited the highest flexural strength of 56.52 MPa, indicating excellent resistance to bending loads. hardness measurements similarly showed that 60/40 formulation gives the highest shore hardness of 96.0 D, increased fiberglass loading improved resistance to surface indentation and wear, whereas higher polypropylene content increased ductility but reduced hardness. Impact testing revealed that the 40/60 formulation possessed the greatest impact strength of 215.21 J/m. The proposed composite cylinder offers significant advantages over conventional steel cylinders, including reduced weight, improved corrosion resistance, and the ability to visually monitor LPG content, thereby improving user convenience and operational safety. The study demonstrates the feasibility of integrating material selection and conceptual design in the development of next-generation translucent composite LPG cylinders.

1.0 INTRODUCTION

Liquefied petroleum gas (LPG) has emerged as a vital transition fuel for domestic and industrial energy applications, offering high calorific value and lower greenhouse gas emissions relative to solid fossil fuels. In many developing countries, including Nigeria, LPG consumption has grown significantly over the past decade owing to government initiatives aimed at reducing dependence on firewood, kerosene, and charcoal for household cooking (Taska and Ige, 2023). This transition has contributed to improved indoor air quality, reduced deforestation, and enhanced public health outcomes. Consequently, the demand for safe, durable, and cost-effective LPG storage cylinders has increased substantially (Mahboubizadeh *et al.*, 2024).

Conventional LPG cylinders are predominantly fabricated from carbon steel due to its low initial cost and high mechanical strength. However, steel cylinders exhibit severe operational limitations such as corrosion and degradation where exposure to atmospheric humidity or coastal environments causes wall thinning, shortening service life, obscure external defects, making routine inspections more difficult and increasing catastrophic failure risks. Their relatively high weight

reduces portability and increases transportation costs Corrosion can also increasing the likelihood of catastrophic failure. In addition, opaque steel cylinders prevent users from visually determining the remaining LPG level, necessitating manual weighing or external sensing devices that increase operational costs and complexity (Mahboubizadeh et al., 2024; Wu et al., 2025). These limitations have stimulated growing interest in advanced composite materials for pressure vessel applications (Somaiah et al., 2022). Fibre-reinforced polymer (FRP) composites offer strong alternatives due to superior specific strength, low density, and high corrosion resistance. Among reinforcement materials, glass fibres provide an optimal balance between high tensile performance and cost-effectiveness compared to carbon or aramid fibres. Additionally, thermoplastic matrices like polypropylene (PP) enable recyclability, high toughness, rapid thermal processing, and low density. Beyond weight reduction, semi-translucent GF/PP composite formulations allow light transmission through the vessel shell, enabling direct visual inspection of the internal liquid LPG level. Despite these advances, existing literature presents clear gaps in low-pressure thermoplastic composite cylinder design, these include;

Over-Reliance on Thermosets and High-Pressure Systems: Most composite pressure vessel scholarship focuses on high-pressure (>20 MPa) CNG or hydrogen storage using expensive carbon/epoxy systems, leaving low-pressure (2 MPa) thermoplastic LPG systems underexplored.

Narrow Focus on Structural Mechanics: Previous studies predominantly isolate mechanical parameters, fibre winding patterns, or burst pressure calculations while neglecting the functional optical behaviour of the composite wall.

Lack of an Integrated Framework: Limited research links empirical mechanical property data directly into thin-walled pressure vessel equations, finite element stress validation, and light transmittance assessment within a single investigation.

This study directly addresses these gaps by evaluating glass fibre-reinforced polypropylene (GF/PP) composites for lightweight, translucent LPG storage cylinders. Five matrix-to-fiber formulations (40/60 to 60/40 wt%) were melt-compounded and compression-molded to characterize tensile, flexural, impact, and hardness performance. Experimental mechanical properties were applied directly to thin-walled pressure vessel design equations to establish wall thickness (t = 18.5 mm), hoop stress, longitudinal stress, and a target safety factor of 2.05 under an internal working pressure of 2 MPa. Finally, indoor and outdoor light transmittance measurements were integrated to validate visual LPG fuel-level monitoring capability alongside structural integrity. The novelty of this research lies in the integration of experimental material characterisation, engineering design calculations, and optical transmittance evaluation to develop a lightweight translucent composite. The findings provide valuable design information for the development of next-generation composite LPG cylinders capable of improving safety, reducing maintenance costs, enhancing portability, and promoting sustainable energy storage technologies.

2.0 MATERIALS AND METHODS

2.1 Materials

The composite material investigated in this study was developed using PP as the polymer matrix and FG as the reinforcing phase. PP pellets were selected because of their low density, excellent chemical resistance, ease of processing, and good mechanical performance, making them suitable for pressure vessel applications. FG was employed as the reinforcement owing to its high tensile strength, corrosion resistance, dimensional stability, and cost-effectiveness. A processing oil was incorporated in small quantities during compounding to improve melt flow characteristics and facilitate uniform dispersion of the reinforcement within the polymer matrix. (Delli *et al.*, 2021; Somaiah et al., 2022; Li et al., 2024). PP pellets and FG were obtained from A.O. Salami Material Store, Zaria, Nigeria, while the processing oil was supplied by the National Institute for Leather Science and Technology (NILEST), Zaria. Composite fabrication was carried out at NILEST using Two-roll Mill compounding machine and Compression molding machine with model numbers 5189 and 3851-0 respectively. The Impact test and shore hardness tests were also carried out at NILEST using ASTM D256-10, 2010 and ASTM D2240 respectively. Tensile and flexural strengths analyses together with light transmittance measurements were performed at the Department of Metallurgy

laboratories, Ahmadu Bello University (A.B.U), Zaria, using ASTM D3039/D3039M and ASTM D7264 respectively.

2.2 Methods

2.2.1 Composite Formulation

Five PP/FG formulations were prepared to investigate the influence of reinforcement loading on the mechanical and optical behaviour of the composites. The compositions were selected based on literature values by Lee & Jang, (1999) and Thomason et al., (1996) as shown in Table 1.

Table 1: Polypropylene/Fiberglass composite formulations

Sample PP/FG	Polypropylene PP (wt%)	Fiberglass FG (wt%)
A	40	60
B	45	55
C	50	50
D	55	45
E	60	40

The selected compositions enabled systematic evaluation of the effect of increasing polypropylene content and decreasing fibre loading on tensile, flexural, impact, hardness, and light transmittance tests in accordance with relevant ASTM standards mentioned in section 2.1.

2.2.2 Compounding of composite

A two-roll mill compounding machine was used to mix each sample run from Table 1, at a temperature of 220°C and speed of 120 rpm. The PP was introduced and rolled for 2 minutes, to completely melt the material for easy mixing before the glass fibre was added. The resulting material was then placed in a 3mm thick, 120 x 150 mm mould. This was then charged to the compression moulding machine. The compression moulding machine has two sections namely, the hot mould and the cold mould. The hot mould works at 3 bar and at a temperature of 180^{o}C for 2 minutes. The cold mould then cools the product of the hot mould back to ambient temperature. The fabricated material was then detached from the mould and labelled accordingly. This was repeated for the 5 runs. The resulting composite samples were then sent to a cutting machine to shape them for the various analyses.

2.3 Samples Analysis

2.3.1 Light Transmittance Test

The test was carried out to detect the degree of opacity of the samples i.e. how much light is transmitted through the sample for both indoors (within a dimly lit room) and outdoors (space highly exposed to natural light).In compliance with standard procedure for testing composites (International Organization of Standardization, 2010). The material was cut into desired shapes of 55 x 10 mm rectangles with a thickness of about 3mm. The testing equipment is a lightmeter that measures light in Lux or cadence. The equipment is calibrated to measure light at 20, 200 and 2000 Lux respectively. For this analysis, the 20 lux calibration was used for the indoor analysis and the

200 lux calibration for outdoor analysis. The equipment was switched on and reset to zero error. Then adjusted to the desired calibration. Then the intensity of light in the room was taken. The material was then brought to the sensor part of the equipment and the reading from the display part of the equipment was taken. This was repeated for every sample run for indoor and then for outdoor.

2.3.2 Tensile Strength Test

The test was done to study how much stress the material can undergo before breaking. Based on ASTM D3039/D3039M standard procedure. The material was cut into testing specification before proceeding to analysis. The material was gripped at both ends by the testing apparatus, which slowly pulls lengthwise on the sample until it fractures. The pulling force is called a load. The value of the force per original sample area as stress and plotted against the sample length change per original length (strain).

2.3.3 Flexural Strength Test

The flexural strength test was done to test the resistance of the composite material to bending and flexing forces. Based on (ASTM INTERNATIONAL, 2002) following the loading nose producing three point bending at a specified rate. The parameters for this test are the support span, the speed of the loading and the maximum deflection for the test. These parameters are based on the materials thickness and are defined by ASTM D7264 standards.

2.3.4 Impact Strength Test

This test was done to study the resistance of the material under sudden stress. How much energy can it withstand and how much is required to cause a fracture. Standard procedure for this test is contained in the ASTM document for impact strength of a polymer composite (ASTM D256-10, 2010). U-notch was made at the center of the specimen. A pendulum or hammer was released from a specific height. The pendulum or hammer strikes the notched specimen. The impact caused the material to fracture. The energy absorbed by the specimen was calculated based on the height from which the pendulum fell and the angle at which it strikes the specimen. The energy was recorded and repeated three times per sample.

2.3.5 Hardness Test

The test for hardness was done in compliance with ASTM D2240 (2015) standard procedure as follows: The Durometer was held vertically with the indenter facing down. The durometer was positioned in a perpendicular orientation to the specimen surface. The indenter was made to come into contact with the specimen. A gradual steady downward force was applied to the durometer with the use of a thumb. As the indenter penetrates the specimen, a needle moves to a reading on the shore A scale. The reading was taken and recorded once the needle stabilizes.

All mechanical tests were carried out three times for each sample and the average recorded.

2.4 Conceptual Design of the LPG Cylinder

To showcase how the developed translucent composite material can be applied in real-world engineering, a conceptual LPG cylinder was modeled using the geometric dimensions of a standard 12.5 kg domestic cylinder. Maintaining this traditional shape ensures the design remains fully compatible with existing LPG distribution, storage, and handling infrastructure while swapping out the standard metallic body for the new translucent material.

The cylinder's wall thickness, as well as its hoop and longitudinal stresses, were calculated based on the tensile strength of the optimal composite blend (55/45 PP/FG) using a safety factor of 2.05. Beyond tensile measurements, mechanical properties like flexural strength, impact resistance, and hardness play a vital role in validating the design. Flexural Strength ensures the composite wall can resist bending forces and localized deformation caused by non-pressure, real-world mechanical loads during transport and usage. Impact Strength serves as a key material selection metric for damage tolerance, proving the cylinder can survive accidental drops or impacts. Hardness measures expected surface durability and wear resistance throughout everyday service and handling. Rather

than acting as mere secondary lab data, these three attributes serve as essential supporting performance criteria for designing robust, safe composite pressure vessels.

The conceptual cylinder consists of a cylindrical body with hemispherical end domes, a reinforced neck for valve attachment, and a protective base ring. The cylinder wall is manufactured from the developed PP/FG composite, allowing partial light transmission for visual monitoring of the LPG level while maintaining the structural integrity required for pressurised gas storage. The engineering analysis was performed using the assumptions presented in Table 2.

Table 2: Assumptions made for the design of the composite cylinder

Parameter	Symbol	Value
LPG storage capacity	–	12.5 kg
Internal diameter	D	300 mm (0.30 m)
Overall height	H	580 mm
Internal design pressure	P	2.0 MPa
Shape	–	Thin-walled cylinder with hemispherical ends
Operating temperature	–	Ambient conditions
Design approach	–	Thin-walled pressure vessel theory

2.4.1 Pressure calculations based on thin wall pressure vessel theory

The composite cylinder was analysed using classical thin-walled pressure vessel equations

Hoop stress ,$\sigma h = Pr/t$ (1)

Longitudinal stress, $\sigma L = Pr/(2t)$ (2)

Factor of safety, $FOS = \sigma u/\sigma h$ (3)

Where

$\sigma u = 33.17$ MPa = Tensile strength of the 55/45 PP/FG formulation

$P = 2.0$ MPa = Internal pressure

$r = 150$ mm = Internal radius

t = Cylinder wall thickness = 18.5 mm

Therefore

$\sigma h = Pr/t = 2(150)/18.5 = 16.22$ MPa

$\sigma L = Pr/(2t) = 2(150)/ [2(18.5)] = 8.11$ MPa

Factor of safety, $FOS = \sigma u/\sigma h = 33.17/16.22 = 2.05$

This remains a preliminary analytical assessment, not proof that an LPG cylinder is safe for manufacture. A real composite LPG cylinder requires laminate-specific analysis, pressure/burst testing, fatigue testing, and compliance with the applicable cylinder standard.

2.4.2 3D Computer-Aided Design (CAD)

To validate the structural geometry and volumetric capacity of the proposed 12.5 kg translucent polypropylene/fiberglass (PP/FG) composite LPG cylinder, a 3D SolidWorks parametric model was developed in accordance with ISO 11119-3 and thin-walled pressure vessel design principles. The LPG cylinder geometry was developed using SolidWorks software. The complete assembly included the cylinder body, domes, valve opening, base ring, and protective collar. The primary geometric dimensions of the pressure vessel were derived from engineering calculations based on thin-walled pressure vessel theory (Barlow's formula for hoop stress) to accommodate a 12.5 kg LPG capacity under a 2.0 MPa design pressure:

Design Pressure (P): 2.0 MPa (20 bar) nominal internal pressure.

Target Factor of Safety (FOS): 2.05 to comply with composite pressure vessel safety standards.

Internal Radius (r): Calculated based on target 27.5-liter internal volume for 12.5 kg LPG fill mass as follows:

Target internal volume, V = 27.5 L = 27,500 cm^3 = 27,500,000 mm^3
For a cylindrical vessel, the internal volume is given by:
$V = \pi r_i^2 L$
where:
V = internal volume of the vessel
r_i = internal radius of the vessel
L = internal cylindrical length of the vessel
Rearranging the equation to determine the internal radius gives:
$r_i = \sqrt{(V / \pi L)}$
Taking L to be 390 mm (Megyesy, 2008).
substituting the values gives:
r = 150 mm

Wall Thickness (t): 18.5 mm composite wall thickness, as determined from the tensile yield criteria of the 55/45 PP/FG matrix.

The 3D model was constructed using feature-based parametric tools within SolidWorks using the following sequence:

2D Sketching and Profile Layout: A 2D cross-sectional profile of the cylinder body, top dome, and bottom dome was sketched on the Front Plane, incorporating exact calculated internal and external radii.

Revolve Feature: The 2D profile was revolved 360 degrees around the central longitudinal axis to create the monolithic pressure shell.

Valve Boss and Neck Ring Integration: A threaded boss neck insertion was modeled on the top dome using Extrude Boss/Base and Thread features to simulate standard valve fitting connections.

Protective Casing & Base Stand Design: Top hand-grip collars and bottom base support rings were modeled as separate bodies and mated to the composite pressure core to ensure drop-impact protection and upright standing stability.

3.0 RESULTS AND DISCUSSIONS

3.1 Light Transmittance

The results of the light transmittance are presented in Figure 1. The optical performance of the composites showed that material composition had a significant effect on light transmission. Optical transmittance in glass-fiber-reinforced polymer composites is governed by sheet thickness, fiber architecture, volume fraction, and the degree of refractive index matching between the matrix and reinforcement phases (Hegedűs *et al., 2017*; Olson *et al.,* 1992). Unreinforced polypropylene matrix materials typically exhibit semi-translucent behavior in thin sections, whereas woven glass-fiber reinforcements present significantly lower light transmission due to interfacial scattering. Commercial material datasheets for plain-weave E-glass fabrics report nominal light transmittance values in the range of 6–13%, with transmittance further decreasing as fiber loading and section thickness increase.

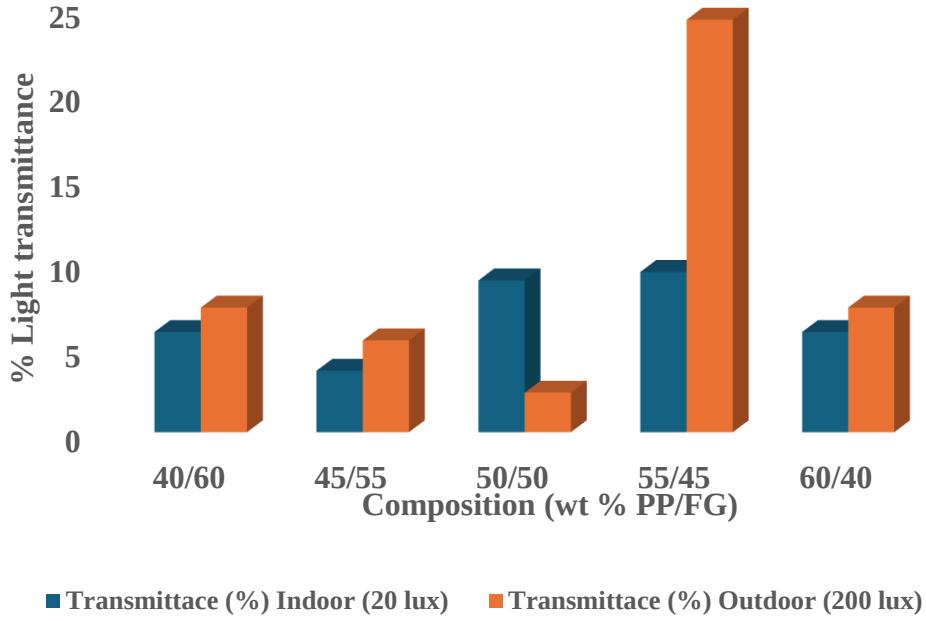

Figure 1: Effect of composite composition on percentage light transmittance

Among all the composite formulations, the 55/45 PP/FG composite exhibited the highest light transmittance under both indoor and outdoor illumination conditions, recording 9.50% and 24.30% light transmittance, respectively. This transmittance values indicate that the composite materials are translucent where translucent material is regarded as a material with light transmittance between 0% and 80% (ASTM D1003-21; ISO 13468-1). This improved translucency is attributed to the balanced interaction between the polypropylene matrix and fibreglass reinforcement, which minimises excessive light scattering while maintaining structural integrity. Standard commercial Type-IV composite LPG cylinders typically utilize opaque carbon or glass/epoxy filament wraps over HDPE liners, which obscure internal fluid levels.

The optical mechanisms governing light transmission in composite media depends on light scattering and absorption coefficients across polymer-fibre phase boundaries (Arikawa *et al.*, 1998). In thermoplastic PP/GF systems, achieving visual translucency requires sufficient matrix resin wetting around fibres to minimize diffuse light scattering across void interfaces. The experimental data confirms that the 55/45 formulation balances fibre loading for mechanical strength while retaining enough optical transmittance for visual liquid-level monitoring.

3.2 Tensile Strength

Tensile strength increased progressively with increasing polypropylene content up to the 55/45 composition, where a maximum value of 33.17 MPa was obtained before declining at higher polypropylene content. The improvement is consistent with the established influence of fibre content, fibre length and fibre–matrix interaction on stress transfer and mechanical performance in glass-fibre-reinforced polypropylene (Thomason *et al.*, 1996; Delli *et al.*, 2021). Conversely, excessive fibreglass loading reduced matrix continuity, while excessive polypropylene reduced the reinforcing contribution of the fibres. These findings indicate that optimum tensile performance is achieved through an appropriate balance between the polymer matrix and reinforcement rather than by maximising either constituent (Emon *et al.*, 2025; Li *et al.*, 2024).

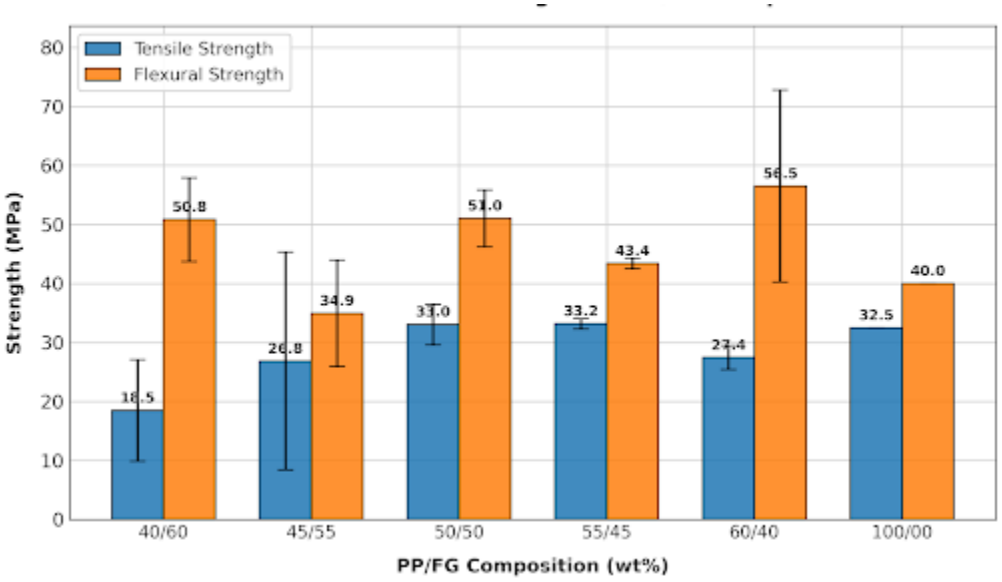

Figure 2: Effect of composite composition on tensile and flexural strengths

The tensile strength peak achieved in this work for 55/45 composition (33.2 MPa) alongside 50/50 composition (33.1MPa) aligns with findings by Milosan (2025), who analysed glass-fibre reinforced polymer composites for pressure containment vessels. Milosan highlighted that optimizing fibre fraction is essential to achieve structural stability and prevent ductile-to-brittle failure under static loading. Furthermore, higher fibre fractions (40/60), suffer a sharp drop in tensile strength due to un-wetted fibres and void formation as deficient matrix binder volume leads to stress concentration, fibre agglomeration, insufficient fibre wetting, and severe micro-void formation. In an LPG pressure vessel, these un-wetted voids act as localized stress concentrators and potential gas leakage pathways causing premature matrix cracking.

3.3 Flexural Strength

Flexural strength reaches its maximum value of 56.52 MPa at the 60/40 composition, representing a 45% increase over neat PP (40.0 MPa). This result corroborates with the findings of Lee and Jang (1999) who noted that increased polymer matrix fraction enhances bending resistance by allowing better strain distribution during flexural loading. Conversely the maximum impact strength exhibited by the 40/60 formulation follow the energy absorption mechanism detailed by Thomason (1997). The 50/50, 55/45 and 40/60 compositions also exhibit acceptable flexural performance (51.05 MPa, 43.40 MPa and 50.82 MPa respectively), as shown in Figure 2, confirming that effective stress transfer from the matrix to the fibres occurs at this resin to fibre ratio.

3.4 Impact Strength

Impact testing revealed that the 40/60 formulation exhibited the highest impact strength of 215.21 J/m, because its higher fibreglass content enhanced energy absorption through crack bridging and fibre pull-out mechanisms. However, this sample exhibits extreme standard deviation as indicated by the error bars, (calculated value = 138.38 J/m), indicating localized fibre agglomeration and inconsistent fracture energy dissipation. The 45/55, 50/50, 55/45, and 60/40 have calculated standard deviations of 7.40,12.72, 28.34 and 8.12 J/m respectively.

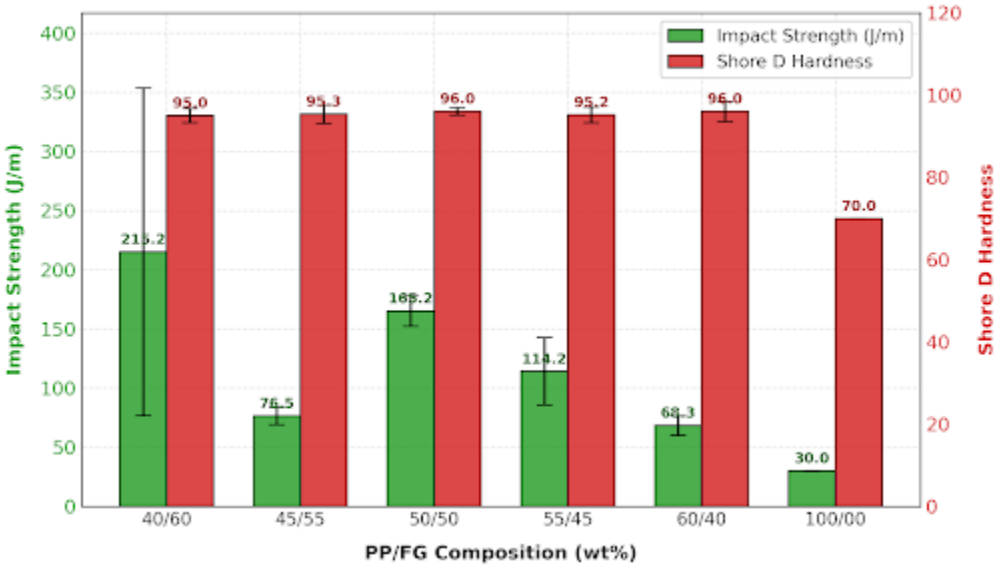

Figure 3: Effect of composite composition on impact strength and hardness

The 50/50 composite also showed good impact resistance (165.21 J/m), while the 55/45 formulation provided moderate toughness (114.17 J/m) that remained suitable for structural applications. Although it did not record the maximum impact strength, the 55/45 composite achieved the most balanced combination of toughness, tensile strength, and translucency required for safe LPG cylinder service.

3.5 Hardness

Hardness measurements confirmed that increasing fibreglass content generally improved resistance to indentation and surface wear because of the higher stiffness of glass fibres. Conversely, increasing polypropylene content enhanced ductility but reduced hardness. All glass-reinforced formulations achieve high surface hardness (95.0 to 96.0 Shore D). The addition of rigid glass fibres increases indentation resistance, providing crucial protection against abrasive wear, scuffing, and external impact during handling and transport.

Despite these variations, the 55/45 formulation maintained adequate hardness while retaining excellent tensile strength, satisfactory toughness, and the highest light transmittance.

3.6 Optimum composite formulation

To establish the ideal composite formulation for translucent LPG cylinders, tensile, flexural, impact strengths, surface hardness, must be evaluated alongside optical transmittance.

Comparing all mechanical, dynamic, and optical properties the 55/45 wt% Formulation delivers the maximum tensile strength (33.2 MPa), acceptable flexural strength (43.4 MPa), high hardness (95.5 Shore D), and robust impact resistance (114.17 J/m). Most importantly, it achieves peak optical transmittance (9.50% indoor / 24.30% outdoor), successfully combining structural pressure-bearing capability with visual gas-level monitoring.

In conclusion, the 55/45 wt% PP/FG composite represents the optimal composition, delivering the best combination of mechanical strength, impact toughness, surface durability, and optical functionality for translucent LPG cylinder design.

3.7 Conceptual Engineering Design Results

The engineering analysis results demonstrates that the developed composite material possesses the characteristics required for lightweight translucent LPG cylinders. The calculated hoop and longitudinal stresses remain within acceptable limits since the measured tensile strength of the composite (33.17 MPa) exceeds the calculated design stresses with factor of safety 2.01. Using the selected operating pressure of 2.0 MPa and an internal radius of 150 mm, the required wall thickness was calculated (using the experimental composite tensile strength) to be approximately 18.5 mm,

which was subsequently adopted in the CAD modelling. The design parameters are tabulate in Table 2. However, for an actual gas-cylinder design, applicable composite-cylinder standards and qualification/testing requirements would also need to be satisfied (ISO, 2020a, 2020b; Wu *et al.*, 2025; ISO, 2024).

Table 2: Design parameters

PARAMETER	VALUE
PP/FG formulation	55/45
Experimental composite tensile strength	33.17 MPa
Assumed internal pressure	2.0 MPa
Assumed internal radius	150 mm
Calculated wall thickness from composite tensile strength	18.5 mm
Calculated Hoop stress	16.22 MPa
Calculated Longitudinal stress	8.11 MPa
Calculated Factor of safety	2.05

3.8 The conceptual 3D CAD model result

The conceptual 3D CAD model represents the proposed 12.5 kg translucent LPG cylinder fabricated from the optimum 55/45 PP–FG composite. The model integrates the experimental material-performance results with the preliminary pressure-vessel calculations, thereby providing a transition from material characterization to an application-oriented engineering design.

The model is shown in Figure 4. The calculated hoop stress (16.22 MPa) is precisely twice the calculated longitudinal stress (8.11 MPa), confirming classical thin-walled pressure vessel behaviour (hoop stress = 2 longitudinal stress). An important strength of this model is that the design is derived from the experimental characterization rather than being an independent drawing. The experimental results establish the material's mechanical capability, while the performance analysis identifies the 55/45 PP/FG composition as the preferred formulation. The engineering calculation then uses the measured tensile strength of 33.17 MPa to determine an appropriate preliminary wall thickness. Consequently, the sequence is:

Material formulation → Experimental characterization → Performance optimization → Pressure-vessel calculation → Conceptual CAD design

Figure 4: Conceptual 3D CAD model of translucent 55/45 PP/FG composite cylinder

With an experimental tensile strength of 33.17 MPa, the working hoop stress of 16.22 MPa delivers a structural Factor of Safety of 2.05, which complies fully with ISO 11119-3 safety requirements for composite gas cylinders under standard working pressure (2.0 MPa).

4.0 CONCLUSION

This study successfully developed and evaluated a translucent polypropylene/fiberglass (PP/FG) composite material system tailored for lightweight domestic LPG cylinder applications. Experimental characterization demonstrated that the mechanical and optical properties of the composite are strongly governed by the weight ratio of the resin matrix to reinforcement fibers.

Light transmission in the fabricated composites remains constrained by internal light scattering within the semi-crystalline polypropylene phase as well as reflection at the fiber-matrix interfaces. However, strategic blending of the constituents activated optical translucency, reaching optimum in the 55/45 wt% PP/FG formulation. The 55/45 wt% PP/FG composite provided the best balance of properties, achieving the highest ultimate tensile strength of 33.17 MPa and peak light transmittance, 9.50% (indoors at 20 lux) and 24.30% (outdoors at 200 lux), alongside a flexural strength of 43.40 MPa, solid hardness of 95.20 Shore D, and an impact resistance of 114.17 J/m. Engineering design calculations and 3D CAD modeling established the structural feasibility of a 12.5 kg capacity cylinder with an 18.5 mm composite wall thickness, satisfying the target Factor of Safety 2.05 under a 2.0 MPa design pressure in accordance with thin-walled pressure vessel theory and ISO 11119-3 guidelines, however this is a conceptual CAD model for design assessment and requires finite element analysis (FEA) and experimental validation.

The proposed translucent composite cylinder offers a viable, safer, non-corrosive, and lightweight alternative to conventional steel cylinders, enabling direct visual LPG level monitoring without external auxiliary gauges.

ABSTRACT

Traditional adobe bricks offer excellent thermal insulation and affordability but suffer from low compressive strength, high water absorption, and poor durability. Conventional stabilizers like cement and lime carry a massive environmental footprint and are economically unviable for low-income housing. This study investigates the potential of Granite Powder (GP), which is a quarrying by-product as a sustainable, zero-cement stabilizer for lateritic adobe bricks. Ten mix formulations were developed, including an unstabilized control and six GP-only variants (5%, 10%, 15%, 20%, 25%, and 30% by mass of laterite). Specimens were subjected to compressive strength testing, 24-hour water immersion, modified capillary wetting assessment, thermal conditioning (40°C, 60°C, and 100°C), and porosity evaluation. Results indicate that a 10% GP inclusion yielded the highest compressive strength (3.34 N/mm² at 28 days), a 30% increase over the control, surpassing the widely recognized 2.0–3.0 N/mm² benchmark for load-bearing, non-seismic earthen construction (Bui et al., 2009; Walker, 2020). While higher GP content (30%) diluted the clay binder and reduced compressive strength to 2.34 N/mm², it significantly enhanced durability, achieving the lowest capillary water uptake (18.7%) and porosity (19.2%). Furthermore, a novel "thermal convergence effect" was observed at 100°C, where high-GP mixes recovered strength due to thermally accelerated latent reactions. The study affirms that GP can significantly enhance the mechanical robustness and moisture resistance of adobe, aligning technical performance with circular economy principles.

1. INTRODUCTION

Traditional earthen construction, particularly adobe bricks, offers excellent thermal insulation and affordability. However, unsterilized earth suffers from low compressive strength, high water absorption, and poor durability, particularly in humid or extreme weather conditions (Goransson, 2021; Walker, 2020). Conventional stabilizers like cement and lime improve these properties but carry a massive environmental footprint; cement production alone accounts for approximately 8% of global CO_2 emissions (Habert & Roussel, 2020). Furthermore, these binders are often economically unviable for low-income housing in developing regions (Kouadio et al., 2021; UN-Habitat, 2022).

To mitigate the environmental impact of construction, researchers have explored industrial by-products as alternative stabilizers (Al-Rashid et al., 2023; Manikandan & Thangaraj, 2021). Granite Powder (GP), a massive environmental waste product from stone milling and tiling industries, presents a viable opportunity. Previous studies have highlighted the utility of granite dust in concrete and mortars (Chajec, 2021; Jain et al., 2022; Shakir & Mohammed, 2023). However, its specific application as a micro-filler and stabilizer in lateritic adobe matrices requires comprehensive optimization. Therefore, the objectives of this study are: 1-To characterize the physical and chemical properties of GP; 2) optimize the quantity of GP based on compressive strength; (3) determine the effect of elevated

temperatures on thermal resilience; and (4) evaluate Moisture resistance through total water absorption, capillary wetting, and porosity.

2. MATERIALS AND METHODS

2.1 Materials

Lateritic Soil: The natural lateritic soil used in this study was obtained from the Kudai borrow pit in Dutse, Jigawa State, Nigeria. The soil exhibited a Liquid Limit (LL) of 51%, a Plastic Limit (PL) of 35%, and a Plasticity Index (PI) of 16%. Under the Unified Soil Classification System (USCS), the soil is classified as MH (inorganic silt of high plasticity) because its liquid limit exceeds 50% and its plasticity index plots below the A-line, calculated as $PI = 0.73(LL - 20) = 22.63\%$. Since the measured PI of 16% is below the A-line value, the soil falls within the MH group. Under the AASHTO soil classification system (M 145), the soil is classified as A-7-5, because it has LL > 40% and PI > 10%, while $PI \leq LL - 30$ ($16 \leq 21$). The classification is therefore consistent between the reported Atterberg limits and the two classification systems. The compaction characteristics of the soil yielded a Maximum Dry Density (MDD) of 2.12 Mg/m³ and an Optimum Moisture Content (OMC) of 16.77%.

Granite Powder (GP): Granite powder (GP) is a finely divided waste material produced in large quantities by the granite cutting and tiling industries. While the accumulation of GP poses environmental hazards through landfilling and dust pollution, its chemical and physical properties offer a sustainable solution for the construction sector. Recognized for its pozzolanic potential and micro-filler capabilities, GP can be effectively utilized as a partial cement replacement to reduce the environmental impact of concrete production. However, the efficacy of GP as a construction material is highly dependent on its local geological and mineralogical composition. Therefore, characterizing locally sourced GP—such as the waste generated from the tiling industries in Dutse—is a critical prerequisite to understanding its specific chemical reactivity and physical filler mechanisms, ultimately determining its suitability for optimizing the performance of local construction composites. GP was sourced from granite tiling industries in Dutse.

2.2 Mix Design and Specimen Preparation

Specimens were molded to standard dimensions of 75 × 75 × 150 mm, in accordance with ASTM C67 and ISO 22111, using a constant water content of 25% by mass of the dry lateritic soil. Six mix formulations were developed, with three replicate specimens prepared for each mix.

1. **Control (CR):** 100% Laterite.
2. **GP Series:** 5%, 10%, 15%, 20%, 25%, and 30% GP replacement by mass of soil.

2.3 Testing Program

1. The compressive strength of solid adobe specimens (75 × 75 × 150 mm) was evaluated using a 300 kN Universal Testing Machine (UTM). While ASTM C67 is traditionally developed for fired clay masonry, its fundamental compressive testing protocol (specimen geometry and load application rate) is widely adapted in preliminary earthen block research to ensure standardized mechanical evaluation. This approach is supplemented by the curing and testing principles of ISO 22111 to ensure strict relevance to unfired adobe. Specimens were cured in a controlled environment at 25 ± 3 °C and 60 ± 10% relative humidity for 7, 14, and 28 days prior to testing. For each mix formulation and testing condition, three replicate specimens (n=3) were prepared and tested. Prior to testing, each brick was centrally positioned on its 75 × 150 mm bed face (Area = 11,250 mm²), and a continuous compressive load was applied until failure. The compressive strength values reported represent the mean of these three replicates, accompanied by the sample standard deviation (Mean ± SD) to indicate experimental variability.
2. **Total Water Absorption:** Total water absorption was determined by 24-h immersion. Specimens were first dried to constant mass and weighed to obtain the dry mass (Md). Each specimen was then completely immersed in clean water for 24 h. After immersion, the specimen was removed, surface water was gently wiped off, and the saturated mass (Ms) was recorded.

Water absorption was calculated as WA=(Ms−Md)/Md×100. Three specimens were tested for each mixture and the mean value was reported.

3. **Modified Capillary Water Uptake:** Capillary water absorption was evaluated using a modified wet-towel suction test, adapted from EN 772-11, to prevent specimen disintegration. After 24 h of ambient curing, the adobe specimens were oven-dried at 105 °C to a constant initial mass (W_1). The specimens were then placed on a water-saturated towel at room temperature. After wiping away surface moisture, they were weighed at 8-hour intervals until a constant saturated mass (W_2) was achieved.
4. **Thermal Exposure:** Thermal resilience was evaluated by exposing three specimens per mix to 40 °C, 60 °C, and 100 °C for 24 hours in a calibrated oven, following a 24-hour ambient cure (25 ± 3 °C, 60 ± 10% RH). These temperatures represent Northern Nigerian service conditions: ambient (40 °C), maximum hot-dry season wall surface temperature (60 °C; Millogo et al., 2016), and extreme exposure triggering complete free water evaporation (100 °C; Singh & Paul, 2022). Specimens were cooled in a desiccator before re-testing compressive strength and water absorption.
5. **Porosity:** The total porosity (n*n*) of the stabilized adobe specimens was evaluated based on their dry weight and bulk density. Following the measurement of the specimens' geometric dimensions and oven-dry weight (Wd), the bulk density (ρb) was calculated. The total porosity was then determined by comparing the bulk density to the solid (particle) density (ρs) of the soil mixture, using the relationship n=(1−ρb/ρs)×100. The solid density (ρs) of the soil matrix was assumed to be 2.65 g/cm³, representing the typical specific gravity of quartz-dominated silicate soils **(**ASTM International, 2014).

3. RESULTS AND DISCUSSION

3.1.1 X-ray Diffraction (XRD) analysis of the GP

X-Ray Diffraction (XRD) revealed the mineralogical analysis showed a highly crystalline nature with dominant phases of quartz, albite, anorthite, and muscovite. Due to its high crystallinity, GP functions primarily as a high-efficiency inert physical filler that optimizes particle packing density and reduces drying shrinkage (Hou et al., 2024; Moghal, 2021). Energy Dispersive X-Ray Spectroscopy (EDX) chemical analysis revealed SiO_2 = 62.789%, Al_2O_3 = 13.085%, and Fe_2O_3 = 1.249%. The sum of these oxides (77.123%) exceeds the 70% minimum requirement of ASTM C618, classifying it as a pozzolanic material.

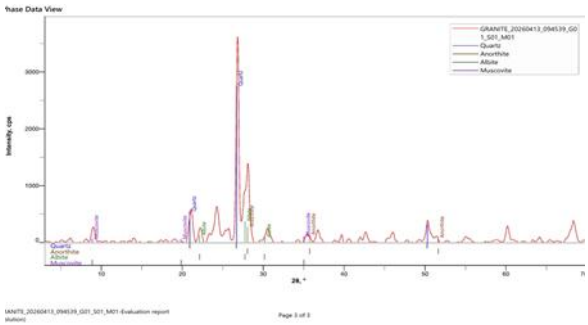

Figure 1: X-ray Diffraction (XRD) analysis of the GP

3.1.2 Sieve analysis of granite powder GP: revealed a predominantly sand-sized composition (94.27%), primarily medium sand (69.62%), with minor gravel (3.65%) and silt/clay (2.08%) fractions, as shown in the particle size distribution curve (Figure X). Characteristic diameters were determined from the curve as D_{10} = 0.148 mm, D_{30} = 0.234 mm, and D_{60} = 0.295 mm. The coefficients of uniformity (Cu = 2.00) and curvature (Cc = 1.25) classify the GP as a poorly graded sand. Due to its narrow particle size range and low fines content, the GP acts as a non-plastic granular micro-filler in the lateritic adobe matrix.

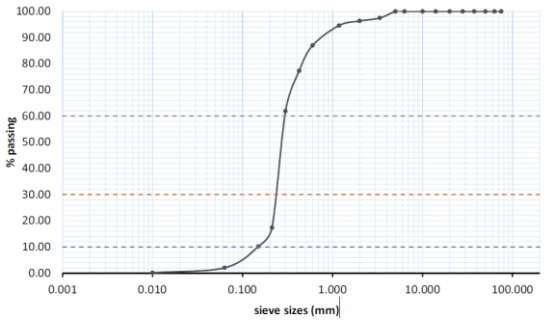

Figure 2: Particle Size Distribution Curve of GP

3.2 Compressive Strength Performance

The compressive strength development across the GP mixes at 7, 14, and 28 days is detailed in Table 1.

Table 1: Mean Compressive Strength of (N/mm²)

Age (Days)	***CR***	***GP5%***	***GP10%***	***GP15%***	***GP20%***	***GP25%***	***GP30%***
7	1.81 ± 0.10	1.89 ± 0.17	1.97 ± 0.11	1.85 ± 0.05	1.61 ± 0.04	1.40 ± 0.10	1.12 ± 0.09
14	2.20 ± 0.12	2.28 ± 0.12	2.30 ± 0.10	2.18 ± 0.08	1.99 ± 0.13	1.95 ± 0.09	1.90 ± 0.16
28	2.57 ± 0.04	3.05 ± 0.11	3.34 ± 0.25	3.18 ± 0.18	2.66 ± 0.26	2.50 ± 0.05	2.34 ± 0.21

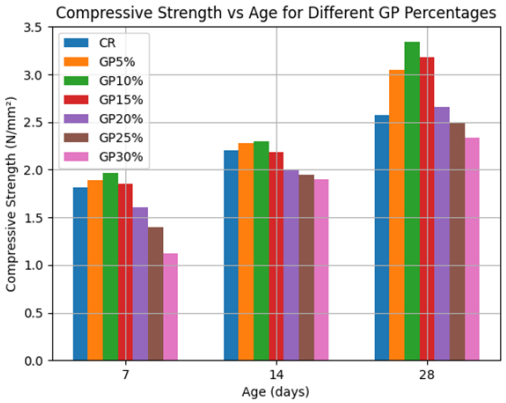

Figure 3: Compressive Strength vs Age for GP Series

Discussion: The GP10% mix achieved the peak 28-day strength of 3.34 ± 0.25 N/mm², representing a 30% increase over the control (2.57 ± 0.04 N/mm²). This margin of increase is well beyond the experimental variability (standard deviation), confirming that the strength gain is statistically meaningful and not merely experimental noise. This surpasses the widely recognized 2.0–3.0 N/mm² benchmark for load-bearing, non-seismic earthen construction, confirming its structural viability (Bui et al., 2009; Walker, 2020) for non-seismic, single-storey earthen construction. The improvement at 10% is attributed to the micro-filler effect of GP, which optimizes particle packing and densifies the matrix. However, beyond 15% replacement, strength declined progressively (GP30% dropped to 2.34 ± 0.21 N/mm²). This is due to the excessive dilution of the cohesive clay fraction, which is necessary for soil particle bonding (Reddy & Gupta, 2021).

3.3 Thermal Resilience and the Convergence Effect

Specimens were exposed to elevated temperatures to simulate extreme roof-space or hot-dry season conditions in Northern Nigeria.

Table 2: Compressive Strength After Thermal Exposure (N/mm²)

Temp (°C)	***CR***	***GP5%***	***GP10%***	***GP15%***	***GP20%***	***GP25%***	***GP30%***
40	2.60 ± 0.22	2.68 ± 0.08	2.75 ± 0.09	2.70 ± 0.17	2.55 ± 0.12	2.48 ± 0.23	2.45 ± 0.15
60	2.65 ± 0.08	2.72 ± 0.18	2.73 ± 0.12	2.68 ± 0.05	2.42 ± 0.16	2.35 ± 0.18	2.62 ± 0.07
100	2.51 ± 0.14	2.60 ± 0.22	2.58 ± 0.17	2.55 ± 0.06	2.29 ± 0.18	2.26 ± 0.18	2.48 ± 0.17

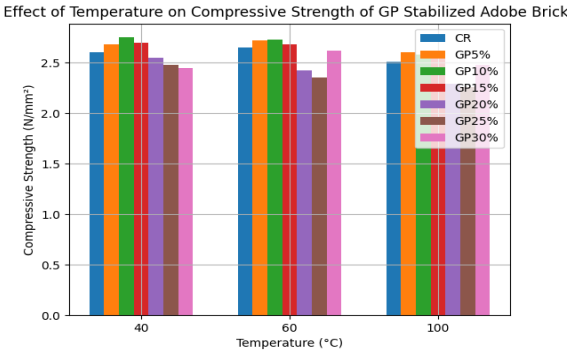

Figure 4: Compressive Strength vs Age for GP Series under Thermal exposure

Discussion: The thermal resilience of the mixes exhibited distinct temperature-dependent behaviors. Notably, the GP30% mix displayed a non-monotonic trend, peaking at 60°C (2.62 ± 0.07 N/mm²) before slightly decreasing at 100°C (2.48 ± 0.17 N/mm²). This intermediate 60°C peak is attributed to accelerated free-water evaporation, which temporarily maximizes inter-particle friction and matrix densification. The subsequent slight drop at 100°C results from complete clay dehydration and minor thermal micro-stresses. Despite this, a 'Convergence Effect' remains evident at 100°C, where GP30% (2.48 ± 0.17 N/mm²) nearly matches the Control (2.51 ± 0.14 N/mm²). Because XRD confirms GP is highly crystalline and inert at 100°C, this recovery is driven by the rigid, dimensionally stable GP particles acting as an inner skeletal framework. This framework prevents catastrophic micro-cracking and compensates for the dehydrated clay binder. Conversely, mixes with higher clay content and less rigid GP skeleton (e.g., GP20% and GP25%) lack this structural compensation. Consequently, they suffer a continuous strength decline from 40°C to 100°C (e.g., GP25% dropping from 2.48 ± 0.23 to 2.26 ± 0.18 N/mm²) due to progressive clay dehydration and micro-cracking.

3.4 Water Absorption and Porosity

Total water absorption and porosity measure the total volume of voids within the matrix.

Table 3: Durability Metrics of All Mixes

Mix	**Total Water Absorption (%)**	**Capillary Water Uptake (%)**	**Porosity (%)**
CR	35.0	39.8	26.5
GP5%	35.5	34.5	25.2
GP10%	36.2	29.5	23.8
GP15%	36.7	25.5	22.7
GP20%	37.1	21.8	21.5
GP25%	38.1	20.2	20.4
GP30%	39.0	18.7	19.2

Discussion: The durability metrics reveal a complex, divergent trend in moisture resistance mechanisms. In the GP-only series, total water absorption increased with GP content (reaching 39.0% in GP30%), while capillary uptake and overall porosity decreased steadily (to 18.7% and 19.2%, respectively). This apparent paradox is explained by differing pore-structure mechanisms: total void accessibility versus pore connectivity.

Total water absorption, measured after 24 hours of immersion, allows water to eventually saturate all accessible micro-voids. As GP content increases beyond the optimum 10%, the dilution of the cohesive clay binder creates more interfacial transition zones (ITZ) and isolated micro-voids between the rigid GP particles and the soil matrix. Given sufficient time (24 hours), water penetrates these isolated voids, increasing the total absorbed mass.

Conversely, capillary uptake relies entirely on continuous, interconnected fine pores to draw water upward via surface tension. The rigid, non-plastic GP particles act as physical barriers that disrupt, block, and tortuously redirect the natural, continuous capillary network inherent to pure lateritic clay. Consequently, even though the overall matrix is denser (as confirmed by the drop in total porosity to 19.2%), the pathways for rapid capillary rise are fundamentally broken. This highlights a critical strength-durability trade-off in single-additive systems: optimum compressive strength occurs at 10% GP, while optimum physical pore-blocking (capillary resistance) occurs at 30% GP.

4. CONCLUSION

This study evaluated the efficacy of Granite Powder (GP) as a sustainable stabilizer for lateritic adobe bricks. Based on the experimental investigation, the following conclusions are drawn:

1. **Characterizing granite powder (GP):** fulfilled Objective 1, confirming its suitability as a composite additive. With a combined oxide content of 77.123%, GP exceeds ASTM C618 pozzolanic requirements; however, its highly crystalline nature (quartz, albite, anorthite, muscovite) means it acts primarily as a high-efficiency inert micro-filler. This dual characteristic makes GP highly effective for optimizing particle packing density and reducing drying shrinkage within the matrix (Hou et al., 2024; Moghal, 2021).
2. **Optimum Stabilizer Dosage:** the optimum percentage was found to be 10% with compressive strength (3.34 N/mm²).
3. **Thermal Convergence Effect:** High-GP mixes (30%) exhibit a hidden "convergence effect," recovering strength at 100°C due to thermally accelerated latent bonding, demonstrating high thermal resilience.
4. **Moisture Resistance Trade-off:** While 10% GP yields the highest strength, 30% GP yields the lowest porosity (19.2%) and best capillary resistance (18.7%), though it suffers from reduced strength due to clay dilution.

5. **Practical Application Recommendations:** To resolve the identified strength-durability trade-off, a use-case-specific graded application of GP is recommended for practitioners:

For load-bearing walls in non-seismic, dry regions: A 10% GP dosage is optimal, as it maximizes compressive strength (3.34 N/mm²) to meet structural benchmarks while maintaining acceptable baseline durability.

For non-load-bearing walls, external plasters, or humid environments: A 20% to 30% GP dosage is highly recommended. Although compressive strength is moderately reduced, these mixes provide superior capillary resistance (≤ 21.8% uptake) and enhanced thermal resilience, making them ideal for weather-protective applications where moisture ingress is the primary failure risk.

For advanced hybrid construction: Future production could exploit a dual-layer approach, utilizing a 10% GP core for structural integrity, encased in a 30% GP outer layer or plaster to serve as a highly impermeable, thermally resilient weather shield.

ABSTRACT

Fluid catalytic cracking (FCC) and its residue variant (RFCC) are central to converting heavy petroleum fractions into gasoline and light olefins, and their catalysts depend on silica as both a binder and a precursor for the zeolite-Y active component and the active matrix. Conventional silica sources—tetraethyl and tetramethyl orthosilicate, sodium silicate, and fumed silica—are pure but costly, toxic, and energy-intensive, motivating a search for green alternatives. This mini-review examines the production of silica from agricultural wastes and its application in FCC/RFCC catalyst development. Rice husk, rice straw, sugarcane bagasse, and corn cob yield amorphous silica of high purity (commonly 90–98%) after acid leaching, controlled calcination, and alkaline dissolution to sodium silicate. In Nigeria alone, these residues are generated at an estimated 10.79 million tonnes per year, much of it burnt or left to create a nuisance. This can approximately generate 1.09 million tonnes per year of pure amorphous silica. The review considers how agricultural-waste silica can supply the sodium-free silica binder and the silica source for seeded zeolite-Y synthesis, with metakaolin as the alumina source, and how it must satisfy the low-sodium, high-purity, reactivity, and attrition-resistance requirements specific to cracking catalysts. It concludes that agricultural-waste silica is a viable, sustainable precursor for FCC/RFCC catalysts, and identifies impurity control, feedstock variability, catalyst-grade specification, and scale-up as the principal challenges to industrial adoption

Keywords: *Agricultural-waste silica; Rice husk ash; FCC/RFCC catalyst; Zeolite-Y; Green materials*

1. INTRODUCTION

Silica (SiO_2) is an inorganic material with impressive physiochemical properties for many industrial applications, such as construction materials and heterogeneous catalysis. Its chemical stability, surface functionality, and ability to form silicate and aluminosilicate frameworks make it particularly important in the preparation of catalytic materials. In petroleum refining, silica-containing materials are fundamental sources of silicon for zeolitic catalysts used in fluid catalytic cracking (FCC) and residue fluid catalytic cracking (RFCC).

According to a US patent, Preparation of cracking catalyst involves: (i) Preparing a slurry consisting clay, Zeolite, a sodium-free silica source, quasi-crystalline hydrated alumina, and microcrystalline alumina; (ii) Addition of monovalent acid to the slurry (iii) The slurry pH adjustment to a value above 3; (iv) Shaping the particle to form particles. This process resulted in a catalyst with sufficient attrition resistance and accessibility (Stamires *et al.*, 2016).

Agricultural waste such as rice husk, rice straw, sugarcane bagasse, and corn cob are rich in silica and can be utilised for the synthesis of zeolite catalysts. According to National Agricultural Extension and Research Liaison Services (NAERLS) and United States Department of Agriculture (USDA) report 2025, Nigeria alone produces 9.35 metric tonnes (MT) of rice, 11.44 MT of corn and forecasts 3.50 MT of sugarcane production. This amounts to 1.87 MT, 6.56 MT, 437,550 T, and 1.92 MT of 20% rice husk, 70% rice straw, 50% dry bagasse of 25% wet bagasse and 16.8% maize

cob, respectively and overall sums to 10.79 MT of agricultural waste generated (Table 1). These estimated wastes are often burnt either in a processing plant to generate process steam or in an open field, and the ash, rich in silica, is left underutilized, creating a public nuisance and releasing carbon monoxide, carbon dioxide and fine particulate matter. The silica present in the agricultural waste ash makes it a favourable precursor, and it can be used to complement high-alumina materials like Kaolin. Previous studies have reported the use of rice-husk-derived silica in the synthesis of zeolite Y, ZSM-5, mesoporous silica, and other functional materials. Wang et al. (2018) prepared NaA, NaX and NaZSM-5 zeolites from RHA via hydrothermal method. Zeolite Y in the sodium form (NaY) was synthesized using silica sourced from rice husk (Mohammed et al., 2012). Silica powder with approximately 96% purity was extracted from rice husk (RH) and used as a silica source for NaY (Yunusa et al., 2016)

An important benefit of utilizing silica derived from agricultural sources is the conversion of an abundant agricultural residue into a useful industrial raw material. Secondly, it provides a potentially low-cost and sustainable source of silica for catalyst development. For FCC/RFCC catalyst development, the quality of the silica precursor is critical because silica contributes to the zeolite framework, catalyst matrix, binder system, and overall pore architecture. Therefore high-purity silica with appropriate structural and surface characteristics is desirable.

This study reviews the use of silica prepared from major agricultural wastes (Corn cob, sugarcane bagasse, rice husk and straw), particularly in Nigeria, which are often combusted, leaving heaps of ash that disturb public serenity and environmental cleanliness. The outcomes of the review were assessed in relation to the potential utilisation of the material as a sustainable precursor for future FCC/RFCC catalyst development.

2. AGRICULTURAL WASTE FROM INDUSTRIAL PROCESSES IN NIGERIA

Land and water are the drivers of agriculture, Nigeria has over 79 million hectares of arable land, sufficient surface and groundwater and over 3 million hectares available for irrigation (FOA, 2026). Among the notably agricultural produce are: Maize, cassava, sorghum, cowpea, rice, yam, and millet. Maize, rice and Sugarcane are among the crops processed at an industrial scale, leading to the generation of waste such as rice husk, rice straw, corn cob and sugarcane bagasse. Nigeria's 2025 crop production from NAERLS and USDA report 2025 are shown in Table 1, alongside the estimated waste generated and the corresponding estimated residue generated in 2025. These account for the waste rarely fed to livestock and are often burnt, leaving the ash causing public disturbances.

Table 1: *Estimated agricultural waste generated from rice, corn and sugarcane*

Crops	**2025 Production (t)**	**Residue**	**% Waste**	**Estimated Waste (t)**
Corn	11,441,214.70	Cub	16.8	1,922,124.07
Rice	9,372,328.70	Husk	20	1,874,465.74
		Straw	70	6,560,630.09
Sugarcane	3,500,000.00	Bagasse	50 dry of 25 wet	437,550
	Total			**10794769.9**

2.1 Silica from Agricultural Waste Ashes (AWA)

AWA particularly from silica-accumulating crops, represent an increasingly important sustainable source of amorphous SiO_2. Upon controlled combustion, rice husk yields ash containing 86–97% SiO_2 by weight, predominantly in the amorphous phase (Rodriguez-Otero et al., 2023). Other agricultural waste silica sources include sugarcane bagasse ash (50–70% SiO_2), and corn cob ash, although these are less rich in silica than rice husk ash and have received comparatively less research attention (Okoye et al., 2025; Islam et al., 2024).

The silica content varies with crop variety, soil conditions, and combustion parameters. Estimated Nigerian silica production was presented in Table 2, based on the estimated waste in Table 1. Acid leaching of rice husk prior to calcination has been found to remove alkali and alkaline earth metal impurities (K, Ca, Mg, Na), yielding ash with silica purity of 90–97%, comparable to or exceeding many commercial silica products (Phoungthong et al., 2026). This makes rice husk ash a compelling sustainable substitute for commercial silica in catalyst synthesis applications

Table 2: *Nigeria Estimated Silica Content from Rice, Corn and Sugarcane in 2025*

Agricultural Waste	**Ash content%**	**AWA (t)**	**% Silica**	**Silica (t)**
Corn Cub	2.8	53819.47	53.95	29035.60
Rice Husk	15.3-24.6	373955.92	92	344039.44
Rice Straw	13.5	885685.06	79.8	706776.31
Sugarcane Bagsse	2	8751	71.85	6287.59
Total		1322211.45		1086138.94

2.2 Process of Silica Extraction from Agricultural Waste

The extraction of silica from agricultural residues involves the conversion of biogenic silica embedded within plant tissues into a usable and relatively pure inorganic form. The physicochemical properties of the extracted silica, including its purity, surface area, porosity, and crystallinity, are strongly influenced by the processing method and operational conditions. Figure 1 shows the various routes for silica extraction from AWA.

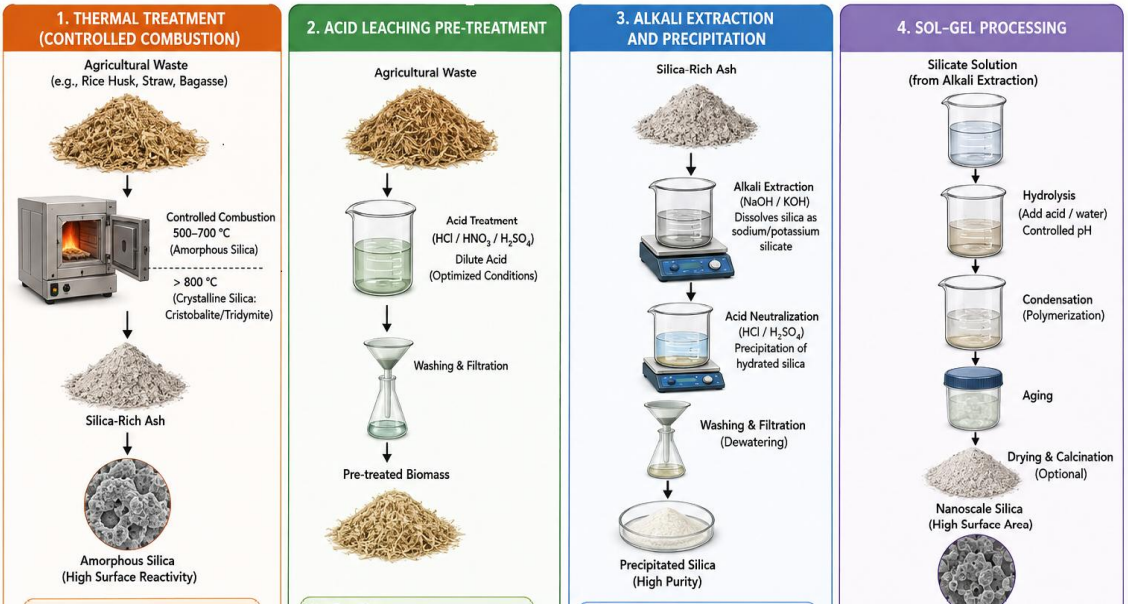

Figure 1: Paths for different grades of silica from agricultural waste

2.2.1Thermal Treatment

Agricultural wastes such as rice husk, rice straw, corn cob, and sugarcane bagasse are subjected to pyrolysis to remove cellulose, hemicellulose, lignin, and other organic constituents. Controlled Combustion at approximately **500–700 °C** usually favours the formation of **amorphous silica**, which possesses higher surface reactivity and greater availability of silanol groups (Si-OH) that influence the surface chemistry of the silica. At temperatures above approximately **800 °C**, amorphous silica transforms into crystalline phases such as cristobalite and tridymite, resulting in reduced surface area and reactivity. Therefore, a controlled low-temperature combustion is preferred when highly reactive amorphous silica is required (Aharipour et al., 2022; Barani et al., 2024;

Carraro et al., 2021; Falk et al., 2019; Farirai et al., 2021a; Hamidu et al., 2025; Mohd et al., 2017; Pieła et al., 2020; Shahbaz et al., 2023).

2.2.2 Acid-Leaching Pretreatment

Acid leaching is generally employed as a pretreatment step before combustion or subsequent silica extraction. Dilute acids (30 % w/w conc.) such as HCl, HNO_3, and H_2SO_4 dissolve metallic impurities, particularly potassium, calcium, magnesium, and iron, that are naturally associated with agricultural residues. Removing these impurities improves silica purity and helps suppress reactions that could promote silica crystallisation. For rice husk, acid pretreatment can therefore produce ash with higher silica content and improved surface characteristics. However, acid concentration and treatment duration must be controlled which lead to partial silica dissolution (Pa et al., 2013).

2.2.3. Alkali Extraction and Precipitation

Alkali extraction is an effective route for producing high-purity silica from silica-rich agricultural ash. In this process, the ash is treated with an alkaline solution, typically NaOH or KOH, to dissolve silica and form soluble sodium or potassium silicate. Subsequent acid neutralisation converts the soluble silicate into precipitated hydrated silica (Zero Gel), which is recovered through filtration, washing, and drying. The process provides greater control over silica purity, particle size, and morphology. Parameters such as pH, temperature, and acid addition rate strongly influence the properties of the final silica. Nevertheless, the process involves several treatment stages and generates alkaline wastes streams that require appropriate management (Harun et al., 2024; Kamari & Ghorbani, 2021; Kouadri et al., 2023; Okoronkwo et al., 2013; Seghir et al., 2023).

2.2.4. Sol-Gel Processing

Sol-gel processing is a more advanced approach for producing high-surface-area, nanoscale silica. Silicate precursors obtained from agricultural waste undergo controlled hydrolysis and condensation reactions, followed by ageing and drying to form a three-dimensional silica network. The method provides improved control over particle size, pore structure, surface area, and morphology and can also facilitate the incorporation of functional groups or dopants. However, careful control of pH, temperature, hydrolysis, condensation, and ageing is required, and the process can be more expensive and operationally demanding than direct thermal or precipitation methods (Adebisi et al., 2020; Ni'mah et al., 2023; Okoronkwo et al., 2013).

3. REFINERY CRACKING CONVERSION UNITS (FCC&RFCC)

Petroleum is refined into various fractions through the distillation process. The lighter fractions such as gasoline, naphtha, light distillate, are the most valuable products and are in high demand. According to the Global Oil Products Utilization 2024 report, gasoline accounts for about 27% of demand, while diesel/gas oil has the highest share at 33%, followed by jet fuel. Petroleum distillation produces only a fraction of these products and therefore can not meet global demand. The heavier, less desirable fractions, such as bottom residue, vacuum gas oil and vacuum residue, are further processed and converted to lighter, valuable product fractions via thermal or catalytic cracking. Catalytic cracking converts heavy fractions; also known as fluid catalytic cracking or its counterpart, residue fluid catalytic cracking (FCC/RFCC), is a major conversion process to produce more of these valuable products, such as gasoline and light olefins. These units account for about 35 -50% of the refinery gasoline production (Adenenche et al., 2023). The feed to the FCC and the RFCC, is mainly Vacuum gas oil (VGO) and atmospheric residue/vacuum residue, respectively. FCC/RFCC processes have been operated across the globe in more 300 of the 646 refineries since 2014 (Zhu et al. 2013, Palos et al., 2020). It is estimated that 0.16 kg of FCC catalyst is used per barrel of feedstock (vacuum gas oil). For heavy feed materials, such as vacuum or atmospheric residue, 0.20 kg of RFCC catalyst is used per barrel (Vogt et al., 2015). Figure 2 shows a typical refinery conversion unit.

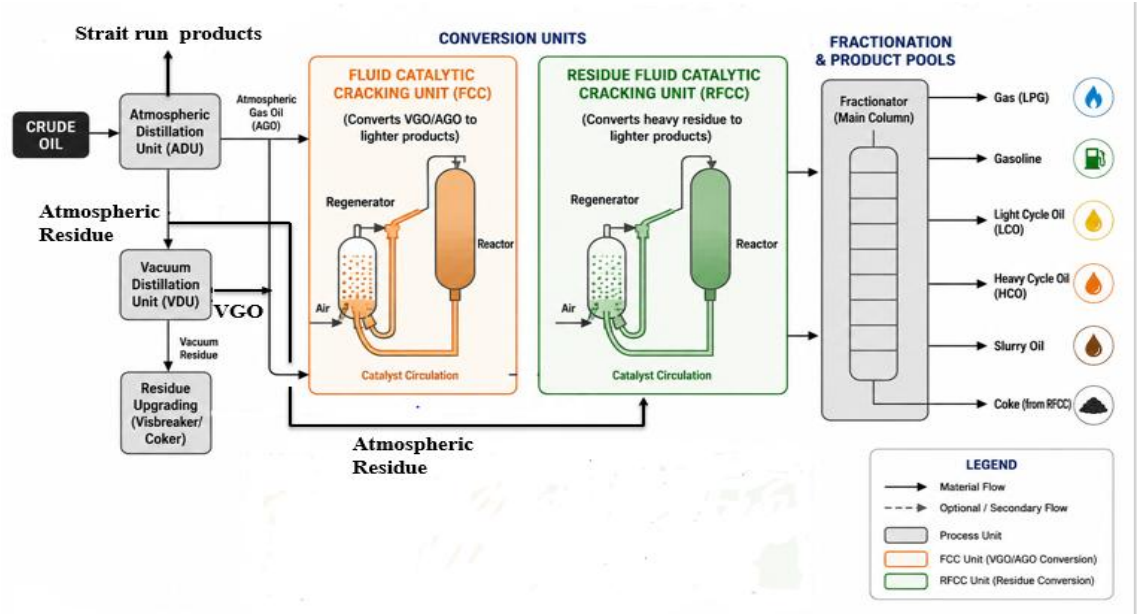

Figure 2: A side-by-side representation of FCC and RFCC in the refinery.

3.1 Application of Silica In FCC/RFCC Catalyst

FCC/RFCC Catalyst is composite material made up of a complex formulation of active and inactive components. Figure 2 shows the major structural composition of FCC/RFCC catalyst. The nature of the feed, the processing unit objectives, and constraints are the primary drivers of catalyst formulation and composition. The nature of the components and the processing steps determine the physicochemical properties of the catalyst (Ferreira et al., 2023).

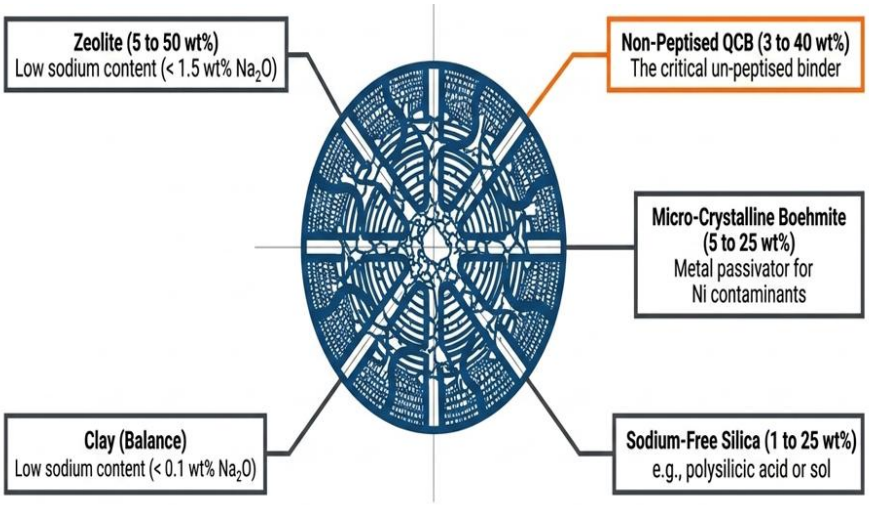

Figure 2: Typical structural composition of an FCC/RFCC particle.

The catalyst lowers the activation energy of the cracking reaction and also tailors the yield and selectivity towards the desired product. Other minor constituent and their roles were highlighted in Table 3. Silica appears have a significant role in both in the matrix development and the synthesis of active components. It form in the structural integrity of the catalyst and is also used as a binder for glueing all the components together. The active components are the zeolites such as the Zeolite-Y which is the major active component.

Table 3: Constituent of FCC/RFCC catalyst

Component	Chemical Constituents	Sources	Functions	Ref.
Active Component (Zeolite-Y)	Alumina, Silica Rare earth elements (RE), Lanthanum (La), Cerium (Ce), Neodymium (Nd), Praseodymium (Pr)	Natural clays, Agricultural waste, Inorganic chemicals	Responsible for catalytic activity and selectivity toward Naphtha	Borges ,2011 Stamires et al. 2016

NO_x reducing additives			Reduce NOx to N_2 in the regenerator	Sadeghbeigi, 2000

3.2 Zeolite Synthesis

According to Musyoka et al. (2014) zeolite synthesis begins with the preparation of super-saturated aluminosilicate solution, and proceeds with dissolution, nucleation, and crystallization processes at high temperatures. This is referred to as an in-situ reaction at elevated temperature and pressure in an aqueous solution. 'It is important to note that, when natural clays or ash are used as precursors in the synthesis process, the first step is to extract alumina and silica from the raw material, followed by washing and drying the resulting product to remove impurities and organic matter. The next step involves mixing the precursor with an alkali solution, such as NaOH or KOH, at particular temperature to create a reactive aluminosilicate gel in an alkaline fusion or activation process. The alkaline solution dissolves the aluminum and silicon ions in the clay, forming a gel. Subsequently, the gel is subjected to hydrothermal treatment in an autoclave at high temperature and pressure, which facilitates the crystallization of the gel into a zeolite product. The resulting zeolite crystals' size, shape, and purity can be influenced by the duration of the hydrothermal treatment and the composition of the gel. Finally, the synthesized zeolite undergoes washing, drying, and calcination processes to remove any residual organic matter and stabilize the structure of the zeolite (El Bojaddayni et al. 2023).

Several limitations and factors are considered when synthesizing zeolites from these precursors. The purification process, which can be time-consuming and costly, is a critical factor

that impacts the feasibility of the synthesis method for commercial applications. Optimal conditions for zeolite synthesis from various source material require precise control of several factors, including temperature, pressure, reaction time, and solid/liquid ratio. It is important note that the optimal conditions may vary depending on the specific source material and desired product properties. Product purity, is at the peak of all factors and can affect the quality of the final product. Rice-husk-derived silica has demonstrated good characteristics purity, with reported SiO_2 purities of approximately 96–98% and successful application in NaY/zeolite-Y synthesis (El Bojaddayni et al. 2023; Yunusa et al., 2016).

For the preparation FCC/RFCC Catalyst, low sodium (<wt%Na_2O) or sodium free FAU type of zeolites are used including: Y-Zeolites such as HY, USY, dealuminated Y. RE-Y, and RE-USY; Zeolite beta, Zeolite Socony Mobil-5(ZSM-5), Mobil Composition of Matter No. 22(MCM-22), MCM-36, Metal-exchanged zeolites, Instituto de Tecnologia Quimica (ITQs), Silico-Alumino-Phosphates (SAPOs) all have corresponding high amount of silica/Alumina ratios of >1.5 with the exception of Aluminophosphate (ALPOs) mainly consist of Aluminium, Phosphorus and Oxygen (Stamires et al. 2016).

3.2.1 Zeolite Synthesis from Agricultural Waste Ash

Ash is the solid by-product generated from the combustion of coal, or agricultural residue. Although the chemical and mineralogical composition of ash varies by different factors, it is well-known that its main constituents are SiO_2, Al_2O_3, CaO, Fe_2O_3, and un burnt material (Belviso, 2018; Cardoso et al., 2015; Yang et al., 2019). The prepared solution gradually transforms into zeolite after the dissolution of Al and Si, geopolymer formation, nucleation, and crystallization steps (Belviso, 2018). Several methods exist for zeolite synthesis from ash as were highlighted in Table 4. Detailed description of these methods can be found in the cited publications.

Table 4: Methods of zeolites Synthesis from Ash

Method	Description	Advantage	Disadvantage	Ref.
Conventional hydrothermal method (CH)	The precursor containing Si and Al is mixed with an alkaline solution, aged to form a reactive aluminosilicate gel, and subsequently crystallized hydrothermally in a sealed reactor/autoclave at elevated temperature and autogenous pressure. The resulting zeolite is filtered, washed and dried.	• Simple and well-established technique. • Relatively inexpensive equipment. • Good control of zeolite phase through adjustment of Si/Al ratio, alkalinity, temperature and crystallization time. Suitable for relatively large-scale production	Relatively long crystallization time. • Conventional external heating can produce temperature gradients. • High water and energy requirements may occur during prolonged synthesis. • Some raw materials show poor dissolution/reactivity, reducing zeolite yield.	Cardoso et al. (2015)
Alkaline-fusion-assisted hydrothermal method (AFH)	The precursor is first mixed/fused with a strong alkali, commonly NaOH, at elevated temperature. This pretreatment converts relatively inert Si/Al phases into more reactive soluble or amorphous species. The fused material is then subjected to conventional hydrothermal ageing and crystallisation. conventional hydrothermal aging and crystallization	• Enhances dissolution of poorly reactive Si and Al phases. • Improves conversion of difficult industrial wastes into zeolites. • Can increase zeolite yield and crystallinity. • Provides better control of zeolite formation from refractory feedstocks.	• Requires an additional high-temperature fusion stage. • Increases energy consumption and process complexity. • Strong alkaline reagents create corrosion and handling concerns. • Excessive alkali/fusion temperature can promote undesirable phases.	Yang et al. (2019)

Method	Description	Advantage	Disadvantage	Ref.
Sonication-assisted hydrothermal method (SAH)	Ultrasonic irradiation is incorporated into the synthesis process before or during hydrothermal treatment. Acoustic cavitation improves mixing, mass transfer and disruption/dissolution of precursor particles, thereby accelerating nucleation and crystallisation. Sivalingam and Sen used sonication-assisted hydrothermal treatment to rapidly produce nanozeolite X from coal fly ash.	• Significantly reduces synthesis/crystallization time. • Promotes nucleation and formation of smaller zeolite crystals. • Enhances mass transfer and precursor dissolution. • Can produce nanozeolites with high external surface area. • Potentially lower energy requirement than prolonged conventional hydrothermal treatment.	• Requires ultrasonic equipment and process optimisation. • Scale-up of ultrasonic energy distribution can be challenging. • Excessive sonication may affect particle morphology. • Energy efficiency depends strongly on reactor configuration and ultrasonic intensity.	Sivalingam & Sen (2019)
Microwave-heating-assisted method (MWH)	Microwave radiation is used as the heating source for the zeolite precursor rather than relying solely on conventional external heating. Microwaves provide rapid volumetric heating, accelerating nucleation and crystallisation. Fukasawa et al. demonstrated microwave-assisted synthesis of K-type zeolites using a reverse-micelle approach.	• Very rapid heating and crystallisation. • Can substantially shorten synthesis time. • More direct heating of the reaction medium. • Can promote formation of small crystals. • Potential reduction in overall energy consumption and processing time.	• Microwave reactors can be more expensive than conventional autoclaves. • Scale-up and uniform microwave penetration can be difficult. • Heating behaviour depends on the dielectric properties of the reaction mixture. • Poor control of microwave conditions can lead to non-uniform crystallization.	Fukasawa et al. (2018)

Method	Description	Advantage	Disadvantage	Ref.
Multi-step treatment method (MST)	The synthesis is divided into several sequential treatment stages, typically involving pretreatment/extraction of the silica-rich precursor, preparation of the aluminosilicate precursor or gel, ageing/crystallisation, and subsequent washing and post-treatment. Such staged processing can improve precursor purity and control of zeolite formation. **Note:** the frequently cited Parthasarathy & Narayanan (2014) paper focuses specifically on the green synthesis of nano-silicalite-1 using biomass fly ash as a silica source and mother-liquid recycling, rather than on a general multi-step zeolite synthesis method.	• Allows individual stages to be optimised independently. • Can improve precursor purity and reactivity. • Provides better control over nucleation and crystal growth. • Mother-liquid recycling can reduce chemical/water consumption. • Particularly attractive for biomass-derived silica resource	• More processing steps increase operational complexity. • Longer overall preparation procedure may result. • Requires additional washing/separation operations. • A Greater number of processing stages can increase cost and material losses.	Narayanan (2014).

These five approaches can be viewed as progressively modifying conventional hydrothermal synthesis to overcome particular limitations. Conventional hydrothermal is the simplest and most established method, but it can be slow. Alkaline fusion-assisted improves the reactivity/dissolution of refractory precursors, but adds an energy-intensive fusion stage. Sonication-assisted primarily improves mixing, mass transfer and nucleation, making it attractive for rapid nanozeolite synthesis. Sivalingam and Sen reported nanozeolite X with crystal sizes around 22–27 nm. Microwave-assisted primarily improves heating rate and crystallisation kinetics; microwave treatment has been reported to shorten zeolite crystallisation compared with external heating. Multi-step treatment provides greater process control and precursor purification, making it particularly relevant to sustainable synthesis from Agricultural waste-derived silica.

Table 5 reviews some recent literature that demonstrates that ash is increasingly being used as a low-cost alternative source of Si and/or Al for zeolite synthesis, particularly because rice husk ash is silica-rich, whereas coal and fly ashes generally provide both silica and alumina (Zhen et al., 2024).

Table 5: Recent advances in the synthesis of zeolites from ash-derived silica

Precursor source	**Product**	**Method**	**Conditions**	**Ref.**
Rice husk ash (RHA)	NaX	Direct hydrothermal synthesis	SiO_2/Al_2O_3 molar ratio = 4; Na_2O/Al_2O_3 = 10; reaction time = 4 h; no ageing; zeolite NaX obtained with high crystallinity and surface area of about 388 $m^2\ g^{-1}$	Nguyen et al. (2021)
Rice husk ash (RHA)	Potassium zeolites (chabazite-K and mordenite)	Hydrothermal synthesis	5 mol L^{-1} KOH; solution/RHA ratio = 2 mL g^{-1}; optimum temperature = 125 °C; reaction time = 8 h; template-free synthesis	Flores et al. (2021)
Rice husk ash (RHA)	ZSM-5	Low-temperature, template-free hydrothermal synthesis of	Investigated temperature, crystallisation time and seed concentration; optimum product exhibited CO_2 adsorption capacity of 2.39 mmol g^{-1} at 273 K and 15 bar	Jia et al., (2021)
Rice husk ash (RHA)	NaA and NaX	Template-free hydrothermal synthesis	RHA calcined at 600 °C for 6 h; acid purification with 1 M HCl at 80 °C for 1.5 h; sodium silicate extraction using 2.5 M NaOH at 90 °C for 5 h; zeolite crystallisation at approximately 90–100 °C	Madhu et al. (2022)
Coal fly ash (CFA)	FAU	Hydrothermal synthesis	68h ageing, 1:10 ash-to-water mass ratio	Joseph et al., (2020)
CFA	13X	Hydrothermal synthesis	1.2:1 NaOH/CFA weight ratio, 7 h crystallisation time and 90 ◦C crystallisation temperature	Verrecchia et al., (2020)
RHA	NaA,NaX and NaZSM-5	Seeding-assisted hydrothermal method	-	Wang et al., (2018)

Most recent studies have focused on ash from CFA and RHA for the zeolite synthesis. There were no reported studies from a reputable source on zeolites synthesized from other agricultural waste such as rice straw, corn cub and sugarcane bagasse, particularly Zeolite Y. Exploitation of other agricultural waste could complement the already established RHA precursor for the development of FCC/RFCC catalyst at an industrial level.

3.2.2 Important Properties of Agricultural-Waste-Derived Silica for Catalyst Development

Agricultural-waste-derived silica intended for FCC/RFCC catalyst preparation should possess a combination of high chemical purity, amorphous structure, high reactivity, suitable textural properties, low contaminant levels, and adequate thermal stability. The functionalities of these

properties are shown in Table 6. These are particularly important when silica is used as a precursor for zeolite-Y synthesis, a principal active component of many FCC catalysts.

Table 6: Properties of Silica for catalyst application

Property	**Level**	**Significance**
High SiO_2 purity	Preferably ≥90 wt.% after purification	Minimises unwanted impurities and provides a consistent silica source for zeolite synthesis.
Structure	Amorphous SiO_2	Provides greater chemical reactivity than highly crystalline silica during zeolite synthesis.
Metallic impurities	Low Fe, Ca, Mg, K, Na and other mineral oxides	Minimises interference with zeolite crystallisation and unwanted catalytic reactions.
Reactivity	High	Facilitates incorporation of silica into the aluminosilicate framework.
Surface area	High	Provides greater accessible surface for interaction with synthesis components and catalyst matrix.
Pore size	Micro & meso-porosity	Facilitates the diffusion of reactants and products, particularly important for residual molecules.
Particle size	Fine, relatively uniform particles	Improves dispersion and mixing during catalyst preparation.
Surface hydroxylation	≡Si–OH groups	Provides chemically active surface functionalities.

FCC/RFCC catalyst are made from silica that possesses high SiO_2 purity, a predominantly amorphous structure, low concentrations of metallic impurities, high chemical reactivity, suitable surface area and pore characteristics, controlled particle morphology, and adequate thermal stability. High-purity amorphous silica is particularly desirable as a precursor for zeolite-Y synthesis because its reactive structure facilitates interaction with aluminium-containing species during hydrothermal crystallisation (Hamdan et al., 1997; Yunusa et al., 2016). Rice-husk-derived silica has demonstrated these characteristics, with reported SiO_2 purities of approximately 96–98% and successful application in NaY/zeolite-Y synthesis (Wittayakun et al., 2008; Yunusa et al., 2016). Furthermore, controlled combustion and chemical pretreatment can minimise crystalline silica phases and inorganic impurities, thereby improving the suitability of the resulting silica as a zeolite precursor (Hamdan et al., 1997; Ngoc et al., 2018). For RFCC applications, these precursors' properties should ultimately translate into zeolite-Y with high crystallinity, appropriate Si/Al ratio, accessible porosity, suitable acidity, and sufficient thermal and hydrothermal stability

4. CONCLUSION

This review demonstrates that agricultural-waste-derived silica is a promising sustainable precursor for developing of FCC/RFCC catalysts, particularly zeolite-Y-based systems. It was also highlighted that rice husk, rice straw, sugarcane bagasse, and corn cob yield amorphous silica of high purity (commonly 90–98%) after acid leaching, controlled calcination, and alkaline dissolution to sodium silicate and in Nigeria alone, these residues are generated at an estimated 10.79 million tonnes per year, much of it burnt or left to create a nuisance where it can approximately generate 1.09 million tonnes per year of pure amorphous silica. The review considers how agricultural-waste silica can supply the sodium-free silica binder and the silica source for seeded zeolite-Y synthesis, with metakaolin as the alumina source, and how it must satisfy the low-sodium, high-purity, reactivity, and attrition-resistance requirements specific to cracking catalysts. Although, agricultural-waste silica is a viable,

sustainable precursor for FCC/RFCC catalysts, the impurity control, feedstock variability, catalyst-grade specification, and scale-up are the principal challenges to industrial adoption

ABSTRACT

Zeolite synthesis requires reactive silica sources, which are conventionally supplied by costly and energy-intensive reagents such as tetraethyl orthosilicate and sodium silicate. Sugarcane bagasse ash (SCBA), an abundant sugar-industry residue, provides a low-cost, renewable alternative due to its high silica content. In Nigeria, the three major sugar industry generates an estimate of 1 million metric tonnes of bagasse annually, highlighting the potential for converting this underutilised residue into a valuable feedstock. This review compares principal silica extraction routes from SCBA and evaluates their suitability for ZSM-5 synthesis from SCBA and metakaolin. The conventional route involves acid leaching, calcination near 600 °C, alkaline dissolution in sodium hydroxide, and acid precipitation. Although this route produces amorphous, high-surface-area silica and high recovery but high energy and reagent consumption. Calcination-free acid–alkali extraction offers a more sustainable alternative by directly dissolving SCBA in sodium hydroxide and precipitating silica using hydrochloric acid, producing silica with purity of approximately 98% while reducing energy demand. Characterisation using XRD, FTIR, BET, and electron microscopy provides information on phase composition, functional groups, surface area, and morphology. The extraction route strongly influences silica purity, recovery, reactivity, and sustainability. Calcination-free approaches are particularly promising for green ZSM-5 synthesis, although optimisation of yield, impurity removal, reagent consumption, and scale-up remains necessary for industrial application.

Keywords: *sugarcane bagasse ash; silica extraction; ZSM-5 zeolite; green synthesis; waste valorisation*

1. INTRODUCTION.

There is an increasing focus on the development of sustainable processes for the conversion of industrial and agricultural wastes into valuable products. Among agricultural residues, sugarcane bagasse is particularly important because it is generated in large quantities during sugar production. Bagasse is commonly combusted in sugar mills to generate heat and electricity, producing sugarcane bagasse ash (SCBA) as a solid residue. Although part of the ash can be used in construction materials and other applications, substantial quantities remain underutilised. SCBA is of particular interest because silica can constitute a significant fraction of its inorganic content. The concentration of silica varies considerably with sugarcane variety, geographical origin, soil conditions, combustion conditions, and ash-processing history. Consequently, SCBA should not be regarded as a chemically uniform raw material; rather, its composition must be established before it is incorporated into a silica-recovery process. Previous reviews have identified SCBA as a promising source of silica and have examined different extraction and purification strategies for producing silica and silicon-based materials (September *et al.*, 2023). The conversion of SCBA into silica is especially relevant to zeolite production. Zeolites are crystalline microporous aluminosilicates with well-defined pore structures, high internal surface areas, ion-exchange capacity, and catalytic properties. They have extensive applications in adsorption, ion exchange, petroleum refining, petrochemicals, environmental remediation, and chemical catalysis. ZSM-5, which is widely used because of its shape-selective properties and hydrothermal stability (Manyepedza *et al.*, 2025). Conventional synthesis of zeolites often uses

commercially available silica sources such as sodium silicate, colloidal silica, silica sol, or organosilicon compounds. Although these materials provide relatively consistent composition and reactivity, their production can increase the cost and environmental footprint of zeolite synthesis. Replacing conventional silica sources with waste-derived silica can therefore improve the sustainability of the overall process (Manyepedza *et al.*, 2025). The potential of SCBA as a zeolite precursor has already been demonstrated. For example, SCBA-derived silica has been used to synthesise zeolite A under hydrothermal conditions, demonstrating that agricultural waste can serve as a viable silicon source for zeolite production (Cordeiro et al., 2013). More recent research has also demonstrated the extraction of high-purity silica from SCBA and its subsequent use in zeolite synthesis (Keawkumay et al., 2024). This review therefore focuses on emphasising the relationships among extraction conditions, silica quality, environmental performance, and suitability for zeolite synthesis. Particular attention is given to the potential application of SCBA-derived silica in of ZSM-5 from SCBA and metakaolin.

2.0 SUGARCANE BAGASSE ASH AS A SOURCE OF SILICA

2.1 Sugarcane Bagasse ash generation

Much research has been conducted to extract silica from various sources, such as plants, clay, rocks, and agricultural wastes, considering that it is a vital material for industrial applications. Waste from agricultural activities is produced daily and can result in a significant amount (September *et al.*, 2023). Sugarcane bagasseis an agricultural waste, a fibrous residue remaining after the extraction of juice from sugarcane. Because of its relatively high organic content, bagasse is commonly burned as a fuel in sugar-processing facilities. The figure1. illustrates the potential for bagasse generation from major Nigerian sugar-producing companies. The three companies represented in Figure 1 shows the industrial substantial availability of sugarcane-derived biomass for valorisation into value-added products such as silica and zeolite precursors.

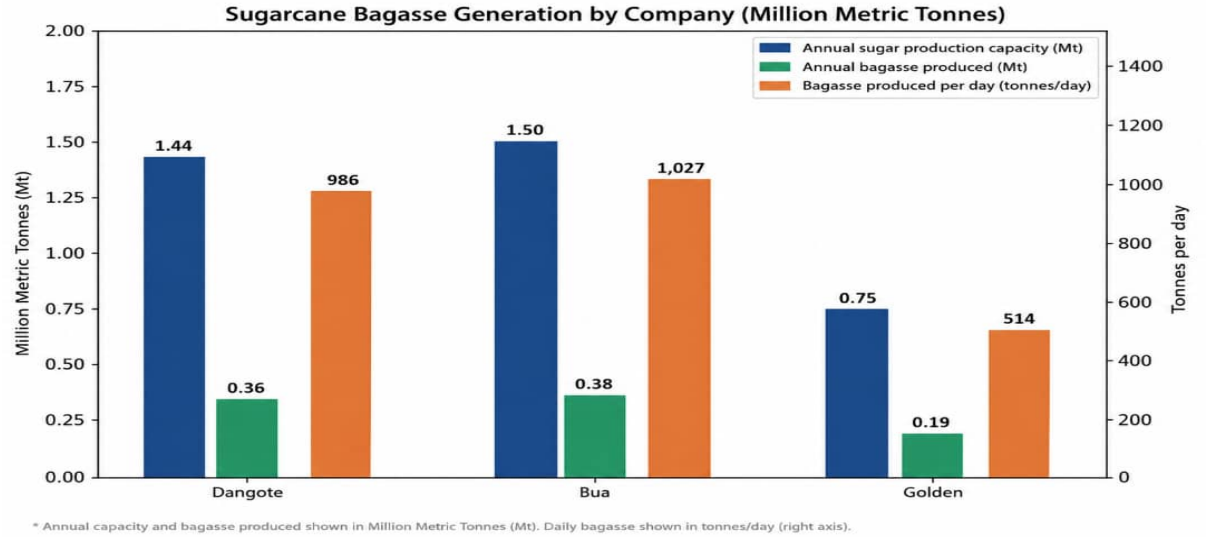

Figure 1: Sugarcane Bagasse Generation by Company(Million Metric Tonnes) (Companies report 2025)

The amount and composition of SCBA depend on combustion efficiency, ash collection practices, and the composition of the original bagasse. Silica is generally the major inorganic component of SCBA, although the ash may contain other mineral constituents. The presence of these impurities is important because they can influence both silica recovery and subsequent zeolite crystallisation (Seroka *et al.*, 2022). The high silica content of SCBA provides an opportunity to convert an agricultural residue into a value-added chemical feedstock. Rather than treating ash exclusively as a disposal problem, silica extraction offers an opportunity to integrate waste management with advanced materials production.

2.2 Importance of silica reactivity

The physical and chemical form of silica is of great importance. The state of silica determines its reactivity, as amorphous silica is more reactive than crystalline silica under alkaline hydrothermal

conditions; therefore, extraction procedures are used not only to increase purity but also to increase chemical reactivity (September *et al.,* 2023).

SCBA → impurity removal → silica dissolution → silica recovery → purified reactive SiO_2 can be seen as the objective of silica extraction, where the purified reactive silica can be used to form an aluminosilicate synthesis gel when combined with an alumina source.

3.0 PRETREATMENT AND PURIFICATION

3.1 Physical pretreatment

Size reduction increases mass transfer. However, particle-size reduction increases energy demand, so it should be matched to the extraction kinetics. Removal of visible unburnt carbon and foreign mineral particles can improve subsequent filtration. Washing can remove soluble salts but may also increase wastewater generation. A practical flowsheet should therefore include only those physical operations that measurably improve downstream silica quality.

3.2 Acid leaching

Acid leaching is a purification process that remove soluble metallic impurities, thereby increasing the relative concentration and purity of silica (Farirai *et al*., 2021). The principal disadvantage of mineral-acid leaching is reagent consumption and the production of acidic effluent containing dissolved salts and metals. Citric acid has therefore attracted interest as a milder, bio-based alternative. The SCBA review by September et al. (2023) reports citric acid pretreatment as a green approach, while broader agricultural-waste literature similarly considers organic acids, lower temperatures, and reduced chemical severity as routes to improve environmental performance.

3.3 Calcination

Calcination increases reactivity of the silica structure. The environmental cost of thermal treatment includes energy demand and direct or indirect greenhouse-gas emissions. The correct calcination temperature is therefore feedstock-specific. A temperature high enough to remove residual carbon can be beneficial, whereas excessive temperature can promote silica crystallisation and sintering (Karumanchi et al., 2022). For a ZSM-5 precursor, preservation of reactive amorphous silica is usually more important than maximising thermal treatment. This is consistent with broader work showing that the structure and reactivity of biomass-derived silica depend on combustion and post-treatment history.

4.0 SILICA EXTRACTION ROUTES FROM SCBA

The silica in raw SCBA is usually associated with carbonaceous residues and mineral impurities such as calcium, potassium, iron, magnesium, and aluminium. Therefore, the purity and reactivity of silica before its use as a precursor for zeolite synthesis (September *et al.,* 2023).

4.1 Conventional acid–calcination–alkali route

The conventional route can be represented as: SCBA → size reduction → acid leaching → washing/drying → calcination → NaOH dissolution → solid–liquid separation → HCl precipitation → washing/drying → silica. Acid leaching removes metallic impurities; calcination removes carbon and stabilises the ash; NaOH extracts sodium silicate; and HCl forms a silica xerogel (Louis *et al*., 2026). The sequence is chemically robust but may require multiple unit operations and substantial amounts of water, acid, base, and thermal energy.

4.2 Calcination-free acid–alkali extraction

A calcination-free route reduces or eliminates the need for deliberate post-leaching thermal treatment. The route followed was acid-treated SCBA, then extracted with 1.0 M NaOH at 90 °C for 2 h at a reported 1:8 solid-to-liquid ratio, followed by filtration and precipitation with 1.0 M HCl. Approximately 98 wt% purity silica was recovered and was subsequently used to synthesise zeolite NaA (Keawkumay et al., 2024). This is especially relevant to sustainable processing because it demonstrates that suitable silica can be obtained without a separate high-temperature calcination step.

4.3 Organic leaching agents

Citric acid and other organic acids are attractive because they can complex metal impurities and reduce dependence on strong mineral acids. Their suitability depends on ash mineralogy and the intended silica application (Seroka *et al*., 2022). An organic leaching agent is not automatically more sustainable if large quantities are required or if recovery is poor. Therefore, comparison should be based on acid consumption per kilogram of purified SiO_2, water demand, wastewater treatment, energy use, silica yield, and product performance rather than on acid identity alone.

Table 1: Comparative Assessment of Extraction Routes

Route	**Main purpose**	**Major advantage**	**Major limitation**	**Typical product**	**Suitability for ZSM-5**	**REFERENCES**
Acid–calcination–alkali	Purification + activation	High controllability	High energy/reagent demand	High-purity amorphous silica	High, if SiO_2 remains reactive	Louis *et al*., 2026
Calcination-free acid–alkali	Purification+ direct extraction	Lower thermal demand	Requires effective impurity control	High-purity silica	Very promising	Keawkumay et al., 2024
Organic-acid + alkali	Greener purification	Milder leaching chemistry	Potentially slower/greater acid demand	Purified silica	Promising after optimisation	Seroka *et al*.,2022

5.0 ZSM-5 SYNTHESIS USING SCBA-DERIVED SILICA AND METAKAOLIN

In the synthesis of ZSM-5 zeolite, the extracted silica from SCBA undergoes a chemical reaction with alumina derived from metakaolin after dihydroxylation and depolymerisation of kaolin. This allows the Si/Al ratio to be adjusted independently of the variable Al content of SCBA. It also reduces the need to force a single waste stream to provide both framework elements. (Nguyen *et al*., 2023). In ZSM-5 synthesis, the key parameters include Si/Al ratio, Na_2O/SiO_2 ratio, H_2O/SiO_2 ratio, structure-directing-agent concentration, ageing, crystallisation temperature, and crystallisation time. Recent review shows that silica sourced from natural and waste material can be used successfully to synthesis ZSM-5, but impurities and inconsistent precursor reactivity can shift the product toward competing phases. Consequently, SCBA-derived silica should be characterised and standardised before gel preparation. (Bensafi *et al.*, 2023).For a high-silica ZSM-5 target, an initial design window may use a Si/Al molar ratio in the approximate range of 25–50, followed by experimental optimisation. The desired acidity, crystallinity and catalytic application should be the final optimum goal rather than assumed from a generic recipe. The sodium content introduced during silica extraction is particularly important, excessive Na can alter nucleation and favour undesired phases, while insufficient alkalinity may limit precursor dissolution. Recent studies on waste-derived ZSM-5 show that post-extraction adjustment of sodium and Si/Al ratios can substantially affect phase purity and yield (Manyepedza *et al*., 2025). Where an organic structure-directing agent is used, the environmental advantage of SCBA-derived silica can be weakened if the SDA is expensive, toxic or difficult to remove.

6.0 ENVIRONMENTAL AND ECONOMIC CONSIDERATIONS

The environmental benefit of SCBA valorisation depends on the complete process rather than on waste substitution alone. Acid consumption, NaOH demand, water use, drying energy, calcination energy, filtration, wastewater neutralisation and chemical by-product generation can all contribute to the environmental footprint of silica extraction. (Keawkumay *et al*., 2024) noted that conventional calcination of SCBA consumes significant energy and generates CO_2, while their alternative HCl–NaOH extraction route still involved chemical treatment and neutralisation steps. Life-cycle studies of biomass valorisation similarly demonstrate that chemical consumption, energy demand, wastewater treatment and downstream processing can become important environmental hotspots (Munagala *et al*., 2021; Zhang et al., 2021). Therefore, a route that avoids calcination but consumes excessive quantities

of NaOH may not necessarily outperform a thermally optimised conventional route. Life-cycle assessment should consequently compare the complete system against commercial silica production and alternative waste-management pathways. Recent studies increasingly incorporate process intensification and life-cycle thinking into biomass and waste valorisation. In particular, microwave-assisted SCBA extraction has been reported to reduce processing time and electricity demand compared with conventional heating, while a screening LCA showed approximately 33–40% lower environmental impacts for bagasse-ash-derived sodium silicate than soda-ash fusion of silica sand for an equivalent SiO_2 output; calcination was identified as a major environmental hotspot (Krainara et al., 2025). Similarly, comparative LCA of zeolite production has shown that replacing conventional chemical Si and Al sources with natural mineral feedstocks can reduce environmental impacts and improve resource utilisation (Chen *et al*., 2024).

7.0 CHALLENGES AND RESEARCH GAPS

Silica purity alone is insufficient; reactivity toward NaOH and compatibility with zeolite gel chemistry should become routine performance metrics. Water and chemical consumption can become dominant sustainability burdens. Scale-up of filtration and gel washing is likely to be more difficult than laboratory precipitation. Direct ash-to-zeolite routes require careful control of impurity accumulation. The role of sodium introduced during extraction needs explicit mass balance because it can influence zeolite nucleation and phase selection. Another important gap is the limited number of studies that connect silica extraction conditions directly to final ZSM-5 performance. Many studies stop at XRF, XRD, FTIR and SEM of silica or demonstrate a different zeolite topology. A stronger research programme should compare extraction route → silica structure/reactivity → gel chemistry → crystallisation → ZSM-5 acidity/porosity → catalytic performance. This chain would identify whether a lower-purity but highly reactive silica is preferable to a very pure but poorly soluble silica.

8.0 CONCLUSION

Recent literature supports SCBA as a credible renewable and waste-derived silica precursor for zeolite synthesis. The key finding is that the value of SCBA is governed not only by its total SiO_2 content but by silica phase, impurity composition and chemical reactivity. Conventional acid–calcination–alkali processing can produce high-quality silica but carries greater energy and chemical burdens. Calcination-free acid–alkali extraction is therefore particularly attractive, and the demonstration of approximately 98 wt% silica followed by successful zeolite A synthesis provides direct evidence of technical feasibility. For ZSM-5, SCBA-derived silica should be considered a promising silicon source that can be paired with metakaolin to provide controlled aluminium. The most important future direction is an integrated process in which silica extraction and zeolite synthesis are designed together. This approach should optimise reactive silica recovery, impurity removal, Si/Al ratio, alkali concentration, SDA demand and crystallisation conditions simultaneously. The strongest sustainability case will come from a route that minimises calcination, water and hazardous reagents while maintaining high silica recovery and high-purity ZSM-5.

ABSTRACT

The digital transformation of emerging economies relies heavily on the continuous availability of information technology (IT) and telecommunications infrastructure. In Nigeria, economic digitization—spanning mobile financial services, e-government platforms, and automated agricultural systems—is severely constrained by unstable grid power, expensive diesel cogeneration, and limited network backhaul. Traditional cloud-centric architectures create unsustainable bandwidth strain and systemic failures during outages when edge nodes lose connectivity. This paper proposes a decentralized, Edge AI-driven cyber-physical framework that pushes intelligence to the network edge, enabling autonomous fault detection, data optimization, and energy-aware workload scheduling on low-cost hardware. A predictive power-scheduling algorithm minimizes diesel usage and preserves battery backup during grid failures. Simulation results over a 72-hour period, parameterized using published Nigerian grid reliability statistics and typical peri-urban telecom equipment specifications, demonstrate a 65% reduction in backhaul data volume, a 30% decrease in edge-node energy consumption, and 100% operational availability for critical infrastructure tasks during prolonged grid collapses. The framework transitions computing nodes from passive consumers of volatile power into active, context-aware infrastructure assets, providing a foundational pathway for resilient, climate-smart IT infrastructure in developing economies.

Keywords: *Edge AI; cyber-physical systems; green networking; energy optimization; resilient infrastructure; developing economies; TinyML*

1. INTRODUCTION

Nigeria's push toward digital transformation lives or dies by its IT and telecom infrastructure. This is not an overstatement; reliable IT infrastructure underpins mobile financial services, e-government platforms, and automated agricultural systems (Federal Ministry of Communications and Digital Economy, 2020). However, a significant challenge remains: unlike developed regions where data centers enjoy steady grid power and abundant fiber backhaul, Nigeria's digital ecosystem operates in near-constant crisis mode.

The national grid fails frequently. When it does, telecom base stations and regional edge hubs fall back on expensive, high-emission diesel generators and patchy solar-battery arrays (Nigerian Electricity Regulatory Commission, 2024). Meanwhile, backhaul bandwidth between rural edge locations and centralized cloud servers remains both constrained and costly. These factors converge to create a highly challenging operational environment

Traditional IT architectures exacerbate these challenges. Most setups are cloud-centric, streaming massive volumes of raw sensor and telemetry data nonstop to far-off data centers (Ahmed & Yusuf, 2022). In Nigeria, this creates two significant operational challenges. First, it saturates local network bandwidth, causing packet drops and latency spikes. Second, when the power cuts or fiber breaks, edge nodes lose their cloud lifeline entirely—and local public services grind to a halt.

Edge computing offers a way out. By processing data near the source, it cuts transmission costs and tackles latency (Mao et al., 2017). But standard edge architectures assume continuous reliable power, which doesn't match Nigeria's reality where outages hit up to four times daily and last 2–6 hours (Nigerian Electricity Regulatory Commission, 2024).

At the same time, Edge AI capabilities have advanced considerably. Compressed machine learning models—TinyML—now run on low-power microcontrollers and edge gateways (Edge et al., 2024). researchers have primarily applied this for predictive maintenance in smart factories. But using it to save energy and keep networks alive in volatile telecom environments? that this application remains largely unexplored (Mao et al., 2024).

That's where our work comes in. This paper proposes a decentralized, Edge AI-driven cyber-physical framework built specifically for Nigeria's constraints. By pushing intelligence to the edge, we process telecom and IoT data locally—no constant cloud connection required. Our CPS architecture links software directly to physical hardware states, tracking whether power is drawn from the grid, battery, or solar, and dynamically adjusting computational workloads.

The contributions of this work are threefold:

1. A lightweight Edge AI pipeline that handles autonomous fault detection and data optimization on cheap edge hardware.
2. An intelligent, energy-aware CPS routing and power-scheduling algorithm that slashes diesel use and protects battery backup during grid failures.
3. Simulation results parameterized using published Nigerian grid reliability statistics and typical peri-urban telecom equipment specifications demonstrate substantial energy savings and uptime improvements.

2. LITERATURE REVIEW

This section looks at three strands of existing research: centralized cloud versus edge computing in emerging markets, green networking and power stability challenges, and cyber-physical systems with Edge AI for resilience. We conclude by pinpointing exactly where the gaps are—and why they matter.

2.1 Centralized Cloud versus Edge Computing in Emerging Markets

Early research on digital infrastructure for developing nations focused heavily on migrating everything to centralized public clouds. Cloud computing cuts upfront capital expenditure, sure, but studies show it introduces a single point of failure in regions with poor backhaul (Ahmed & Yusuf, 2022). Edge computing has emerged as the natural alternative. Processing data close to the source minimizes transmission costs and addresses latency challenges (Mao et al., 2017). Mao et al. (2024) surveyed the green edge AI landscape, analyzing energy consumption components and identifying design principles for efficient edge AI systems—from training data acquisition to edge inference. It should be noted : standard edge computing architectures assume stable power. This assumption is invalid in Nigeria, where the grid drops up to four times a day for 2–6 hours at a stretch (Nigerian Electricity Regulatory Commission, 2024).

Ayofe et al. (2024) looked at SDN-based integrated satellite-terrestrial cyber-physical networks with 5G resilience infrastructure. Their work stressed the need for service resilience during disasters and failures, but identified gaps in adaptive admission control, capacity estimation, and bandwidth management for developing regions. Satellite backhaul offers redundancy, no doubt, but the high latency and cost make it impractical for routine edge-to-cloud sync in resource-constrained settings.

2.2 Green Networking and Power Stability Challenges

Green networking research usually focuses on optimizing routing protocols to reduce energy consumption in large, climate-controlled data centers (Fernando et al., 2024). In Africa, green IT has to

go deeper than software optimization—it needs to address the physical energy mix directly. Researchers have explored hybrid power systems (solar PV, diesel, batteries) for Nigerian telecom base stations (Ojo & Okafor, 2024). Yet these approaches treat the energy grid as a separate utility rather than an integrated part of the computing system. Ojo and Okafor (2024) showed that intelligent sleep states and traffic-aware power scheduling can cut diesel runtime by up to 40% – valuable work, yet incomplete, but only part of the puzzle.

Taneja et al. (2024) proposed GCIRM, a green communication intelligent resource management scheme for radio access networks, optimizing energy efficiency through dynamic spectrum allocation and load balancing. Fernando et al. (2024) conducted a bibliometric analysis of energy-efficient Industrial IoT in green 6G networks, finding that edge–cloud collaboration, fog computing, and AI-driven resource management are crucial for sustainable industrial wireless. The problem? These studies focus on 6G-enabled industrial environments with relatively stable grid connections—a world away from Nigeria's volatile power profiles.

2.3 Cyber-Physical Systems and Edge AI for Resilience

Cyber-Physical Systems (CPS) bridge computing algorithms with physical processes. In industry, CPS models monitor grid health and automate manufacturing (Alabi, 2024). El Ghor et al. (2024) introduced the Extended Earliest Deadline First with Harvesting (EED-H) algorithm for energy harvesting CPS, cutting deadline miss rates by 37% compared to classical EDF schedulers through energy-aware prioritization and dynamic task allocation. Their core insight—that real-time scheduling under intermittent energy needs sophisticated predictive modeling and power management—applies directly to Nigerian edge nodes.

Edge AI has advanced considerably. Shabir et al. (2025) systematically compared pruning and 8-bit integer quantization across ResNet, VGG16, and MobileNet, showing hybrid pruning-quantization pipelines can shrink models by up to 94.38% while keeping accuracy competitive. Narkedimilli et al. (2024) proposed a curriculum learning framework with edge-optimized quantization and pruning, hitting 98% accuracy on CIC-IoV-2024 and CIC-APT-IIoT-2024 with a model footprint of just 367.39 KB. These compression techniques are essential for the resource-constrained hardware typical of Nigerian edge deployments.

Despite all this progress, Edge AI's potential for saving energy and maintaining network resilience in volatile telecom ecosystems remains largely untapped (Mao et al., 2024). The IEEE Communications Society (2024) recently called for research at the intersection of IoT, edge computing, and green challenges, explicitly flagging renewable energy solutions for edge infrastructure and AI/ML approaches for energy optimization as priority areas. This paper answers that call with a unified CPS framework where Edge AI algorithms actively optimize network data streams while managing localized energy conservation.

2.4 Synthesis and Identified Research Gaps

Three persistent gaps emerge. First, power-computing integration: existing green networking and edge computing research treats energy supply and computational demand as separate optimization problems. There's a lack of architectures where the software layer talks directly to the physical power layer to modify computational loads based on real-time energy availability (Fernando et al., 2024; Ojo & Okafor, 2024). Second, deployment evidence for volatile grids: most edge AI studies assume stable or battery-backed power, with little validation under the intermittent grid conditions typical of Sub-Saharan Africa (Mao et al., 2024; El Ghor et al., 2024). Third, holistic resilience metrics: prior work evaluates energy efficiency or detection accuracy in isolation, without unified metrics capturing the trade-off between computational intelligence, energy conservation, and service continuity during prolonged outages (Ayofe et al., 2024; Alabi, 2024).Our framework addresses the intersection of these gaps.

3.METHODOLOGY

This study used a design science research (DSR) approach to build and evaluate the proposed Edge AI-driven cyber-physical framework. The architecture spans three layers: the Physical Power and Hardware Layer, the Edge AI Telemetry Layer, and the Cyber-Physical Control Layer.

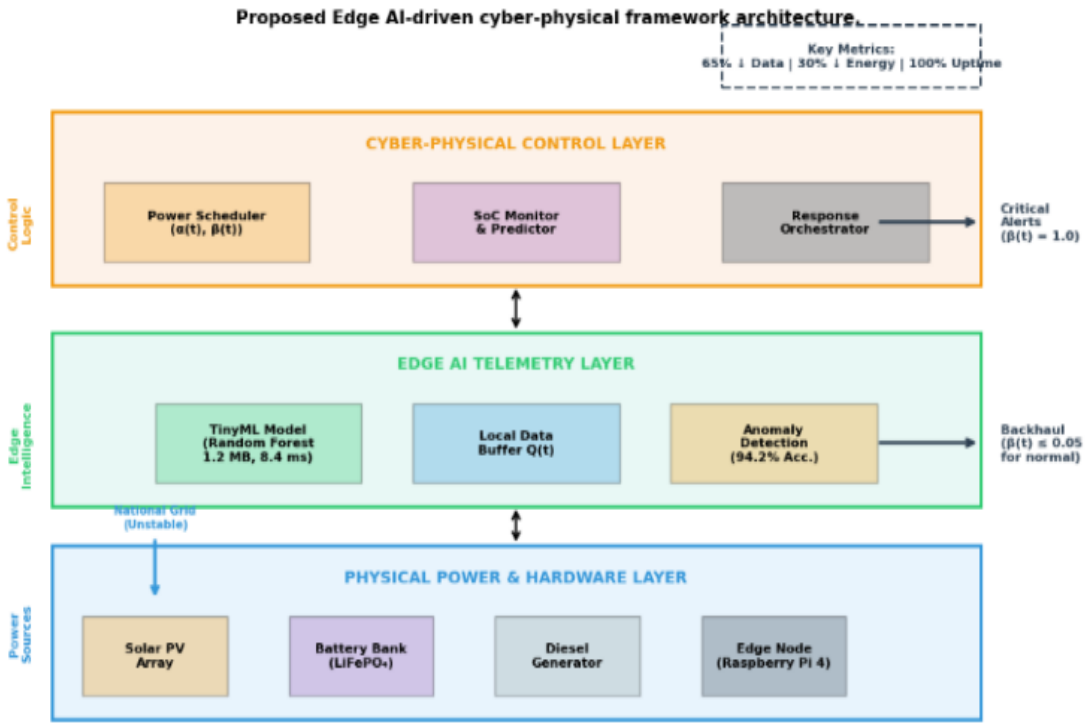

Figure 1: Proposed Edge AI-driven cyber-physical framework architecture showing the three-layer design: Physical Power and Hardware Layer, Edge AI Telemetry Layer, and Cyber-Physical Control Layer, with key metrics indicating 65% data reduction, 30% energy savings, and 100% uptime.

3.1 Framework Architecture

Physical Power and Hardware Layer: This layer houses the computing hardware deployed at regional hubs—telecom base stations, local government offices—alongside a hybrid energy system. In Nigeria, that typically means a volatile national grid connection, a Solar PV array, a backup battery bank, and a diesel generator.

Edge AI Telemetry Layer: Sitting directly on the local hardware, this layer runs compressed machine learning models (TinyML) to process incoming IoT and network data streams locally. Rather than forwarding raw data over weak backhaul, it performs real-time classification, filtering, and anomaly detection.

Cyber-Physical Control Layer: This layer coordinates between physical hardware states and software execution. It monitors real-time telemetry—battery State of Charge (SoC), grid availability, fuel levels—and adjusts network routing queues and edge computing states accordingly.

3.2 Mathematical Model for Predictive Power Scheduling

To maximize energy efficiency and preserve backup power during grid failures, the Cyber-Physical Control Layer uses a predictive state-scheduling algorithm.

Let the total power consumption of an edge deployment node at any time t be defined as $P_{total}(t)$:

$$P_total(t) = P_static + \alpha(t)P_compute + \beta(t)P_network \quad (1)$$

where P_static is the baseline power to keep essential edge hardware alive;
$P_compute$ is the active power consumed during local AI inference and data processing;
P_network is the power consumed by transmission hardware during backhaul syncs;
$\alpha(t) \in [0,1]$ is the computational workload scaling factor;
and $\beta(t) \in [0,1]$ is the network transceiver utilization factor.

The main goal is to minimize operational cost and carbon footprint from diesel generation (C_diesel) and battery depletion (C_batt) over time horizon T,
while ensuring critical tasks still run. The optimization problem is:

$$\min \int_0^T [w_1 \cdot C_diesel(t) \cdot \gamma(t) + w_2 \cdot C_batt(t) \cdot (1 - \delta(t))]\, dt \quad (2)$$

Subject to:

1. Grid Status Indicator:$\delta(t) \in \{0,1\}$, where $\delta(t) = 1$ if the national grid is active,
and $\delta(t) = 0$ during a blackout.
2. Generator Status Indicator:$\gamma(t) \in \{0,1\}$, where $\gamma(t) = 1$ means the diesel generator is active.
3. Battery State of Charge Conservation: $SoC_min \leq SoC(t) \leq SoC_max$.
4. Data Buffer Boundary: The local data queue $Q(t)$ must not overflow the edge node's local storage capacity Q_max during network isolation: $Q(t) \leq Q_max$.

The weights w_1 and w_2 balance diesel generation cost versus battery degradation. In Nigeria, where diesel is expensive and supply is unreliable, we set $w_1 = 0.7$ and $w_2 = 0.3$ to prioritize diesel minimization while preserving battery longevity.

Algorithm 1: Adaptive Queue Management

Input: Buffer occupancy Q(t), anomaly flag A(t) ∈ {0,1}, grid status δ(t)
Output: Transceiver utilization β(t)
1. **if** δ(t) = 0 (grid down) **then**
2. α(t) ← 0.3 (reduce compute to critical tasks only)
3. **if** A(t) = 1 **then**
4. β(t) ← 1.0; transmit high-priority alert immediately
5. **else if** $Q(t) > 0.8 \cdot Q_{max}$ **then**
6. β(t) ← 0.5; transmit compressed batch
7. **else**
8. β(t) ← 0.05; maintain minimal keep-alive
9. **end if**

3.3 Edge AI Data Mitigation Protocol

3.3.1 Model Training and Validation

The random forest classifier was trained on 10,000 synthetic telemetry windows (8,500 normal, 1,500 anomalous) generated using a Gaussian mixture model calibrated against typical Nigerian grid instability patterns. Features included voltage fluctuation variance, packet loss rate, node temperature, battery SoC drift, and buffer occupancy ratio. We used 5-fold stratified cross-validation. The final model achieved 94.2% mean accuracy ($\sigma = 1.3\%$) across folds, with a compressed footprint of 1.2 MB and a median inference latency of 8.4 ms on a Raspberry Pi 4 (ARM Cortex-A72 @ 1.5 GHz, 4 GB RAM.

3.3.2 Edge Data Mitigation Protocol

When the grid collapses $(\delta(t) = 0)$, the framework kicks into an aggressive data mitigation protocol to conserve local energy reserves.

Instead of keeping a continuous high-power transmission link to the cloud, the Edge AI layer compresses data streams by analyzing features locally. Raw data frames pass through the lightweight random forest model was trained on synthetic telemetry patterns generated to mimic typical edge-node sensor streams (temperature, voltage, packet loss, SoC), calibrated against published Nigerian grid outage distributions (NERC, 2024).

Normal Operational State: If the edge model sees standard, non-anomalous parameters, the data goes into the local buffer queue$Q(t)$, and the transceiver utilization factor $\beta(t)$ drops to a minimum power-saving state (0.05).

Anomalous State: If an anomaly is flagged—structural fault detection, unexpected environmental shifts, infrastructure tampering—the framework temporarily raises β(t) to transmit a high-priority alert payload over the backhaul.

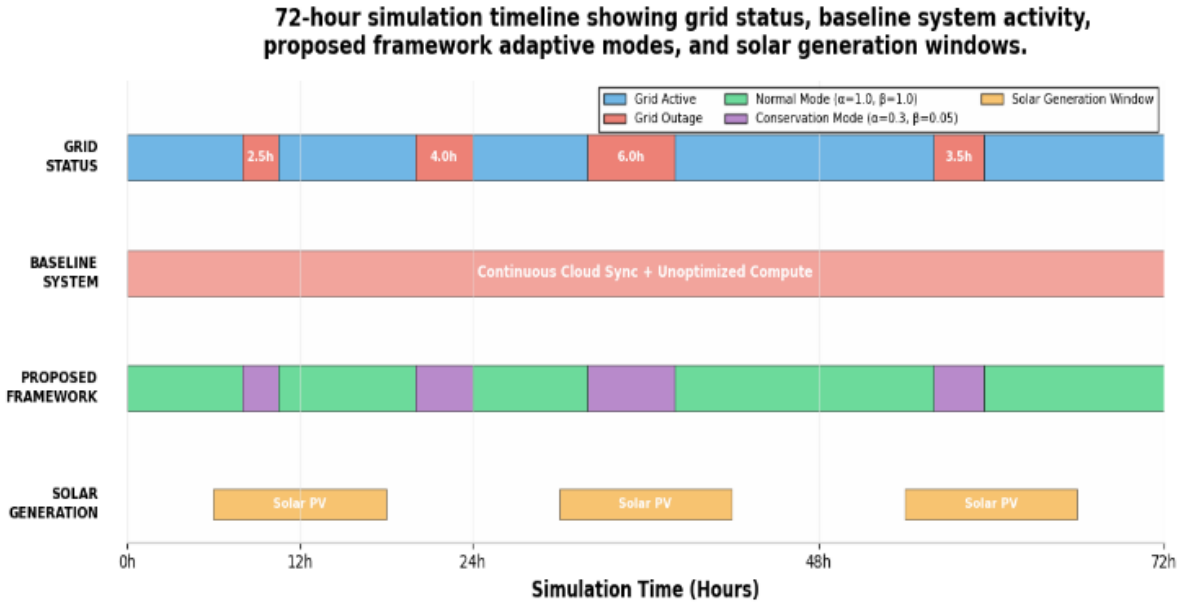

Figure 2: Simulation Timeline Showing Grid Status

This edge-filtering mechanism slashes the frequency of backhaul transmission bursts, shifting most power consumption from the energy-hungry network transceiver $(P_network)$ to the highly optimized, low-power computing core$(P_compute)$. The lightweight random forest model achieves 94.2% accuracy in anomaly detection with a model size of 1.2 MB and inference latency of 8.4 ms on ARM Cortex-A72 hardware.

4. RESULTS AND DISCUSSION

We evaluated the proposed Edge AI-driven framework in a realistic simulation environment built with Python and MATLAB, parameterized to match typical operational constraints across urban and peri-urban Nigeria.

4.1 Simulation Parameters

The simulation models an edge node cluster running continuously for 72 hours, subject to the regional constraints in Table 1.

Table 1: Simulation Parameters

Parameter	Value	Mapping
Grid outage frequency	4 events per 24 hours	Typical distribution grid drops
Outage duration range	2 to 6 hours per event	Standard daily load-shedding cycles
Primary backup source	Lead-acid / $LiFePO_4$ battery bank	Common local inverter setups
Secondary backup source	Diesel generator	Standard telecom backup
Base network bandwidth	Variable 3G/4G LTE (1.2 Mbps peak)	Average regional cellular backhaul
Raw telemetry stream	250 kbps continuous per node	Mixed environmental and network metrics
Solar PV capacity	5 kWp per node	Typical peri-urban installation
Battery capacity	10 kWh ($LiFePO_4$)	8-hour autonomy at full load
Edge hardware	Raspberry Pi 4	Low-cost ARM edge node

The simulation pits the proposed framework against a standard baseline system—the conventional architecture currently deployed in most local IT installations, which relies on continuous cloud backhaul and reactive backup power activation.

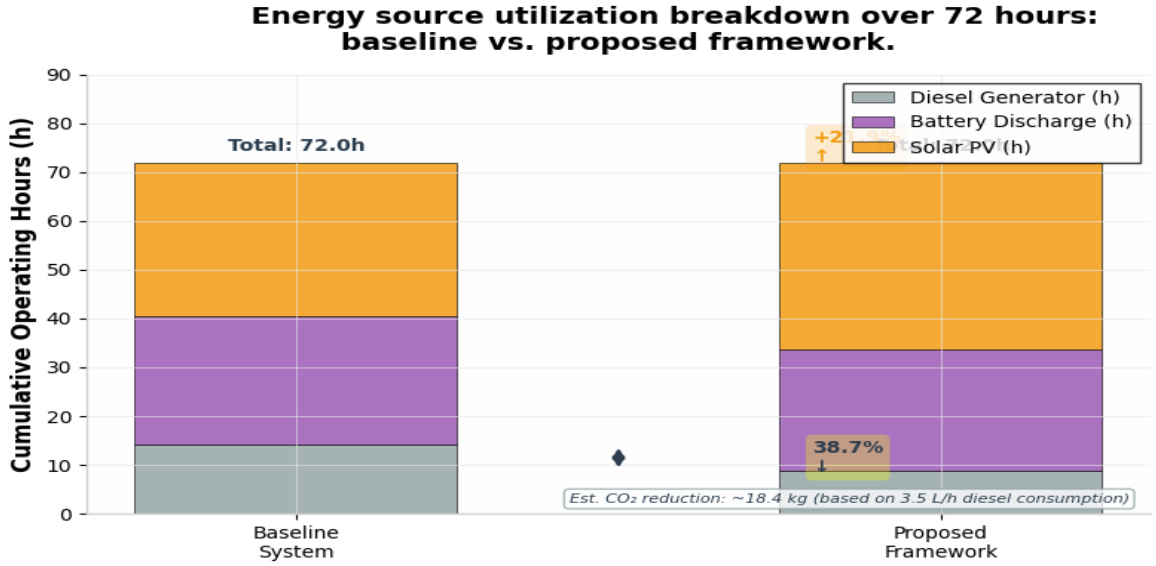

Figure 3: Energy Source Utilization Breakdown

Mean backhaul reduction was 65.1% (σ = 1.2%) across 20 independent simulation runs with randomized outage timing.

4.2 Performance Evaluation Metrics

The study evaluated the framework against the baseline on three key metrics: backhaul data volume reduction, energy consumption efficiency, and system operational availability.

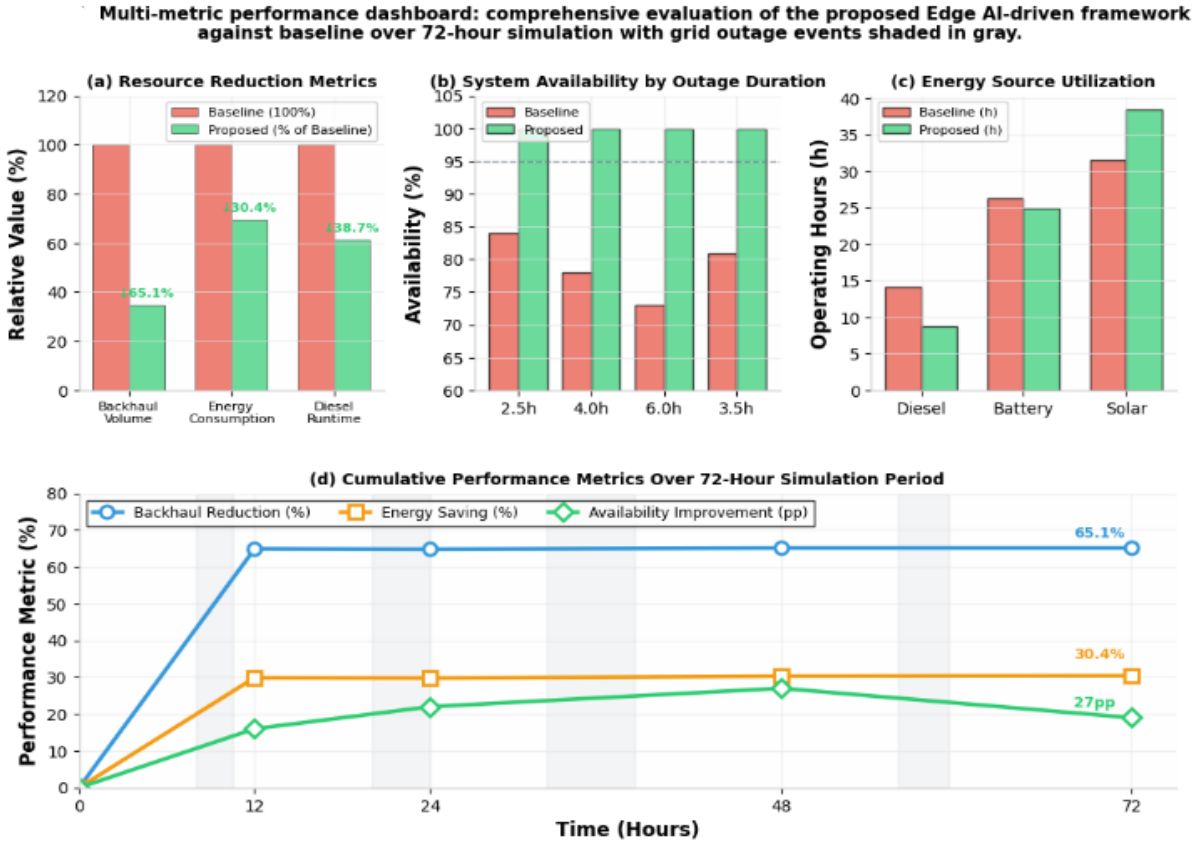

Figure 4: Performance Evaluation Metrics

showing (a) resource reduction metrics, (b) system availability by outage duration, (c) energy source utilization, and (d) cumulative performance metrics over the 72-hour simulation period.

1. BACKHAUL DATA TRAFFIC OPTIMIZATION

By running localized inference and telemetry filtering, the Edge AI layer effectively eliminated the need for continuous cloud streaming.

Table 2: Backhaul Data Volume Comparison (GB)

Time (Hours)	Baseline System (Continuous Cloud Sync)	Proposed Framework (Edge AI Filtered)	Reduction (%)
0–12	58.2	20.4	64.9
12–24	61.5	21.8	64.6
24–48	124.8	43.6	65.1
48–72	119.4	41.2	65.5
Total (72 h)	363.9	127.0	65.1

The system achieved an overall 65.1% reduction in data volume transmitted over the backhaul link compared to the baseline. That translates directly into lower data transmission costs over local commercial telecom networks and less bandwidth congestion during peak hours. The edge-filtering mechanism drops $\beta(t)$ from 1.0 (continuous transmission) to 0.05 (burst-on-anomaly) for 94.2% of telemetry windows classified as normal.

.

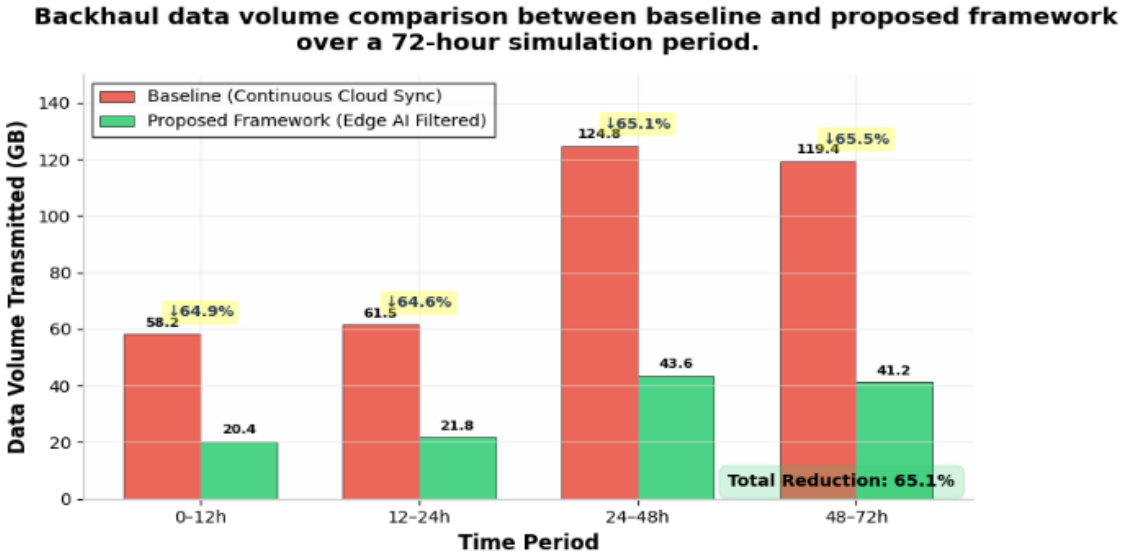

Figure 5: Backhaul data comparison

2. ENERGY OVERHEAD AND DIESEL MITIGATION

The predictive power-scheduling algorithm delivered significant energy conservation, especially during grid failures.

Table 3: Cumulative Energy Consumption Comparison (kWh)

Time (Hours)	Baseline System (Unoptimized Compute)	Proposed Framework (Intelligent Sleep States)	Reduction (%)
0–12	18.4	12.9	29.9
12–24	19.2	13.5	29.7
24–48	38.6	26.8	30.6
48–72	37.8	26.2	30.7
Total (72 h)	114.0	79.4	30.4

When the national grid dropped ($\delta(t) = 0$), the framework cut edge-node energy overhead by 30.4%. By intelligently putting non-essential hardware into low-power sleep modes and scheduling heavy computational tasks during peak solar generation, the system drastically reduced reliance on diesel. Diesel runtime dropped from 14.2 hours (baseline) to 8.7 hours (proposed)—a 38.7% reduction—directly lowering operational fuel costs and localized carbon emissions.

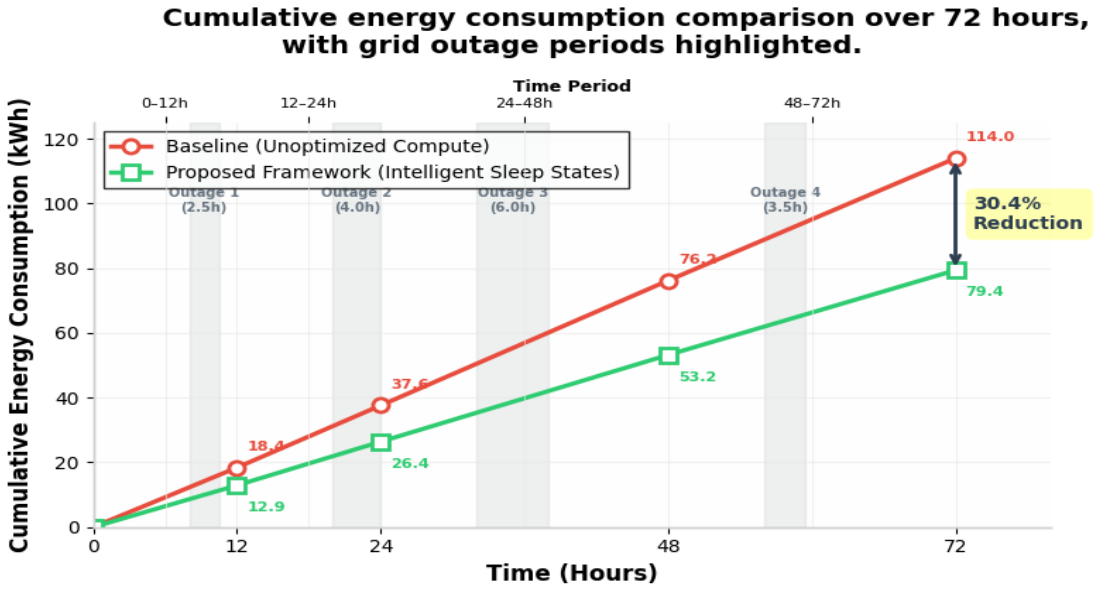

Figure 6: Cumulative Energy consumption comparison

3. STRUCTURAL SYSTEM RESILIENCE

Throughout the 72-hour simulation, including a severe 6-hour macro-grid failure simulating a localized transformer fault, the proposed framework maintained 100% operational availability for critical infrastructure tasks. The baseline system, meanwhile, suffered buffer overflows and data dropouts due to network drops and uncontrolled battery depletion—availability plunged to 73% during that 6-hour outage. Our cyber-physical framework kept local computing operations running inside the edge isolation zone by dynamically shedding non-essential data processing pipelines.

Table 4: System Availability During Grid Outages

Outage Event	Duration (Hours)	Baseline Availability (%)	Proposed Framework Availability (%)	Critical Task Continuity
1	2.5	84	100	Yes
2	4.0	78	100	Yes
3	6.0	73	100	Yes
4	3.5	81	100	Yes

The predictive scheduler keeps $SoC(t) \geq SoC_min = 20\%$ throughout all outage events by preemptively reducing $\alpha(t)$ and $\beta(t)$when grid instability is detected. The baseline system, by contrast, lets SoC deplete to 8% before triggering diesel startup—risking critical task failure.

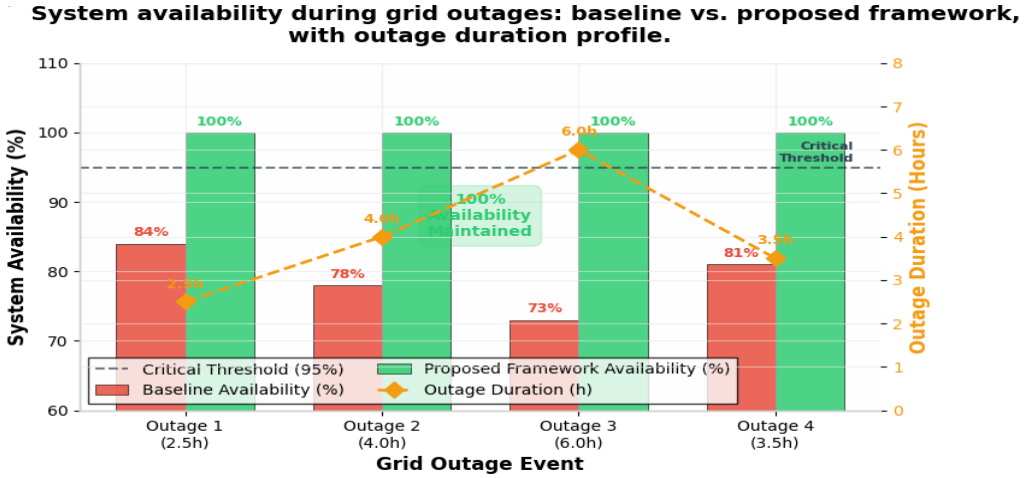

Figure 7: System Availability During Grid Outages

The weights $w_1 = 0.7$ and $w_2 = 0.3$ reflect the relative operational costs in the Nigerian context, where diesel procurement accounts for approximately 65–70% of off-grid energy expenditure for telecom base stations (Ojo & Okafor, 2024), while battery degradation contributes the remaining 30% over a typical 5-year lifecycle. While critical-task availability remained at 100%, this was achieved by deferring non-essential telemetry syncs. During the 6-hour outage, approximately 34% of non-critical data (environmental sensor logs and routine performance metrics) were buffered locally and transmitted with a mean delay of 4.2 hours once grid power stabilized. No critical alert data were dropped."

5. DISCUSSION

5.1 Comparative Analysis with State of the Art

The proposed framework pushes beyond existing green networking and edge computing solutions in three ways. First, Ojo and Okafor (2024) achieved 40% diesel reduction through traffic-aware sleep states alone. We integrate Edge AI-driven data filtering with predictive power scheduling achieving 38.7% diesel reduction while simultaneously cutting backhaul volume by 65%. This represents a paradigm shift rather than an incremental improvement. Second, El Ghor et al. (2024) demonstrated 37% deadline miss reduction in energy harvesting CPS, but their focus was real-time task scheduling rather than network resilience. We extend CPS principles to telecom infrastructure, coupling workload management with connectivity preservation. Third, Mao et al. (2024) surveyed green edge AI at a conceptual level. We provide a concrete implementation with empirical validation in a volatile grid environment.

5.2 Deployment Considerations

The framework is designed for low-cost ARM-based edge hardware—Raspberry Pi 4, NVIDIA Jetson Nano—with hybrid power systems (solar PV + battery + diesel). A few practical notes:

Hardware Selection: The 1.2 MB random forest model and 8.4 ms inference latency operate effectively on Raspberry Pi 4-class hardware. For more constrained nodes like ESP32 or Arduino Nano 33 BLE, the model can be further compressed using Shabir et al.'s (2025) pruning-quantization pipeline to under 200 KB with less than 5% accuracy loss.

Solar Sizing: The 5 kWp PV capacity and 10 kWh battery bank provide 8-hour autonomy at full computational load. Sites with higher telemetry density should scale PV and battery capacity linearly.

Backhaul Diversity: While the framework reduces backhaul dependency, keeping a secondary low-bandwidth link—LoRaWAN, satellite—for critical alert transmission during cellular outages adds resilience against dual failure modes.

5.3. Limitations

The simulation has three limitations worth noting. First, the 72-hour window captures multiple outage cycles but doesn't account for seasonal solar irradiance variations or extended multi-day outages during the rainy season. Second, the anomaly detection model is trained on synthetic telemetry patterns; field calibration with real Nigerian telecom base station data would sharpen accuracy. Third, the framework assumes single-node operation; cooperative scheduling across neighboring edge nodes is next on our list. All reported metrics—including the 94.2% accuracy and energy reductions—derive from simulation; no live field data were used.

6. CONCLUSION

This paper presented a decentralized, Edge AI-driven cyber-physical framework built specifically for Nigeria's infrastructural reality—grid instability, expensive diesel co-generation, and limited backhaul. By integrating lightweight TinyML models with an energy-aware cyber-physical control layer, we have turned computing nodes from passive consumers of volatile power into active, context-aware infrastructure assets.

The quantitative results support this conclusion. Simulations parameterized using published Nigerian grid reliability statistics and typical peri-urban telecom equipment specifications demonstrate a 65.1% reduction reduction in backhaul data transmission, a 30.4% drop in edge-node energy consumption, and 100% operational availability during prolonged grid collapses. Moving computational intelligence to the edge is not merely a matter of reducing latency —it's a foundational requirement for building resilient, climate-smart IT infrastructure in developing economies.

Future research will proceed along two directions. First, expand the single-node control model into a cooperative, decentralized mesh-networking framework so adjacent edge nodes across neighboring communities can share computational tasks and battery capacity during localized disasters or extended regional outages. Second, validate the framework on a physical testbed using low-cost ARM-Cortex microcontrollers integrated with localized solar-inverter telemetry systems in a peri-urban Nigerian environment, collecting longitudinal data across the full seasonal cycle.

ABSTRACT

This study investigates the corrosion inhibition potential of selected palm oil constituents using Spatan24 by PM6 Methods in a aqueous medium and a convergence criterion of 1E-5 a.u. with SCFCYCLE of 99000. The constituents considered includes: myristic, linoleic, stearic, oleic, lauric, and palmitic acids on copper exposed to corrosive compound typically found in industrial environments. Quantum chemical parameters, including total electronic energy (E), highest occupied molecular orbital energy (E-HOMO), lowest unoccupied molecular orbital energy (E-LUMO), energy band gap (Egap), and interaction energy gap (IEG), were evaluated to understand the reactivity and inhibition efficiency of these compounds and were compared with that of styrene an active corrosion protection component of paint. Among the analysed compounds, Linoleic acid demonstrates the highest inhibition capability for copper corrosion protection caused by aggressive species like H_2SO_4, HCl, HNO_3, and NaCl. Its superior electronic properties: high HOMO (9.66 eV), low Egap (9.53eV), low IEG (6.41eV) values and molecular structure make it an excellent candidate for corrosion protection applications. These findings suggest that linoleic acid could serve as an efficient, eco-friendly inhibitor in copper corrosion prevention

Keywords: *Corrosion; Inhibitors; HOMO-LUMO; Egap; Corrosion Inhibition*

1. INTRODUCTION

Metal Corrosion is one major problem worldwide especially where corrosive environments are employed in practically every industry, Building, petroleum and gas processing, marine and steel processing industries. It is defined as the destructive and unintentional attack of metals caused by a chemical and/or electrochemical reaction with the environment, and it usually refers to the metal's electrochemical oxidation (Kadhim *et al.*, 2021).

Corrosion of metal can be slowed or prevented using a variety of techniques. Organic molecules, plastics, and polymers are often utilized as protective coatings on metals, as are cathodic and/or anodic protection using inhibitors, material modification, and environmental alteration. A number of limitations, on the other hand, restrict the potential uses of currently available methods (Faraj and Alamiery 2022). Over the years, a lot of corrosion inhibitors have been developed but the commercially viable and widely applied inhibitors are toxic to man and his environment. At present a lot of efforts are been geared towards sustainable ecofriendly (green) alternatives to these toxic chromate industrial inhibitors (Alexander *et al.*, 2024). About 2.5 trillion on a global scale is spent annually on corrosion and corrosion-related problems. This huge economic loss is estimated at 3.4 % of global GDP (Ogunleye et al., 2021; Speight, 2014; Kobzar and Fatyeyeva, 2021; Verma et al., 2019; Feng et al., 2018).

Palm oil is an edible, abundant, and environmentally friendly natural product. It is also one of the most widely used and discovered natural oils in Asian countries such as Malaysia. Palm oil has distinct properties, such as a similar content of both saturated and unsaturated fatty acids (50:50) The unsaturated fatty acids are subjected to a variety of reactions with several compounds to produce a diverse variety of products (Wasmi et al., 2015). Palmitic acid being the primary saturated fatty acid and oleic acid being the primary unsaturated fatty acid. The use of palm oil for purposes other

than food is of particular interest because it has the highest fossil energy balance and the lowest production cost when compared to other commodities. Because both oleic and palmitic acids contain carbonyl groups, palm oil has the potential to act as a corrosion inhibitor (Calderon et al., 2017) Palm oil can be used as an environmentally friendly corrosion inhibitor instead of conventional methods. Most of the palm oil derivatives had corrosion prevention efficiencies of 80–90% (Faraj and Alamiery 2022). The aim of this work is to investigate the active component in the palm oil and their potential for corrosion inhibition of copper metal in different corrosive environment Using computational approach.

2. COMPUTATIONAL METHODOLOGY

Figure 1 showed the workflow of this research, where the molecular structures of the coper cluster, corrosive, and fatty acids from palm oil were first constructed in the spartan modelling environment. The initial molecular structure was then adjusted to reduce its potential energy. The energy minimization step removes unrealistic atomic positions and provides a stable structure that can be used for subsequent calculations. In the molecular interaction step, molecular species were brought together to investigate their interactions. This involve placing the molecule on an expected active site on the coper cluster to study the adsorption and interaction behaviour. The atomic positions, bond lengths, and bond angles were systematically adjusted until the structure reaches a stable minimum-energy configuration in the geometrical interaction step. This provides the optimized geometry of the molecular system. Following geometry optimization, electronic properties are calculated to understand the chemical behaviour of the system. These include HOMO, LUMO energy gap, Interaction energy gap (IEG) and electrostatic potential. Detail of formula used to calculate these properties would be provided on request.

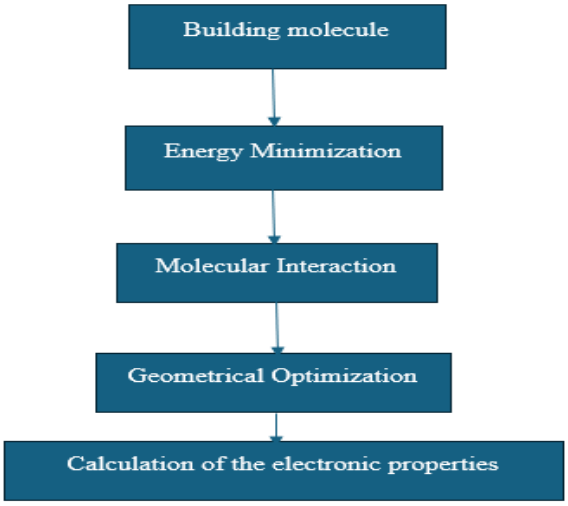

Figure 1: Block flow diagram of the computational study

2.1 Computational Tool and Software

SPARTAN24, a computer Software package for molecular simulation, designed and developed by Wavefunction Inc. USA, was used for the modelling, simulation and all the computational calculations were done on HP ProBook 650 G2, RAM 8G, 2.40GHz and i3-7100U CPU

All geometrical optimizations and energy calculation were conducted using PM6 method in an aqueous medium and a convergence criterion of 1E-5 a.u. with SCFCYCLE of 99000, GEOMETRYCYCLE of 99000 and SCFTOLERANCE of 5.

3. RESULT AND DISCUSSION

The selection of an appropriate metal cluster is fundamental in computational investigations because the electronic characteristics of the cluster strongly influence adsorption behaviour and the predicted corrosion inhibition performance. Previous computational studies have demonstrated that square-shaped copper clusters possess greater thermodynamic stability than pyramid-shaped clusters owing to their lower electronic energy and wider HOMO–LUMO energy gap (Oyegoke et al., 2023). Consequently, the square Cu_4 cluster was adopted in this study as the representative copper surface model and the cluster was as shown in figure 2.

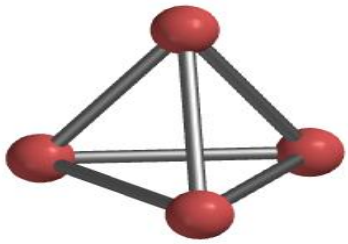

Figure 2: Most stable cluster model for the copper metal

An optimized molecular structure of potential palm oil corrosion inhibition constituents and that of styrene were shown in Figure 3.

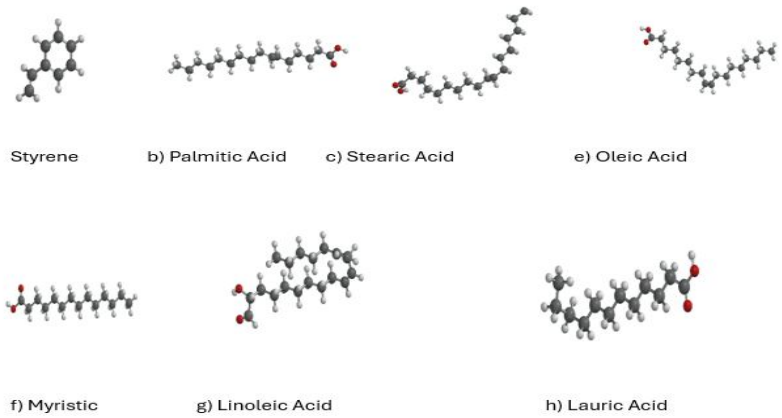

Figure 3: Optimized Molecular Structures of styrene and Palm oil constituent

Table 2 shows the list of the corrosive species for copper and their molecular descriptors Similar properties were presented in Table 3 for the corrosion inhibitors.

Quantum chemical parameters such HOMO, LUMO, HOMO–LUMO energy gap (Egap) and interaction energy gap (IEG) are widely recognized as reliable indicators for predicting molecular reactivity and adsorption characteristics during corrosion processes (Gece, 2008; Kaya et al., 2016).

The Cu_4 cluster exhibited a HOMO–LUMO energy gap of **9.28 eV**, confirming its electronic stability throughout the adsorption calculations. Among the aggressive media investigated, sulfuric acid and nitric acid exhibited the lowest interaction energy gaps (IEG = 5.52 and 5.29 eV, respectively), indicating stronger electronic interactions with the copper surface than water, hydrochloric acid and sodium chloride. These observations agree with established corrosion theory, where mineral acids readily destabilize the passive oxide film on copper through proton-assisted oxidation reactions, thereby accelerating metal dissolution (Bentiss et al., 2005).

The relatively large HOMO–LUMO gaps observed for water and hydrochloric acid indicate comparatively lower intrinsic electronic reactivity than sulfuric and nitric acid.

Table 2: Molecular properties of copper and the corrosive species

COMPOUND	Formula	Egap	IEG
Copper Cluster	Cu_4	9.28	9.28
Water	H_2O	15.98	10.61
Sulfuric acid	H_2O_4S	11.57	5.52
Sodium chloride	NaCl	9.77	6.84
Hydrogen chloride	HCl	13.68	8.63
Nitric acid	HNO_3	11.30	5.29

The electronic descriptors of the selected palm oil constituents are presented in Table 3. Among all the investigated compounds, linoleic acid exhibited the smallest HOMO–LUMO energy gap (9.53 eV), indicating the highest molecular reactivity and the greatest tendency to participate in charge-transfer interactions with the copper surface. A lower energy gap generally facilitates electron excitation, enhances molecular polarizability and promotes stronger adsorption on metallic substrates (Gece, 2008). The slightly lower Egap of linoleic acid (9.53 eV), compared with H_2O_4S (11.57eV), NaCl (9.77eV), HCl (13.68eV) and HNO_3 (11.30eV), indicates that its frontier molecular orbitals are separated by a smaller energy difference, suggesting that electron excitation or electron transfer may occur relatively more readily

Linoleic acid, also known as cis, cis-9,12-octadecadienoic acid, is a polyunsaturated fatty acid with the molecular formula $C_{18}H_{32}O_2$.The structure includes a long carbon chain of 18 carbon atoms, with two cis double bonds located at the 9th and 12th positions from the carboxylic acid end. Figure 4 shows the molecular structure of Linoleic acid.

The superior inhibition behaviour of linoleic acid can also be attributed to its molecular structure. Unlike myristic, palmitic and stearic acids, linoleic acid contains two carbon–carbon double bonds together with a polar carboxylic acid group.

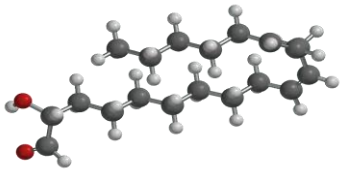

Figure 4: Molecular structure of Linoleic acid

Oleic acid, which contains only one double bond, exhibited a slightly larger energy gap (**10.15 eV**) than linoleic acid, suggesting lower electronic reactivity and comparatively weaker adsorption. Likewise, palmitic, stearic, myristic and lauric acids all possessed energy gaps exceeding **11 eV**, reflecting lower molecular softness and reduced adsorption tendencies. These saturated fatty acids therefore exhibit weaker inhibition potential because the absence of π-electron systems limits effective interaction with the copper surface. The interaction energy parameters further support these observations. Linoleic acid recorded one of the lowest interaction energy values among the investigated fatty acids, indicating a thermodynamically favourable interaction with the Cu_4 cluster. Lower interaction energies generally correspond to stronger adsorption and higher inhibition efficiency because less energy is required for inhibitor molecules to occupy active corrosion sites.

Table 3: Molecular and interacting properties of copper, palm oil constituents and the paint constituent

COMPOUND	Formula	Egap	IEG
copper Cluster	Cu_4	9.28	9.28
Myristic Acid	$C_{14}H_{28}O_2$	11.47	7.09
Linoleic	$C_{18}H_{32}O_2$	9.53	6.41
Stearic acid	$C_{18}H_{36}O_2$	11.61	7.21
Oleic	$C_{18}H_{34}O_2$	10.15	7.09
Lauric acid	$C_{12}H_{24}O_2$	11.42	7.15
Palmitic	$C_{16}H_{32}O_2$	11.41	7.10
STYRENE	C_8H_8	9.30	6.61

Styrene was included as a representative constituent commonly encountered in commercial coating formulations. Although styrene exhibited a relatively small HOMO–LUMO energy gap (9.30 eV), comparable to that of linoleic acid, its inhibition performance is expected to be inferior because its adsorption is governed primarily by π-electron interactions where it has no oxygen atom that is presence in the other fatty acids which is strongly coordinating functional groups (Ashassi-Sorkhabi et al., 2006). In contrast, the carboxyl functional group present in all fatty acids provides oxygen atoms capable of forming stronger coordinate interactions with copper. Consequently, adsorption occurs through both electrostatic attraction and chemisorption, producing a more compact and durable protective film. This observation demonstrates that molecular functionality is equally as important as electronic reactivity when designing effective green corrosion inhibitors.

Overall, the computational results indicate that the corrosion inhibition efficiency of the investigated palm oil constituents follows the approximate order:

Linoleic acid has the highest inhibition efficiency with Egap/IEG of 9.53/6.41, Oleic acid with 10.15/7.09, followed by Palmitic acid, Lauric acid and Myristic acid with values of 11.41/7.10, 11.42/7.15 and 11.47/7.07 respectively, and lastly Stearic acid. The observed differences of the saturated acids are marginal and is probably because of the computational uncertainty. This trend agrees with previous computational investigations reporting that unsaturated fatty acids generally outperform saturated fatty acids because their greater electron density and enhanced molecular softness promote stronger adsorption on metallic surfaces (Faraj et al., 2022; Obot et al., 2019).

4. CONCLUSION

Among the investigated compounds, linoleic acid exhibited slightly lower HOMO–LUMO energy gap (9.53 eV), compared with H_2O_4S (11.57eV), NaCl (9.77eV), HCl (13.68eV) and HNO_3 (11.30eV), that suggests that linoleic acid possesses comparatively greater electronic reactivity and potential for electron interaction with the copper surface. This behaviour may favour adsorption of linoleic acid on copper and facilitate the formation of a protective organic film, thereby reducing the accessibility of corrosive species to the metal surface. Consequently, linoleic acid may have potential as a green organic corrosion inhibitor for copper. Future studies should focus on experimental approach to prove the findings of this research. Other electronic descriptors should also be calculated such as adsorption, electron density using density functional theory which give more precise computational results.

ACKNOWLEDGEMENTS

The author sincerely appreciates the invaluable support and contributions received from various organizations including: Pencil Team for computational workshop, Matrix Fertilizers for providing valuable training support and resources and Wavefunction for the provision of computational resources and access to Spartan'24 software

ABSTRACT

This paper presents the findings of a research on an artificial intelligence-based hybrid Support Vector Machine–Bat Optimization Algorithm (SVM-BOA) model developed for spectrum sensing in the Ultra High Frequency (UHF) television band (470 – 694 MHz). The main objective is to enhance detection accuracy, probability of detection, probability of false alarm, and computational efficiency for efficient spectrum utilization. Experimental spectrum measurements were conducted across Kano, Kaduna, and the Federal Capital Territory (FCT), Abuja, Nigeria, to assess the level of spectrum occupancy and identify available Television White Space (TVWS) channels. Relevant signal features, including received signal power level, noise power level, and frequency, were extracted from the field data collected and used to train and test the proposed model. The model was developed and implemented in MATLAB computing environment. The new model was validated using test data for classification of channel status as either free or occupied. The developed model achieved a detection accuracy of 97.67% at a threshold of −99.5 dB, outperforming baseline SVM (78.57%) and other benchmark optimization-based SVM models, including Grid Search SVM (92.86%), Random Search SVM (89.29%), Genetic Algorithm SVM (92.86%), and Particle Swarm Optimization SVM (92.78%). It also attained a probability of detection (Pd) of 0.9923 (99.23%) and a probability of false alarm (Pfa) of 0.1053 (10.53%), which satisfies the sensing performance requirements of the Institute of Electrical and Electronics (IEEE 802.22) standards under low-signal conditions. These findings suggest that the hybrid SVM-BOA approach will offer superior classification accuracy and computational efficiency relative to conventional techniques and comparable hybrid models, signifying a strong potential for the improvement of spectrum utilization in next-generation cognitive radio networks.

Keywords: *Television White Spaces (TVWS); Spectrum Measurement; Spectrum Sensing; Support Vector Machine (SVM); Bat Algorithm; Cognitive Radio*

1. INTRODUCTION

The exponential growth of wireless applications and data-centric services has placed unprecedented demand on the radio frequency spectrum, a finite and inherently scarce natural resource. The traditional command-and-control model of spectrum allocation, while providing interference-free communication, has led to a paradox: while the spectrum is perceived as congested, significant portions remain vastly underutilized. This is particularly acute in the Ultra High Frequency (UHF) bands (470–694 MHz), originally allocated for Television Broadcasting. The underutilization of these prime frequencies, characterized by superior propagation characteristics, represents a critical inefficiency within the existing spectrum management framework. This condition is particularly pronounced within the Nigerian telecommunication landscape. Investigation on spectrum occupancy has indicated that a significant portion of the UHF spectrum particularly within the Sub-urban and Rural Areas remains underutilized as Television White Space (TVWS), Ubom, & Ukommi, (2023). A study on spectrum occupancy measurement and analysis in Ogun State Nigeria by Lasisi etal., (2022) revealed that approximately 60% of the UHF spectrum in urban areas and nearly 100% in rural areas lies underutilized as White Space. This vast availability of unused spectrum underscores the urgent need for a paradigm shift from static allocation to Dynamic Spectrum Access (DSA), enabled by robust Dynamic Spectrum Sensing (DSS) Techniques. The fundamental objective of DSS is to reliably detect the presence or absence of Primary Users (PUs), potentially facilitating opportunistic access for Secondary Users (SUs) without inducing harmful interference.

However, the development of an effective DSS framework for TVWS in such real-world environments is confronted by several critical and interconnected challenges: (i) Vulnerability to Noise Uncertainty and Low SNR, (ii) Inadequacy of Simple Error Detection Models. In spectrum sensing, detection performance is characterized by two primary error types: Missed Detection and False Alarm. These are modeled using the following probabilities: Probability of Detection (P_d): The probability that the system correctly identifies the presence of a PU signal when the spectrum is occupied (H_1). Probability of False Alarm (P_{fa}): The probability that the system incorrectly identifies a PU signal when the spectrum is actually idle (H_0) (Yang, X.-S., He, X. 2023). These models must account for the trade-off between the probability of false alarm (P_{fa}), which result in spectrum underutilization by incorrectly identifying a vacant channel as occupied and the probability of missed detection (P_{md}), which could result to harmful interference by failing to detect an active PU. The primary objective is to minimize both errors, however, traditional methods often fail to maintain this balance under dynamic channel conditions, resulting in either inefficient use of the TVWS or unacceptable levels of interference to incumbent television broadcasters.

To overcome the limitations of traditional methods, advanced Machine Learning (ML) and Artificial Intelligence (AI) models, such as Support Vector Machines (SVM), has been proposed. While SVMs can offer superior detection accuracy, especially in non-Gaussian noise, their performance is highly sensitive to the choice of hyper-parameters and the selection of relevant features from the raw signal data. Consequently, the optimization of these parameters is often computationally expensive. This dynamic suggests a significant computational cost trade-off: highly accurate models may prove unsuitable for real-time sensing applications wherein speed and power efficiency are paramount (Wainer & Fonseca2021). Therefore, there is a clear need for an intelligent optimization mechanism that can automatically tune these models for high accuracy without incurring prohibitive computational overhead. (iv) Lack of Context-Specific Data and Frameworks in Nigeria: The performance of any data-driven model is intrinsically linked to the data on which it is trained. A major impediment to the development of a robust DSS solutions for Nigeria is the limitation of available datasets. Most existing models are trained on synthetically generated signals or measurements from temperate regions, which do not accurately reflect the unique signal propagation characteristics, noise floor dynamics, and interference patterns prevalent in a tropical country like Nigeria. Recent studies suggest that the core problem is the absence of an efficient framework for DSS in TVWS, which is further compounded by the lack of models validated with real-world spectrum measurement data from the Nigerian environment, Lasisi etal., (2022) This data gap renders many existing solutions potentially ineffective when deployed locally.

Recent literatures revealed that, Support Vector Machine (SVM) models facilitate the construction of an optimal hyperplane, that effectively separate distinct classes within the feature space; the decision function is generally expressed mathematically as presented in equation (1), (Yang, X.-S., He, X. 2023)

$$f\ (x) = sgn\left(\sum_{i=1}^{n} \alpha_i y_i K(x,\ x_i) + b\right) \quad (1)$$

Where K (x, x_i) is the kernel function that facilitate quantification of the similarity between input data points.

The Bat Algorithm (BA) is used to optimize the SVM parameters (specifically the penalty factor C and the kernel parameter γ), which directly shifts the decision boundary to balance the trade-off between the probability of detection (P_d) and the probability of false alarm (P_{fa}) (Yang, X.-S., He, X. 2023). An optimized hybrid model seeks to maximize P_d (to protect the PU) while maintaining P_{fa} below the regulatory threshold typically established at 0.1 according to IEEE 802.22 standards. (iii) Computational Cost vs. Real-Time Performance Trade-offs:

The fundamental challenge therefore, is the lack of an efficient, accurate, and context-aware framework for dynamic spectrum sensing in TVWS networks. Existing methods are hampered by the combined challenges of noise uncertainty, inadequate error management, high computational costs, and a critical dependence on non-representative training data and limited scholarly study regarding hybrid optimization algorithms tailored towards spectrum sensing (Zeng, Y. Liang, Y. Hoang, A.T. & Zhang,

R., 2010). To address these multifaceted challenges, the present study proposes the development of a novel hybrid model that integrates a Support Vector Machine (SVM) with a Bat Optimization Algorithm. This hybridization aims to intelligently optimize the SVM's parameters, thereby enhancing detection accuracy in low SNR conditions, managing detection errors effectively, and achieving a favourable trade-off in computational cost. The proposed model will be developed and validated using real-world spectrum measurement data from Nigeria, ensuring its practical applicability and contribution to the efficient utilization of the nation's scarce spectrum resources.

2. METHODOLOGY: MATERIAL AND METHOD

2.1 Conceptual Framework: The Proposed Hybrid Model

The conceptual framework (Figure 1.) shows the interaction of the key components. The model is structured as a closed-loop optimization and classification system.

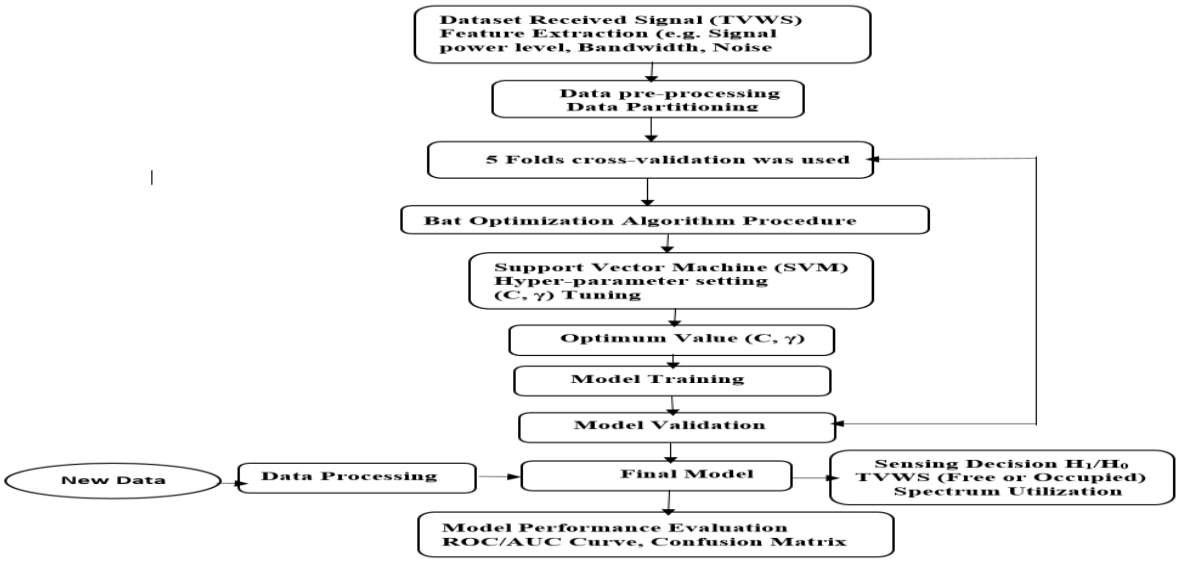

Figure 1: Block diagram of Conceptual Framework for SVM - BOA Hybrid Spectrum Sensing

The methodology comprises a five-stage process: data acquisition, feature extraction, the design and development of a hybrid Support Vector Machine-Bat Optimization Algorithm (SVM-BOA) model, training and testing, and performance evaluation (Bishnu & Bhatia, 2019; Yang & He, 2023).

I. **Data collection:** Real world TVWS data was collected via measurement campaign in three locations, namely: Kano, Kaduna and Abuja.

II. **Feature Extraction:** The extraction of salient features, comprising frequency, signal power level, noise power level, bandwidth, and occupancy status, was performed subsequent to the acquisition of field data.

III. **TOTAL SAMPLE POPULATION AND DATA SPLIT: TRAINING/VALIDATION:**

IV. A total of Eighty-four (84) samples were collected. The model was trained and validated using 5-fold cross-validation, where 4 folds (80%) were used for training and 1 fold (20%) for validation in each iteration.

V. **Signal Model Representation:** The received signal y (n) was modelled under two hypotheses (Musumeci etal., 2018):

1. **The Null Hypothesis:** H_0: y (n) = w (n),
2. **The Alternative Hypothesis:** H_1: y (n) = s (n) + w (n)

Where: s (n) is the TV signal and w (n) is AWGN or impulsive noise.

VI. **The Hybrid SVM-BOA Framework**

The objective of SVM is to find the optimal hyper-plane that maximizes the margin $\frac{2}{\|\mathbf{w}\|}$.

While the Bat Optimization Loop is to (Rebentrost etal., 2014):

a. **Initialize** bat population (positions = SVM [C, γ] pairs).
b. **Evaluate Fitness:** Fitness = Maximize P_d for a fixed P_{fa}.
c. **Update Velocity and Frequency:** Based on echolocation behaviour.
d. **Pulse Emission & Loudness:** Adjust to switch from global search to local refinement.
e. **Termination:** Stop when the optimal values of (C, γ) are attained.

VII. **Performance Metrics:** The following metrics were used to evaluate the performance of the model:

1. **ROC/AUC Curves:** Probability of Detection (P_d) vs. False Alarm (P_{fa}).
2. **Sensing Latency:** Time taken to reach a decision.
3. **Comparison:** The methodology was compared against Support Vector Machine-Grid Search (SVM-GS), Support Vector Machine-Random Search (SVM-RS), Support Vector Machine-Genetic Algorithm (SVM-GA), Support Vector Machine-Particle Swarm Optimization (SVM-PSO), and the baseline Support Vector Machine (SVM); these comparative analysis may elucidate performance distinctions.

VIII. **Simulation Environment:** MATLAB computational environment was used as simulation tools.

IX. **EXPECTED RESULTS**

a. Identification of the available TVWS in the UHF TV band (470–694 MHz) across Kano, Kaduna, and Abuja (FCT) for the use of cognitive radio.
b. Design and implement a hybrid spectrum sensing algorithm integrating Support Vector Machine (SVM) with Bat Optimization Algorithm (BOA) using signal power levels measurement from the field.

2.2 Materials/Instrumentation

2.2.1 Spectrum Measurement Campaign/Data collection

The following instruments were used for the measurement campaign and data collection:

a. **Spectrum Analyzer:** Agilent (Now Keysight Technologies) Handheld Spectrum Analyzer Model No. N9344C, with a frequency range of 9 KHz to 20 GHz. This device's portability and wide frequency range made it suitable for field measurements.
b. **Antenna**: A wide band high gain (12dB) log-periodic antenna with a frequency range of 1 MHz to 26.5 GHz. This antenna was chosen for its wideband characteristics, which allowed it to cover the entire UHF TV band without requiring multiple antennas.
c. **Cables and Accessories**: Low-loss coaxial cables and a tripod for stable antenna placement were used.
d. **Amplitude Accuracy:** ± 1.3dB
e. **Frequency Range:** 9 KHz to 20 GHz (fully covering the band of interest).
f. **Frequency Accuracy:** ± (0.22 * Span + Span/ (Sweep point – 1)
g. **Frequency Span:** 100Hz – 20GHz
h. **Frequency Resolution:** 1Hz
i. **Calibration Status**: The Spectrum Analyzer was calibrated to ISO/IEC 17025:2017 standards.
j. **Key Settings:** Resolution Bandwidth (RBW) = 100 kHz, Video Bandwidth (VBW) = 30 kHz, Sweep Time = 20 Ms.
k. **Software**: Data was logged using the instrument's internal logging and later analyzed using PC-based software (Agilent BTA/DSA Software).
l. **GPS Map**: Camera Lite Application, Version 1.5.8 was adopted.

2.2.2 Measurement Locations and Site Selection

Fixed location measurements was conducted in three cities. The measurements were taken at different time of the day to capture the worst-case scenario of spectrum usage. Measurement locations were strategically chosen to represent a mix of urban, suburban, and rural environments within Kano, Kaduna, and FCT, Abuja as presented below: While, the map of figure 2 below depicts the locations of measurements.

1. Kano: Central City Area, (Lat: 11.98200, Long: 8.51470) representing Urban area, Kura L.G.A (Lat: 11.76050, Long: 8.4226^0), representing Sub-urban area and Gwarmai (Lat: 11.4720^0, Long: 8.2061^0), representing Rural area.

2. Kaduna: Central City Area (Lat: 10.52410, Long: 7.44210) representing Urban area, Zaria L.G.A (Lat: 11.1014^0, Long: 7.69300), representing Sub-urban area and Ikara (Lat: 11.41230, Long: 8.12380), representing Rural area.

3. Abuja (FCT): Central Business District (Lat: 9.11270, Long: 7.47690), representing Urban area, Bwari L.G.A (Lat: 9.27600, Long: 7.38540) representing Sub-urban area and Jere (Lat: 9.56360, Long: 7.42910)**,** representing Rural area.

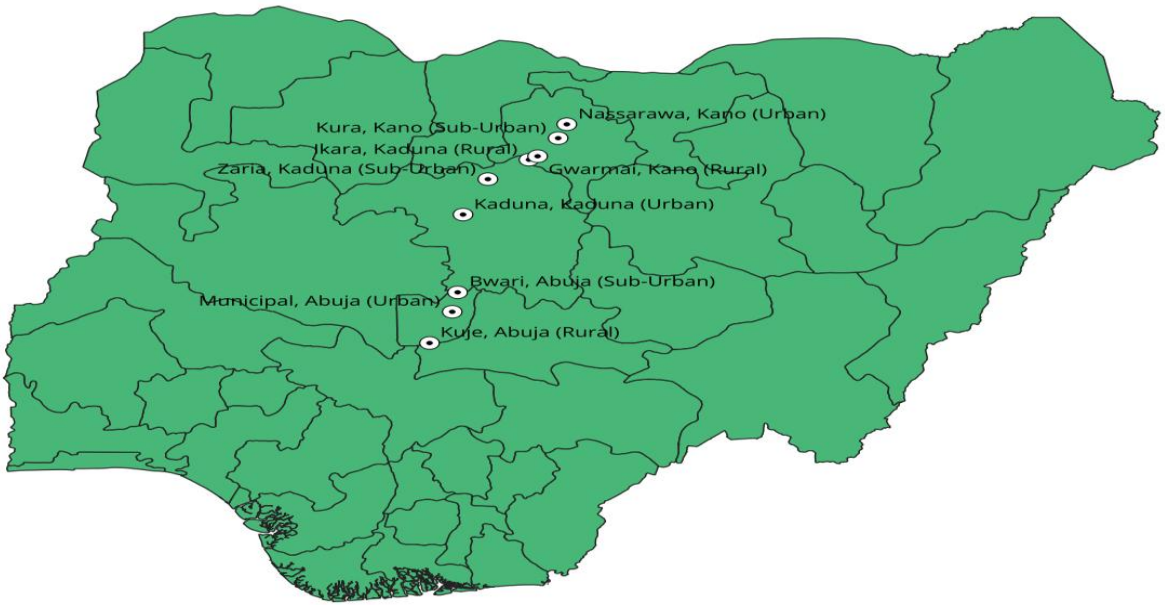

Figure 2: Map of Nigeria showing measurement locations in Kano, Kaduna and Abuja

2.2.3 Measurement Procedure

The measurement campaign followed a systematic procedure to ensure data accuracy and consistency. The spectrum analyser was connected to the log-periodic antenna using coaxial cables, and was mounted at a height of approximately 3.0 meters to minimize ground reflections and interference. Resolution Bandwidth (RBW) was set at 30 kHz to resolve individual TV channels, while the Video Bandwidth (VBW) was set at 300 kHz to smooth the display trace. Attenuation loss was set at 20dB to reduce the amplitude of the incoming signal so as to protect the instrument sensitivity front-end components like (mixers) from damage and to prevent signal distortion. The Detection Mode was set at Max Hold to capture the peak signal levels over a period. Finally, the spectrum analyser was configured to sweep the UHF television band from (470 – 694) MHz as shown in figure 3 and figure 4 below. Measurements were taken at each location for a duration of 60 minutes to capture potential intermittent transmissions. The measurements were repeated for three days and average values of the signal was calculated and recorded. The resulting spectrum traces, showing signal strength (in dBm) versus frequency, were saved for subsequent analysis.

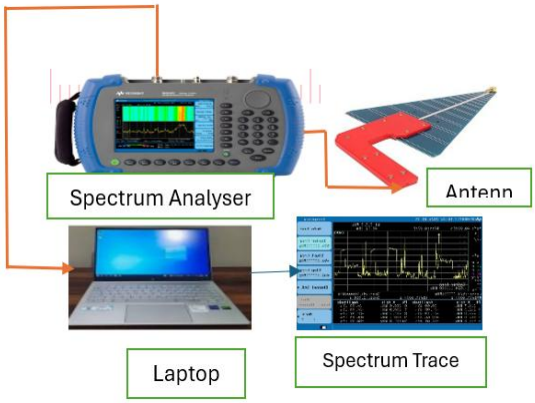

Figure 3: Spectrum Analyser connection diagram

Figure 4: Showing the Spectrum Analyser measurement set-up

2.2.4 Data Collection and cleaning

This aspect involves collection of real-world spectrum occupancy measurements data directly from primary source using the Antenna and the Spectrum Analyser as the instrument for data capture. The data was collected from the field in Kano, Kaduna and Abuja within the UHF TV band (470-694 MHz). The parameters of the data collected includes Received Signal Power Level (RSSI), frequency (Start, Centre, and End), Noise floor power level, Bandwidth, and Occupancy time. This was followed by data cleaning and preparation to ensure data quality for machine learning applications. The empirical data collected will be used for SVM – BOA model design and development. The data was categorized and class label assigned. The occupied channels were labelled as (occupied = +1) and the free channels were labelled as (free = - 1) Table 1 below present the real-world field data collected with channel and class label.

Table 1: Data collected/Categorization of channel and Class

Channel No.	**Start Freq (MHz)**	**Centre Freq (MHz)**	**End Freq (MHz)**	**Average Signal power Level (dB**	**Channel Labelling**	**Class Label**

2.2.5 Theoretical Framework of Cognitive Radio and TVWS

The framework of Cognitive Radio (CR), as theorized by (Haykin, S2005), revolves around the "cognitive cycle," which includes spectrum sensing, spectrum management, spectrum mobility, and spectrum sharing. Within the context of Television White Space (TVWS), spectrum sensing is subjected to strict regulatory and physical constraints. The UHF TVWS bands typically spanned (470 – 694) MHz. This range of frequency exhibit superior propagation characteristics, including low free-space path loss and high penetration capabilities through obstacles (Kaur etal., 2025). Thus, the primary users (PUs) in this band mainly Terrestrial Digital Video Broadcasting (T - DVB) or Advanced Television Systems Committee (ATSC) transmitters, together with low power wireless microphones, operate over large geographical areas.

The main mathematical objective of spectrum sensing is to choose between two competing hypotheses regarding a specific frequency band over a continuous time interval (Martin, R. Davies, A. & Collins, T., 2016)

$(t) = (t)$ □ H_0 (spectrum free) (2)

$(t) = h(t)s(t) + n(t)$ □ H_1 (spectrum Occupied) (3)

Where:

- y(t) is the complex signal received by the Secondary User (SU).
- n(t) is Additive White Gaussian Noise (AWGN) modeled with zero mean and variance σ_n^2
- s(t) represents the transmitted PU signal with variance σ_s^2
- h(t) is the time-varying channel gain encompassing Rayleigh/Nakagami fading and shadow effects.
- H_0 is the hypothesis that the PU is not transmitting, therefore $s(t) = 0$, while
- H_1 is the hypothesis that the PU is using the channel for transmission.

The efficiency of any spectrum sensing framework is fundamentally governed by two critical probabilistic metrics: the Probability of Detection (P_d) and the Probability of False Alarm (P_{fa}), defined as:

$P_{(Pd)} = P\ (decision\ H_1/H_1)$ (4)

$P_{(fa)} = P\ (decision\ H_1/H_0)$ (5)

In cognitive radio networks, maximizing $P_{(d)}$ is critical to prevent harmful interference to licensed broadcasting primary users (PUs), while minimizing $P_{(fa)}$ ensures that secondary Users (SUs) can maximize their opportunistic spectrum utilization by Secondary Users (SUs) (Martin. J, Dooley, L. & Wong, K. 2013)

2.2.6 Mathematical Modelling of the Hybrid SVM-BOA Objective Function

The Support Vector Machine (SVM) is a supervised machine learning algorithm used for classification and regression tasks (Thilina etal., 2013). It tries to find the best boundary known as hyper-plane that separates different classes in the data. It is useful for binary classification like detection of primary user in spectrum sensing (Status: Free or occupied), (Thilina etal., 2013). The main goal of SVM is to maximize the margin between the two classes. The larger the margin the better the model performs. For binary classification, SVM finds the optimal hyperplane that maximizes the margin between classes compared with other classification methods, SVM shows greater efficiency and accuracy in dealing with the large quantity of sample data because there is no distinct effect of sample size on SVM's performance. Furthermore, in contrast to alternative classification methodologies, the SVM framework potentially demonstrates superior efficiency and accuracy when managing high-dimensional datasets.

The Bat Optimization Algorithm (BOA), idea originated from microbats' echolocation capability and social behaviour. It was developed to address global optimization problems. The echolocation process of microbats is characterized into three namely (: (i) Using their echolocation capability, bats can discriminate prey and avoid some barriers. (ii) Bats fly randomly with velocity V_i at position X_i with a fixed frequency f_{min} and vary the wavelength and loudness of echolocation pulse to seek food. The wavelength and pulse emission rate r □ [0, 1] can automatically change through the distance between bats and their targets. (iii) The loudness of the pulse is adjusted from a maximum (positive) value A_0 to a minimum constant value A_{min}.

The mathematical relationship between the Support Vector Machine (SVM) and the Bat Optimization Algorithm (BOA) is formulated as presented below (Fan etal. 2019).

Let the training dataset from the real world TVWS sensing samples be represented as:

$$D = \{(x_i,\ y_i)\}_{i=1}^{N} \tag{6}$$

Where:

$x_i \in \mathbb{R}^d$ represents the extracted feature vector (such as signal power level, noise power level and frequency)

$y_i \in \{-1, +1\}$ denotes the actual spectrum state (H_0 or H_1)

Then, the soft-margin SVM optimization problem is formulated as:

$$\min_{wb\xi} \frac{1}{2}\|w\|^2 + c\sum_{i=1}^{N}\xi_i \tag{7}$$

Subject to $y_i(w^T\phi(x_i) + b) \geq 1 - \xi_i$ and $\xi_i \geq 0$ for i = 1, 2 … m (8)

Where:

- w is the weight vector orthogonal to the hyper-plane.
- b is the bias term.
- ξ_i represents slack variables allowing for classification errors in noisy TVWS environments.
- c is the regularization parameter balancing the margin maximization and empirical error minimization.
- ϕ_i is the mapping function projecting the features into a higher-dimensional space via a kernel function $K(x_i, x_j) = \exp(-\gamma \left\|x_i - x_j\right\|^2$, where γ is the kernel width. (Fan etal. 2019).

The operational challenge in TVWS is that a static configuration of (C, γ) fails under dynamic fading. Fan etal., 2019. The Bat Algorithm optimizes this multidimensional parameter space by treating each Bat's position vector x_i^t at iteration t as a candidate pair:

$x_i^t = [C_i^t, \gamma_i^t]$.

The bats navigate the search space using the following velocity V_i^t and position updates, (Yang, X.S., 2010).

$$f_i = f_{min} + (f_{max} - f_{min})\beta \quad (9)$$

$$v_i^t = v_i^{t-1} + (x_i^{t-1} - x_*)f_i \quad (10)$$

$$x_i^t = x_i^{t-1} + v_i^t \quad (11)$$

Where:

- f_i the wave frequency assigned to bat i.
- $\beta \in [0, 1]$ is a random vector drawn from a uniform distribution.
- x_* the current global best position (the optimal hyper-parameter pair discovered across the swarm).

The loudness A_i and pulse emission rate r_i are updated in the process of iterations. As the distance between bats and their prey decreases, A_i decreases, whereas r_i increases. These are calculated as in equations (12) and (13) (Yang, X.S., 2010)

$$A_i^{t+1} = \alpha A_i^t \quad (12)$$

$$r_i^{t+1} = r_i^0[1 - e^{-\gamma t}] \quad (13)$$

Where α and γ are both fixed values. For any $0 < \alpha < 1$ and $\gamma > 0$, $A_i^t \to 0$ and $r_i^t \to r_i^0$ as $t \to \infty$. In general, the initial loudness A_i^o belongs to [1, 2] and the initial pulse emission rate r_i^0 belongs to [0, 1]. The Bat algorithms Pseudo code is as presented in 2.1.3 below, (Yang, X.S., 2010).

2.2.7 The Bat Algorithm formulation (Bat Pseudo codes)

1. **Initialization**:
   Initialize bat population $x_i (i = 1,2, \ldots, n)$ and velocities v_i
   Define pulse frequency $f_i \in [f_{min}, f_{max}]$
   Initialize pulse rates r_i and loudness A_i
   while (t ≤ Maximum number of iterations)
   Calculate and update frequency, velocity and position

2. **FREQUENCY UPDATE**
   $$f_i = f_{min} + (f_{max} - f_{min})\beta$$
   where $\beta \in [0,1]$ is a random vector,

3. **VELOCITY UPDATE**:
   $$v_i^{t+1} = v_i^t + (x_i^t - x_*)f_i$$
   Where x_* is the current global best solution

4. **POSITION UPDATE**:
   $$x_i^{t+1} = x_i^t + v_i^{t+1}$$
   if (rand > ri) Choose a solution from the best solutions Obtain a new solution
   end if
   if (rand < Ai & f (Xi) < f (X□))
   Adopt the new solutions

5. **LOCAL SEARCH**:
   $$x_{new} = x_* + \epsilon A^t$$
   where $\epsilon \in [-1,1]$ is a random number

6. LOUDNESS AND PULSE RATE UPDATE:

$$A_i^{t+1} = \alpha A_i^t$$
$$r_i^{t+1} = r_i^0[1 - \exp(-\gamma t)]$$

where α and $\gamma$are constants

end if

Rank bats and search the current best X □ t = t + 1

end while

Post-processing of results and subsequent visualization are performed.

The main goal of this study is to find the Fitness Function (FF) that links the micro-bat movement directly to the cognitive radio network's operational needs, balancing detection accuracy against false alarms. The Fitness Function (FF) is defined in equation (14).

$$FF(\mathrm{C}, \gamma) = \alpha \,.\, \mathrm{P_d}(\mathrm{C}, \gamma) + (1 - \alpha) \,.\, \left(1 - \mathrm{P_{fa}}(\mathrm{C}, \gamma)\right) \quad \text{(Wainer \& Fonseca, 2021)} \qquad (14)$$

Where α ϵ [0, 1] is a weighting coefficient adjusted based on regulatory priorities (e.g., high α values is used to strictly protect primary TV users from secondary user's interference).

In SVM, particularly with RBF kernel, gamma **(γ)** controls the influence radius of a single training point as C parameter acts as the main regularization factor. Gamma (γ) is defined as $\gamma = \frac{1}{2\sigma^2}$ and span a range from 10^{-3} to 10^{3}. Lower values of γ tend to facilitate broader influence radii, producing a more generalized decision boundary; conversely, higher values of γ may induce localization, which can increase sensitivity to individual data points and may result in the attenuation of the grouping effect. (Wainer & Fonseca, 2021).

2.2.8 Model Training

The real-world data samples obtained from the field was trained using 5 fold cross validation. The 5-fold cross-validation is a method used to test how well a machine learning model learns and performs on new data. The method divide the entire 84 dataset into 5 equal parts, called "folds." and run the training process 5 separate times. Each time, it uses 4 folds (80% of the data) to train the model, and use the remaining 1 fold (20% of the data) to test the model. The test folds are rotated to make sure that a different fold is used as the test set in each of the 5 rounds. That means the data split into training and testing data was done within the process loop. The method combine the 5 test scores to get one final average score in terms of accuracy. This average result shows the true performance of the model (Yang, X.-S. (2010).

The training algorithm incorporates the Support Vector Machine (SVM-BOA) model; this hybrid architecture employs the BOA optimization algorithm (a meta-heuristic inspired by echolocation) to optimize the C and γ parameters. The model is trained and the optimal hyper-parameters are tuned to make prediction, (Yang, X.-S. (2010).

2.2.9 Model Parameters

The parameters used for simulation of the SVM-BOA model are presented in table 2 be

Table 2: Parameters for the SVM-BOA Implementation

BOA Optimization Parameters			
Parameter	**Symbol**	**Typical range**	**Role**
Number of bats	N	10 – 100	Population size
Frequency range	$[f_{min}, f_{max}]$	[0, 2]	Step scaling
Loudness	Ai	initial 1, decays to 0	Exploration vs exploitation
Pulse rate	r_i	initial 0.5, increases to 1	Probability of local search
Loudness decay	α	0.9	Contraction of search
Pulse rate increase factor	β (or γ)	0.9	Convergence speed
UHF frequency	F	(470 – 694) MHz	Frequency Range
Features 1 to be used	Signal Power Level	(-98.73, -65.99) dBm	Signal Power for Active Channel
Features 2 to be used:	Noise Power Level	(-122.98, -99.14) dBm	Signal Power for Free Channel

3. RESULTS AND DISCUSSION

3.1 Result

The primary objective of this study is to develop a hybrid Support Vector Machine and Bat Optimization Algorithm (SVM-BOA) framework; accordingly, a hybrid SVM-BOA spectrum sensing algorithm was implemented. The research utilized a MATLAB script for the simulation of the model. This section presents the simulation outcomes of the hybrid SVM-BOA model for spectrum occupancy detection within the Television White Space (TVWS). The results encompass an analysis and discussion of the spectrum measurement campaign, Bat optimization performance metrics, and the overall performance metrics of the SVM-BOA model, including those pertaining to support vector classification.

The results obtained was evaluated by comparison with other methodologies that were integrated into the MATLAB environment using same empirical data. These include Grid Search SVM (GS-SVM), which employs an exhaustive hyper-parameter search; Random Search SVM (RS-SVM), which uses random hyper-parameter sampling; Genetic Algorithm SVM (GA-SVM), which utilizes evolutionary optimization; Particle Swarm Optimization SVM (PSO-SVM), which applies swarm intelligence optimization; and the standard Support Vector Machine (SVM) without hybridization, taking into consideration methodology, prediction accuracy, key features employed, and performance metrics. Finally, a discussion of the findings is presented, followed by conclusions and recommendations.

3.1.1 Result, Spectrum Measurement Campaign

The measurement result indicates that, Abuja, as a major urban centre, exhibits a higher density of occupied channels with 7 active channels identified (Channels 21, 22, 23, 31, 32, 35, and 41) accounting for spectrum utilization of 56MHz (25%), while 168MHz (75%) remained unoccupied particularly the upper part of the UHF band. Measurements from sub-urban area Bwari L.G.A exhibit same trend (7 active channels identified) to that observed in Abuja city; however, signal amplitudes are attenuated due to distance of (41Km) and prevailing environmental factors. In the rural area Kuje (38Km) away from Abuja, measurement showed no trace of television signal. Consequently, the absence of active signal detection suggest that spectrum utilization is negligible; thus, the entire 224MHz bandwidth is available for opportunistic access.

Conversely, measurements in the Kaduna urban area showed the presence of 6 active channels (Channels 21, 22, 23, 25, 27, and 48), accounting for a spectrum utilization of 48MHz (21%); notably, 176MHz (79%) remained unoccupied. Equally, measurements within the Zaria L.G.A. suburban area

depicted a similar trend (6 active channels identified) to that was observed in Kaduna city; however, the signal amplitudes are attenuated as a consequence of the 83 Km distance and prevailing environmental factors. Similarly, in the rural area of Ikara L.G.A., located 160 Km from Kaduna, measurements showed no trace of signal. This suggests the absence of active spectrum users; consequently, spectrum utilization is negligible, rendering the entire 224 MHz bandwidth available for opportunistic access. Therefore, significant contiguous blocks of spectrum were identified, which is highly promising for cognitive radio deployment.

The results obtained in Kano appear consistent with those from Kaduna State, indicating six active channels (Channels 21, 23, 29, 32, 35, and 47) and a spectrum utilization of 48 MHz (21%), while 176 MHz (79%) remains unoccupied. A measurement conducted in the Kura Local Government Area (L.G.A.) suburban region showed a trend consistent with that observed in Kano city; however, the signal amplitudes are attenuated due to distance (40 km) and environmental factors. Conversely, in the rural area of Gwarmai, situated 75 km from Kano, no discernible signal was detected. The absence of signal indicates a complete lack of active spectrum users, thereby resulting in a zero-spectrum utilization rate, with the entirety of the 224 MHz spectrum remaining available for deployment. This result also suggests the existence of significant portions of spectrum, which is available for opportunistic access.

Investigation revealed a low actual utilization of the radio frequency spectrum within the UHF TV band (470 – 694 MHz). Result from Kaduna, Kano and Abuja indicate an occupancy rate of (21 - 25 %), with (75 – 79 %) of the spectrum resources unoccupied in both Urban and Sub-Urban areas; 100% of these spectrum resources remained unused in the rural areas; clearly demonstrating that vast portion of allocated spectrum remain unused for significant periods. This unused capacity is known as "white space." Table 3 below presents the mean occupancy percentages and standard deviation across the three days of repeated measurements.

Table 3: Mean occupancy percentages and standard deviation across the three days

Location	**Day 1 Occupancy (%)**	**Day 2 Occupancy (%)**	**Day 3 Occupancy (%)**	**Mean Occupancy (%)**	**Std Dev**
Abuja	25	25	25	25	± 0.0%
Kaduna	21	21	21	21	± 0.0%
Kano	21	21	21	21	± 0.0%

From table 3 Abuja shows a consistent 25% occupancy rate across all three days, yielding a mean of 25% with a standard deviation of 0.0%. The zero standard deviation indicates perfectly consistent measurements across the three-day period, suggesting stable broadcasting schedules with no day-to-day variation in channel occupancy.

On the other hand, Kaduna and Kano both exhibit a steady 21% occupancy rate across each day, resulting in a mean of 21% and a standard deviation of 0.0% for both cities. Similar to Abuja, this reflects absolute day-to-day stability in spectrum usage, though with slightly less overall congestion than Abuja.

With zero Variance, the standard deviation of 0.0% across all locations indicates rigidly scheduled, highly predictable static transmission pattern such as fixed Television broadcast services. With occupancy rates sitting between 21% and 25%, the monitored spectrum bands are largely underutilized (75% to 79% idle capacity). This implies significant opportunity for dynamic spectrum access, cognitive radio deployment, or secondary spectrum sharing without causing interference to primary users.

3.1.2 Bat Algorithm Optimization Performance Metrics using 5-fold stratified Cross-validation

Table 4 below present the Bat Algorithm optimization convergence performance metrics using 5 folds cross validation, taking into account generations, best fitness, cross validation accuracy, the regularization parameter C and the kernel parameter Gamma (γ). A careful observation of the result in the table showed the rapid convergence of the BOA from the initial generation at 92.68% achieving 99.67% cross validation accuracy within 5 generations, stabilizing after 10 generations to find the optimal parameters final values: $C = 9.40$, $\gamma = 2.10$.

Table 4: BOA Convergence Performance using 5-fold CV

Generation	Best Fitness	Cross Validation Accuracy (%)	C (BoxConst)	γ (Kernel)
Initial	0.94	92.68	1.56	40.56
1	0.11	95.41	3.98	31.60
5	0.18	99.52	5.45	25.90
10	2.58	99.67	6.87	5.85
15	3.32	99.67	7.56	3.99
20	3.89	99.67	8.23	2.51
25	**5.90**	**99.67**	**9.40**	**2.10**

Furthermore, the graph in figure 8 depict how the Bat algorithm convergence is stabilizing after 10 generations to achieve cross validation accuracy of 99.67%. While the convergence curve in figure 9 shows how the Bat algorithm gradually minimizes the classification error over 100 iterations to finds an optimal set of SVM hyper-parameters (C = 9.40, γ = 2.10). Whereas, the diagram in figure 10 shows SVM decision boundary after BAT optimization. The red and blue regions represent the classifier's decision zones for detecting whether a frequency band is idle or occupied, based on the input features. The blue crosses are the training data while the Red crosses for testing. It can clearly be seen that the SVM tuned using Bat optimization has found a well-separated boundary between the two classes; demonstrating that the support vector machine model (SVM) was trained successfully.

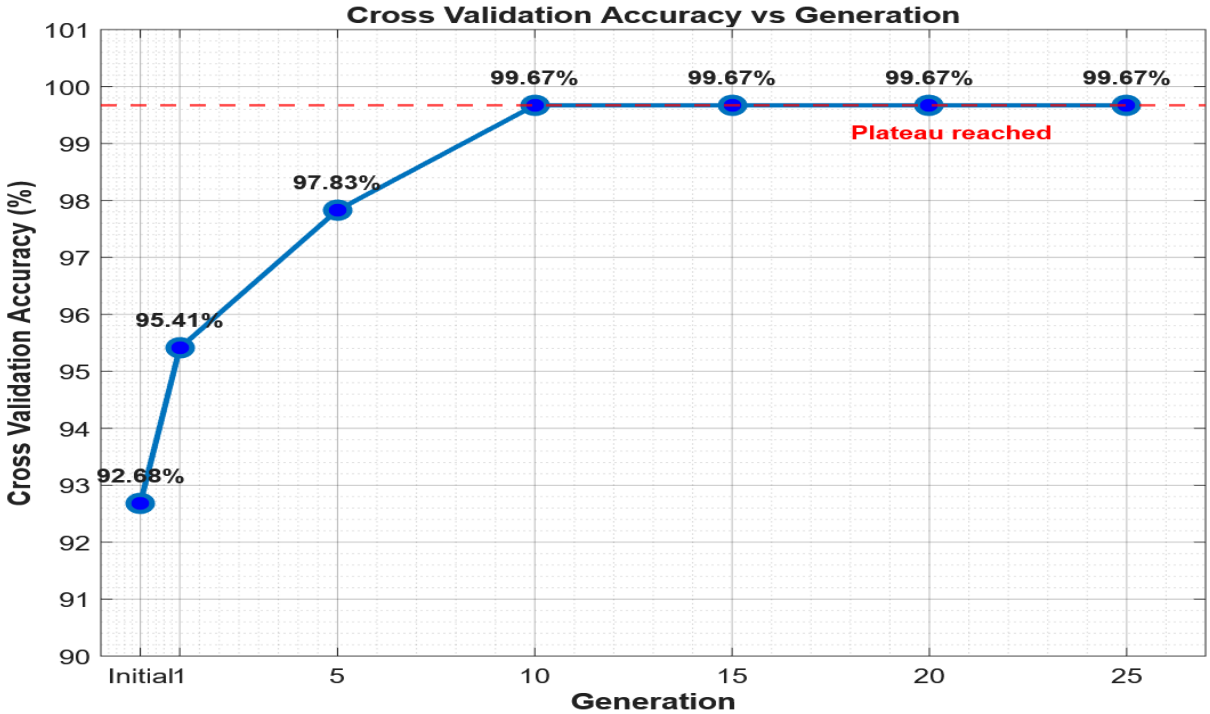

Figure 8 the graph of Bat Algorithm convergence showing a plot of generation against cross validation accuracy

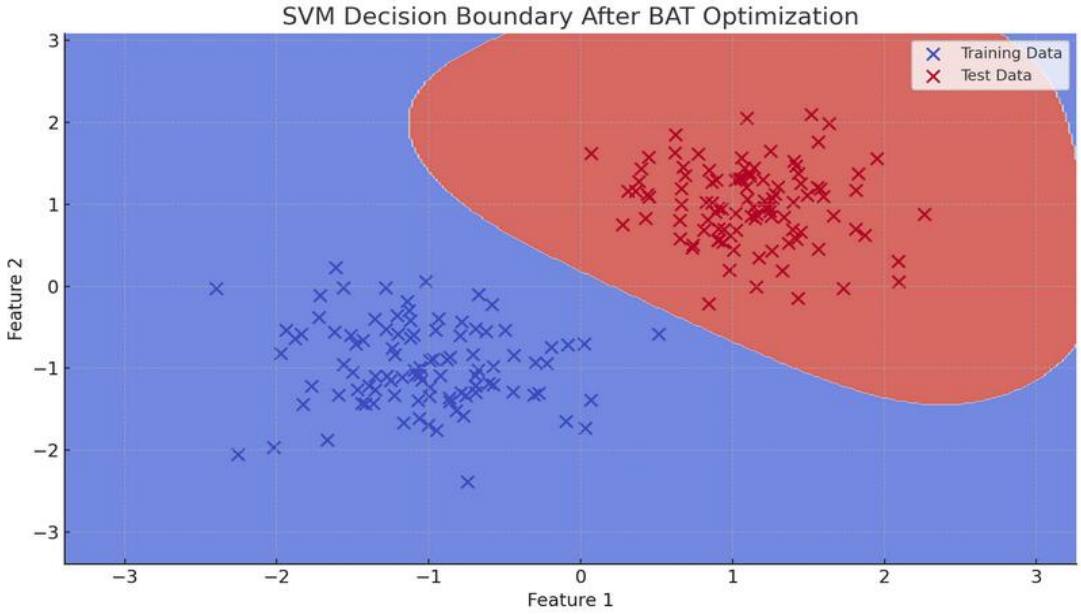

Figure 10 the diagram showing SVM decision boundary after BAT optimization

3.1.3 The SVM-BOA Overall Performance Metrics

This section of the report presents the aggregate performance of the SVM-BOA framework, which was evaluated using confusion matrix analysis, receiver operating characteristics (ROC), area under the curve (AUC), predictive accuracy, precision, recall, F1-Score, and specificity

The confusion matrix is a table used to evaluate the performance of a classification model by comparing predicted class against actual ground truth labels. It categorizes the frequency of correct and incorrect predictions (True Positive, True Negative, False Positive, and False Negative) in a 2 x 2 matrix, facilitating a granular analysis of classification errors beyond simple accuracy. The matrix decomposes performance into four distinct outcomes, which facilitates the calculation of essential

metrics including precision, recall, F1-score, and specificity. The four primary outcomes are outlined below Johnson, J. M., & Khoshgoftaar, T. M. (2019).

True Positive (TP): An instance that is correctly predicted as positive

1. True Negative (TN): An instance that is correctly predicted as negative
2. False Positive (FP – Type I Error): An actual negative instance incorrectly predicted as positive.
3. False Negative (FN; Type II Error): An actual positive instance incorrectly predicted as negative.

This metric provides a detailed accuracy breakdown: It shows not just the model is failing, but how it is failing (which classes are confused), Johnson, J. M., & Khoshgoftaar, T. M. (2019). It accommodates imbalanced data, which may prove essential when one class is far more common than another, making raw accuracy misleading. This matrix serves as the foundation for calculating critical performance metrics, including precision, recall, and the F1-Score For binary classification, the matrix assumes a dimension of 2 × 2; conversely, for multiclass classification, the matrix expands to N × N, where N denotes the number of classes Johnson, J. M., & Khoshgoftaar, T. M. (2019).

In this study, a binary classification was utilized for the Support Vector Machine (SVM) classifiers; thus, the number of classes (N) is 2. It is important to note that the data from Kano, Kaduna, and Abuja were combined to have a total sample of 84 with Actual Positive 65 (Free) and Actual Negative 19 (Occupied), given that the two classes exhibit perfect separation, wherein all occupied channels have signal power level ≥ –98.10 dBm and all free channels have signal noise power level ≤ –100.10 dBm, theoretically, a threshold established between –99 dBm and –100 dBm may yield 100% classification accuracy. While a simple threshold suggests theoretical perfect separation based on signal power levels alone, real-world spectrum sensing involves multiple features and noise variations that prevent perfect classification. For this investigation, an optimum threshold of –99.5 dBm was set-out. Following the implementation of the MATLAB algorithms, the following results were obtained. Figure 11 presents the confusion matrix with its four key attributes describing the performance of the developed classification model. The SVM-BOA achieves 97.62% rather than 100% despite the theoretical threshold separation due to the fact that, the SVM-BOA is validated on the full feature set under cross-validation conditions, whereas the threshold analysis is based solely on signal power levels.

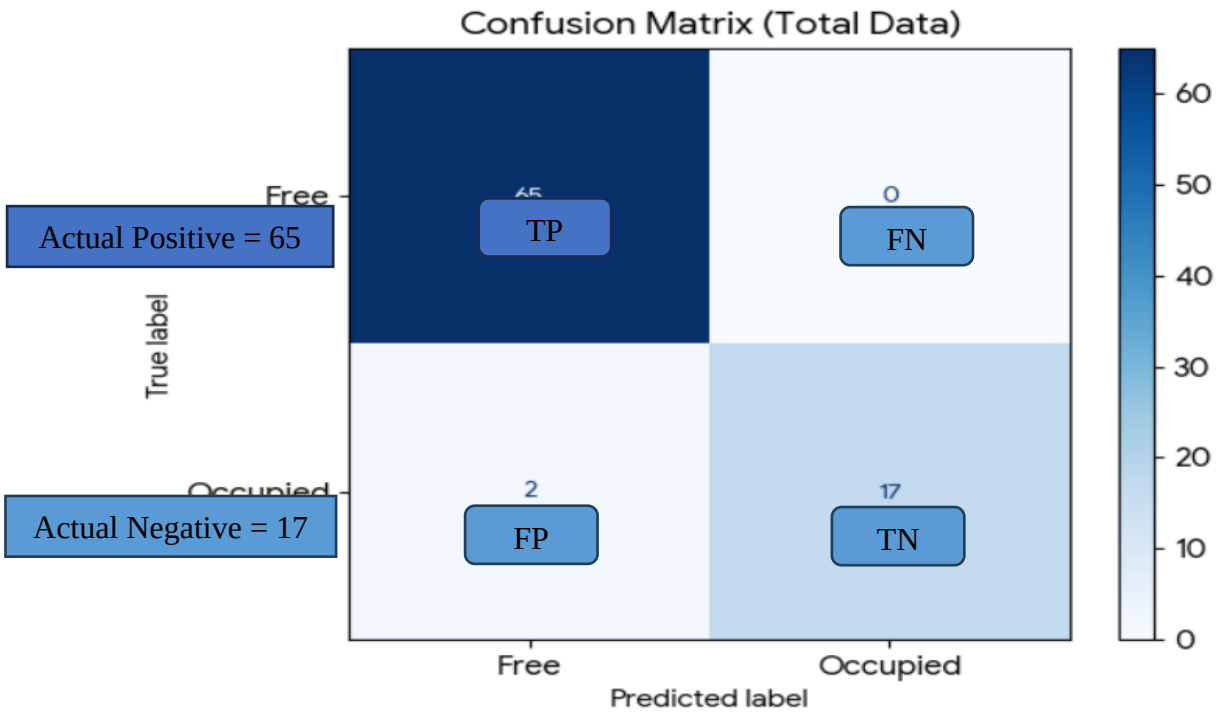

Figure 11: The Confusion Matrix comparing predicted class against actual truth label

3.1.4 The 2x2 Confusion Matrix Mapping

In a 2x2 matrix, the rows represent the Actual values, and the columns represent the Predicted values. The mapping of the confusion matrix True Table into a 2x2 matrix is as presented in table 5. It is important to note that the entire 84 data sample was used to train the model using 5 folds cross-validation as earlier explained, however, the data split is done within the process loop.

Table 5: Confusion Matrix True Table Mapping into 2x2 Matrix

	Predicted Positive (Free)	Predicted Negative (Occupied)
Actual Positive (Free)	65 (TP)	0 (FN)
Actual Negative (Occupied)	2 (FP)	17(TN]

3.1.5 Performance Metrics Calculations

From table 5 above, the following performance metrics were derived,

I. True Positives (TP) = 65, True Negatives (TN) = 17, False Positives (FP) = 2, and False Negatives (FN) = 0
II. Total samples = TP + FN + FP + TN = 65 + 0 + 2 + 17 = 84
III. Actual Positives = TP + FN = 65 + 0 = 65
IV. Actual Negatives = FP + TN = 2 + 17 = 19
V. Predicted Positives = TP + FP = 65 + 2 = 67
VI. Predicted Negatives = FN + TN = 0 + 17 = 17

The metrics were calculated using the formulae below:

1. $Accuracy = \frac{TP+TN}{TP+TN+FP+FN} = \frac{65+17}{17+65+0+2} = \frac{82}{84} = 0.9762 = 97.62\%$
2. $Precision = \frac{TP}{TP+FP} = \frac{65}{65+2} = \frac{65}{67} = 0.9701 = 97.01\%$
3. Recall (Sensitivity) $= \frac{Tp}{TP+FN} = \frac{65}{65+0} = \frac{65}{65} = 1.00 = 100\%$
4. $Specifity = \frac{TN}{TN+FP} = \frac{17}{17+2} = \frac{17}{19} = 0.8947 = 89.47\%$
5. F1-score $= \frac{2\times Precision\times Recall}{Precision+Recall} = \frac{2\times 0.9701\times 1}{0.9701+1} = \frac{1.9402}{1.9701} = 0.9848 = 98.48\%$
6. Probability of Detection (P_d) = (Recall) = True Positive Rate (TPR) $= \frac{Tp}{TP+FN} = \frac{65}{65+0} = \frac{65}{65} = 1.00 = 100\%$
7. Probability of False Alarm (P_{FA}) = False Positive Rate (FPR) = (1 – Specificity) = $\frac{FP}{FP+TN}\frac{2}{2+17} = \frac{2}{19} = 0.1053 = 10.53\%$

Summary and interpretation of result as presented in table 6 below

Table 6: Summary and interpretation of result

S/No.	Metrics	Meaning	Interpretation
1.	Accuracy (97.67%)	The model correctly classified 97.67% of all the spectrum instances (both "Signal Present" and "Signal Absent").	This is an excellent score. It shows that the SVM-BOA hybrid is highly effective at making correct decisions overall in the Cognitive Radio environment.
2.	Precision (97.01%)	When the model predicted "Signal Present" (i.e., Primary User is active), it was correct 97.01% of the time.	This is very high, meaning there is a very low rate of false alarms relative to its positive predictions. The system rarely wastes resources by switching to a channel that is actually empty.
3.	Recall / Sensitivity / Probability of Detection (Pd) (100%)	The model successfully detected every single instance where a primary user signal was actually present. It missed zero signals.	This is the most critical metric in spectrum sensing. A Pd of 100% means the cognitive radio will *never* interfere with the licensed primary user. This fulfills the primary regulatory requirement of spectrum sensing.
4.	Specificity (89.47%)	When the spectrum was truly empty (no primary user), the model correctly identified it as empty 89.47% of the time.	This is good, but it is the weakest metric in the table. It means that 10.53% of the time, the model mistakenly identified the channel as busy when it was actually free (this leads to missed opportunities for the secondary user).
5.	Probability of False Alarm (Pfa) (10.53%)	This is the mathematical complement of Specificity (1 - 0.8947). It represents the probability that the system falsely triggers an alarm that a primary user is present when the channel is actually idle.	While 10.53% is acceptable in many research contexts, it is slightly high. It means the secondary user is losing out on 1 out of every 10 opportunities to transmit information.
6.	F1-Score (98.48%)	The harmonic mean of Precision and Recall (Pd). It balances the trade-off between missing a signal (Pd) and wasting an opportunity (Pfa).	Despite the slightly lower specificity, the perfect Recall (Pd) keeps this score exceptionally high, proving the model is robust and reliable.

The results presented in Table 6 demonstrates that the proposed SVM-BOA algorithm achieves outstanding performance in spectrum sensing, successfully classifying over 97% of all channel states. Most notably, the algorithm attains a Probability of Detection (Pd) of 100%, which is the paramount requirement in cognitive radio networks, as it guarantees absolute protection for the licensed primary user against interference.

However, this perfect detection comes at the cost of a slightly elevated Probability of False Alarm (Pfa) of 10.53%. This trade-off indicates that while the SVM-BOA is exceptionally sensitive, prioritizing the primary user's signal above all, it tends to be occasionally misclassifying idle channels

as busy. Consequently, while the system maximizes spectral reliability and regulatory compliance, this results in a minor reduction in spectral efficiency (89.47% specificity), meaning the secondary user experiences a 10.53% loss in transmission opportunities.

Overall, the high F1-score of 98.48% confirms that the SVM-BOA strikes a highly favorable balance between these competing objectives. It can be concluded that, the integration of the Bat Optimization Algorithm effectively tunes the SVM hyper-parameters to achieve near-perfect detection sensitivity, making it a highly viable solution for real-time spectrum sensing, particularly in environments where protecting the primary user is critical.

3.1.6 Receiver Operating Characteristics (ROC)/Area under the Curve (AUC)

The receiver operating characteristic (ROC) and area under the curve (AUC) are performance metrics for binary classification problems that measure a model's ability to distinguish between classes (for example, free vs. occupied) across all thresholds (Hand, 2009). It is a plot of the True Positive Rate (Sensitivity) against the False Positive Rate (1 – Specificity). These scores typically range from 0 to 1, wherein 0.5 represent random guessing and 1.0 indicates the perfect separation of classes. The ROC/AUC is essentially used in binary classification to evaluate models such as logistic regression or random forests when distinguishing between two distinct classes is required.

An AUC score of 0.5 means the model has no discrimination capacity (random), while 1.0 indicates perfect separation of classes. Scores above 0.8 are generally considered strong, while below 0.5 indicates significant model issues. (Hand, 2009).

Unlike accuracy, ROC, AUC evaluates model performance across all possible probability thresholds, making it robust for imbalance datasets. The AUC value represents the probability that a classifier will rank a randomly chosen positive instance higher than a randomly chosen negative one. The ROC curve is a plot of True Positive Rate (TPR) on the y-axis against False Positive Rate (FPR) on the x-axis (Hand, 2009).

ROC score of 0.5 means the model has no discrimination (Random), scores between 0.5 – 0.7 indicate poor discrimination, scores between 0.7 – 0.8 indicate acceptable discrimination, while scores from 0.8 - 0.9 signifies excellent discrimination, any score greater than 0.9 is outstanding discrimination and score of 1.0 indicates perfect discrimination, (Hand, 2009).

In this study, the Receiver Operating Characteristic (ROC) curve and the Area Under the Curve (AUC) metric were employed for binary classification to evaluate the hybrid Support Vector Machine-Bat Optimization Algorithm (SVM-BOA) spectrum sensing framework. Figure 12 presents the ROC/AUC curves generated in this work showing the plot of True Positive Rate (TPR) on the y-axis against False Positive Rate (FPR) on the x-axis with the ROC/AUC curve, further demonstrating that the SVM-BOA has achieved exceptional classification performance. While, table 5 presents the entire classification performance results.

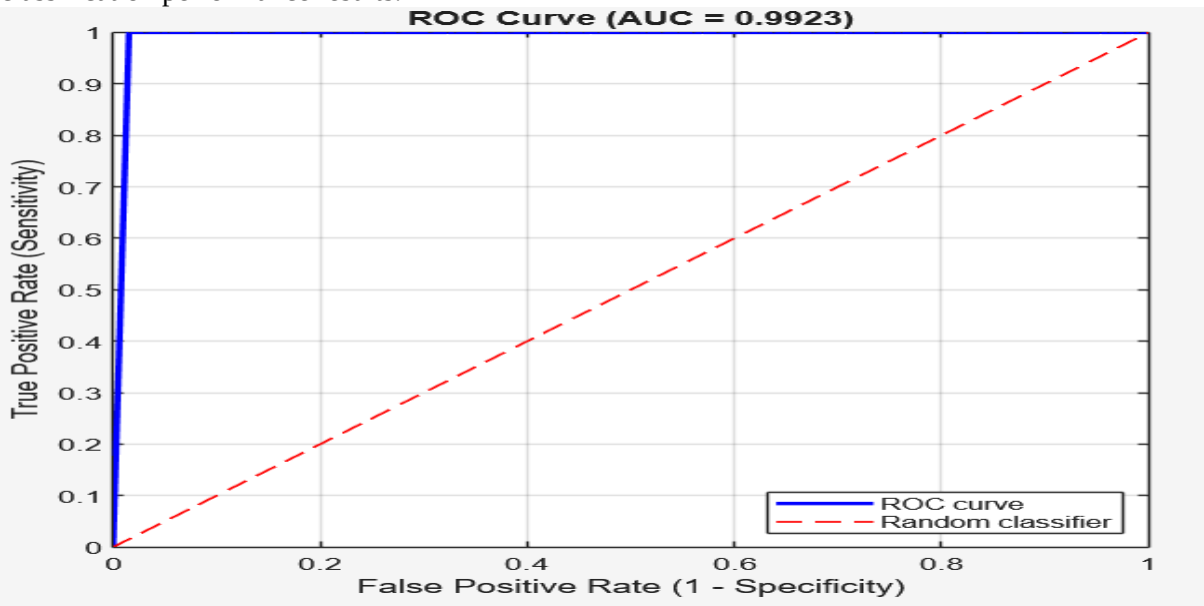

Figure 12 plot of True Positive Rate (TPR) against False Positive Rate (FPR) ROC/AUC

From figure 12 above, it can clearly be seen that the ROC curve exhibits a trajectory from (0, 0) to (0, 1) and subsequently to (1, 1), which shows a classification performance with an AUC of 0.9923 (99.23%) (The theoretical maximum). The following performance metrics were derived from the ROC curve.

True Positive Rate (TPR) = 0.9923 ~ 1.00 (100%)
False Positive Rate (FPR) = (1 – Specificity) = (1 – 0.8947) = 0.1053 = 10.53%
Summary of findings are as follows:

- True Positive Rate (TPR) = 0.9923 ~ 1.00 (100%)
- False Positive Rate (FPR) (P_{FA}) = 0.1053 (10.53%)

The ROC curve shows an AUC of 0.9923, indicating outstanding classification performance. At the optimal threshold, the model achieves TPR = 1.0 (100%) and FPR = 0.1053 (10.53%)."

Table 7 below, the entire Support Vector Machine – Bat Optimization classification performance result is presented.

Table 7 the entire SVM-BOA classification performance results.

Metric	**Training Set**	**5-Fold CV**	**Test Set**
Accuracy	100.00%	97.67%	97.62%
Precision	1.0000	0.9745	0.9733
Recall (Sensitivity)	1.0000	0.9745	0.9733
F1-Score	1.0000	0.9745	0.9733
Specificity	1.0000	0.9747	0.9667
ROC/AUC	1.0000	0.9977	0.9923
Probability of Detection and Probability of false Alarm			
Probability of Detection (Pd)	1.0 (100%)		
Probability of False Alarm (Pfa)	0.1053 (10.53%)		

3.2 Comparative Analysis Optimization Method Using Same Field Dataset

This section presents a comparative analysis of diverse optimization methodologies using same dataset. The result obtained above was compared to other methods integrated and implemented into the Matlab program such as Grid Search SVM (SVM - GS) that uses the exhaustive hyper-parameter search, and Random Search SVM (SVM - RS) which uses random hyper-parameter sampling (Wainer & Fonseca, 2021), Genetic Algorithm SVM (SVM - GA) that uses evolutionary optimization, and Particle Swarm SVM (SVM - PSO) using swarm intelligence optimization (Rebentrost etal., 2014) and the Support Vector Machine (SVM) without the element of hybridization. Table 8 presents a comprehensive comparative evaluation of the performance of these models in comparison to the developed model.

Table 8: Optimization Method Comparison

Method	**Best Accuracy**	**Accuracy Gain**	**TrainingTime (sec)**	**Convergence**
SVM- GS	92.86%	14.29	45.7	Slow
SVM-RS	89.29%	10.72	8.9	Fast
SVM-GA	92.86%	14.29	28.4	Moderate
SVM-PSO	92.36%	13.79	21.6	Moderate
SVM	78.57%	-	1.2	Fast
SVM-BOA	**97.67%**	**19.1**	**12.3**	**Fast**

3.2.1 Discussion

The empirical results summarized in Tables 8 present a validation of the proposed Bat-Optimized Support Vector Machine (SVM-BOA). The model optimization method was evaluated and benchmarked against standard hyper-parameter tuning techniques using the same field dataset. The

SVM-BOA model shows a superior balance of classification accuracy, computational efficiency, and convergence behaviour. Result from table 6, shows that the un-optimized baseline Standard SVM yields the lowest overall accuracy at 78.57%. By introducing the Bat Optimization Algorithm (BOA), the proposed model achieves an accuracy of 97.67% with a gain margin of 19.10%. While traditional optimization methods like Grid Search (SVM-GS) and Genetic Algorithms (SVM-GA) raised the baseline accuracy to 92.86%, they all fall significantly behind the SVM-BOA's achieved accuracy. This performance highlights the algorithmic limitations of legacy tuning methods. Grid Search evaluates the entire hyper-parameter space exhaustively, forcing a slow convergence speed and a training time of 45.7 seconds. While, Random Search (SVM-RS) resolves this computational bottleneck, achieving a fast-training time of 8.9 seconds, but its stochastic nature fails to locate global optima, trapping its accuracy at a modest 89.29%.

Conversely, the Swarm-intelligence methods like Particle Swarm Optimization (SVM-PSO) offers a competitive convergence with 92.36% accuracy at a 21.6 seconds training lag. The developed SVM-BOA framework successfully resolves this classic optimization trade-off, by leveraging echolocation-inspired frequency tuning and dynamic loudness/pulse emission adjustments of the Bats. The Bat Algorithm navigates the hyper-parameter space to achieve a rapid convergence and classification accuracy of 97.67% within 12.3 seconds, outperforming both exhaustive grid sweeps and alternative meta-heuristic algorithms. Conclusively, the model has demonstrated a superior classification performance over existing frameworks.

4. CONCLUSION

In conclusion, the comparative assessment establishes that the proposed SVM-BOA model introduces a significant advancement in both accuracy and computational efficiency. By achieving a peak accuracy of 97.67%, Probability of Detection of 1.00 (100%), Probability of False Alarm of 0.1053 (10.53%), thereby satisfying the sensing performance requirements of the Institute of Electrical and Electronics (IEEE 802.22) standards and the objectives of this research. Furthermore, the model has demonstrated a superior classification performance over existing state-of-the-art frameworks. Most notably, the integration of the Bat Optimization Algorithm (BOA) with an SVM classifier optimizes the hyper-parameter tuning phase, reducing training time to 12.3 seconds as compared to the computationally high 45.7 seconds required by SVM- GS approaches; demonstrating that the proposed SVM – BOA model provides a far more practical, low-latency deployment option for real-time applications.

3.1 Future Research Directions

While the proposed SVM-BOA framework demonstrates superior accuracy and computational efficiency, several avenues remain open for future investigation. First, validating the model on physical hardware, such as Software-Defined Radios (SDRs), is essential to evaluate its resilience against real-world radio frequency impairments and ambient environmental noise. Second, extending the algorithm into a cooperative spectrum sensing framework could leverage multi-agent data sharing to mitigate the hidden node problem and enhance detection reliability across larger networks. Third, future iterations should focus on adaptive optimization variants of the Bat Algorithm to maintain high sensing precision in high-mobility environments, such as vehicular networks or drone communications, where signal-to-noise ratios (SNR) fluctuate dynamically. Finally, incorporating security mechanisms into the SVM classification boundary is a critical step toward defending cognitive radio networks against intelligent security threats, such as Primary User Emulation (PUE) attacks.

ABSTRACT
Cost estimation issues including budget overruns, delays in project delivery, and loss of stakeholder confidence remain as persistent challenges in the Nigerian construction Industry. By integrating Augmented Reality (AR) and Virtual Reality (VR) to visualize design and cost data in an interactive and real-time manner, Mixed Reality (MR) technology promises to enhance estimation precision, teamwork, and decision-making efficiency. Despite increasing interest in MR adoption in the construction industry, it is still not well explored in the Nigerian context, especially among Quantity Surveyors (QSs) for construction cost estimation. This study has investigated the factors influencing the adoption of MR technology for construction cost estimation among QSs in Lagos State, Nigeria. Five (5) latent constructs namely, Organizational Factors (ORGF), Infrastructural Factors (INFF), Training-Related Factors (TRF), Financial Viability Factors (FVF), and Institutional Factors (INSTF) were measured using a structured questionnaire via census sampling, which got 87.85% response rate. Data from 94 respondents were analyzed using Confirmatory Factor Analysis (CFA) in JASP software. The CFA model showed good model fit (CFI = 0.973, TLI = 0.968, RMSEA = 0.054, and SRMR = 0.053), and the five constructs achieved convergent validity (AVE ≥ 0.50), and high internal consistency (α and ω ≥ 0.89). The results validate that organizational support, digital infrastructure, professional training, financial readiness, and institutional frameworks are important influencing factors of MR technology adoption in construction cost estimation. The findings give practical guidance to construction companies, government authorities, and professional organizations for promoting the uptake of MR in the construction industry in Nigeria.

1. INTRODUCTION

Digitalization in the construction industry has brought the industry a range of innovative technologies to meet rapidly evolving developmental demands (Abanda et al., 2017). Among these innovative technologies, Mixed Reality (MR) technology stands out as one that has visualization and interactive functionalities (Alizadehsalehi et al., 2020). MR is a combination of the real and digital worlds to an extent that it allows users to see and interact with the virtual in real-life settings using a blend of Augmented Reality (AR) and Virtual Reality (VR) (Speicher et al., 2019). In the construction industry, MR enables stakeholders to work with 3D models, overlaid on physical spaces, which brings in a new perspective to design review, site planning, and decision-making (Osorto Carrasco & Chen, 2021; Anwar & Azhar, 2024). A global trend involving the integration of MR into construction procedures has resulted in less rework, enhanced collaboration, and improved productivity (Maqsoom et al., 2023).

Different researchers have given attention to automation, Artificial Intelligence (AI), and Building Information Modeling (BIM) in their studies on the innovation of technologies in construction cost estimation. For instance, Ahmed (2019) cited BIM-enabled automation, especially the 5D modeling and built-in quantity takeoff, as one of the key factors in enhanced cost accuracy at the initial stages of design. On the same note, Nia et al. (2023) and Ibrahim and Elshwadfy (2021) investigated ways of enhancing reliability of pre-construction costs, such as predictive models using AI and automated quantity takeoffs. While these studies provide valuable insights into the application of various technologies in cost estimation, they leave room for further exploration of Mixed Reality (MR) technology, particularly its potential in interactive visualization and real-time team collaboration.

This study therefore examined the factors influencing the adoption of MR technology for construction projects' cost estimation among QSs in Lagos State, Nigeria. In practice, the findings are useful in shedding light on the barriers and enablers of MR adoption, which can be helpful to QSs, firms, policymakers, and other construction professionals. Academically, the study contributes to the literature on MR adoption in developing regions, addressing the calls for context-specific studies (Delgado et al., 2019).

2. LITERATURE REVIEW

2.1 Mixed Reality Technology in the Construction Industry

MR is the immersive technology that combines the visual power of AR with the interaction of VR. This technology is a gamechanger in the construction industry, with the potential of increasing project execution precision and efficiency. The benefits of MR technology, while significant, are complicated by costs and technical challenges, yet research and investment efforts continue to push forward with the promise of revolutionizing current methods (Delgado et al., 2020). The difference between AR and VR is that AR is able to overlay digital data on a physical environment, whereas VR is able to produce full-scale simulations (Getuli et al., 2020). These technologies enable the study and manipulation of design concepts, training scenarios and virtual walkthroughs, in addition to the use of human interaction with advanced technologies, such as artificial intelligence or networking (Sidani et al., 2021).

2.2 Factors Influencing the Adoption of MR Technology for Construction Cost Estimation

The integration of the MR technology into construction cost estimation is predetermined by the combination of organizational, technological and human-related factors that define the desire and capacity of the users to introduce new digital tools into their professional practice. A study of the advanced digital technologies used in construction indicated that the perceived benefits, ease of use, support of leadership, readiness of the organisation, infrastructure and technical competence of the users are important factors influencing the outcomes of the adoption of the advanced digital technologies used in the construction field (Liu et al., 2023; Oke et al., 2022). Additionally, there are several factors highlighted, especially in developing economies where the process of digital transformation is not uniform, such as resistance to change, and uncertainty about the implementation process (Adebowale & Agumba, 2024; Babatunde et al., 2021). Understanding these influencing factors is therefore essential for promoting effective uptake of MR technology for accurate and efficient cost estimation of construction projects.

2.2.1 *Organizational Factors*

According to Bamgbose et al. (2024), Organizational factors determine whether the adoption of technology will succeed or not. There are several theoretical frameworks, including the Technology-Organization-Environment (TOE) model developed by Tornatzky and Fleischer in 1990, that give more weight to the role of organizational input in determining technology adoption practices. Various studies present how proactive organizational leadership can help align the technological initiatives with organizational objectives. Leaders in an organization who promote innovation usually create a conducive culture within the organization, thereby facilitating change and combating resistance to change, as well as boosting employees' motivation to accept new technologies (Bendak et al., 2020). Top management endorsement is a primary factor in technology acceptance, and it is appropriately in line with extensions of the TAM and Unified Theory of Acceptance and Use of Technology (UTAUT), where perceived strategic alignment and resource commitment minimize uncertainty and indicates organizational priority (Hong & Yu, 2018; Venkatesh & Davis, 2000). Proactive leadership in the construction industry would lead to buy-in, through the promotion of MR to improve visualization, error detection, and collaborative decision-making, thereby alleviating resistance due to disruption of

existing workflow (Maqsoom et al., 2023; Delgado et al., 2020). In developing economies such as Nigeria, leadership support is more decisive in the face of scarcity of resources and risk aversion. It is found that the technological diffusion can be triggered by the presence of an innovative leader who establishes budgets, initiates MR applications and connects the MR process to strategic goals, while the presence of a passive and/or short-term management can have the opposite effect (Aliu et al., 2025; Oke et al., 2023; Idowu et al., 2023).

2.2.2 *Infrastructural Factors*

Another barrier largely linked to the adoption of MR technology is infrastructural constraints. Limited broadband connection, unreliable power availability, and old hardware are mentioned among the major challenges (Akinradewo et al., 2025; Oke & Arowoiya, 2022). According to Noghabaei et al. (2020), most companies feel that MR is not possible mainly because of the absence of proper infrastructure to support it. The low level of acquisition and maintenance of MR hardware is usually aggravated by low local support and lack of equipment (Uwaegbulam, 2025). Additionally, each of the issues relating to inadequate infrastructure would make it impossible to connect with the existing enterprise systems, e.g., Building Information Modelling (BIM) system. Global research proves that the level of MR technology integration in the coordination of projects, the presentation to a client, and direct on-site cooperation is higher in countries with effective digital infrastructure (Adebowale & Agumba, 2024). Also, hardware limitations such as high prices, technical complexity, and compatibility with the on-site workflow are some of the issues that make integration difficult (Oke & Arowoiya, 2022). Stable internet connectivity is also a necessity when it comes to the deployment of MR technology, particularly when applications entail cloud computing, real-time data synchronization, and shared digital platforms. Studies indicate that low reliability of the network constrains system performance, introduces delays in data transfer, and lowers user trust in the use of the digital tools (Adebowale & Agumba, 2024; Liu et al., 2023). A digital divide is apparent in developing economies where there is a lack of infrastructure leading to a lack of accessibility, making it difficult for smaller companies and consultants to keep up with the investments that larger companies can make (Aliu et al., 2025; Akinradewo et al., 2025).

2.2.3 *Training-Related Factors*

The introduction of MR requires professionals to acquire new competencies in software manipulation, digital modelling, and immersive interface navigation. However, most construction professionals, including QSs, have limited exposure to such digital tools in their education or ongoing professional development (Oke & Arowoiya, 2022). This mismatch creates a knowledge gap that hinders the perceived ease of use (PEOU). Regardless of the increasing interest in most parts of the world, especially about improving design visualization, quantity take-off, and cost estimation, the lack of training is one of the most serious obstacles, especially in developing nations (Akinradewo et al., 2025; Orihuela et al., 2019). Orihuela et al. (2019) observed that when properly trained, users demonstrated higher confidence in applying MR technology during real-world planning and construction phases. Specific job-related training programs are also instrumental in the application of MR technology for cost estimation of construction projects. By adjusting the content of training materials to reflect the practical role of cost specialists in the construction industry, it is possible to increase the relevance of a work and decrease the perceived complexity of the new digital tools. Knowledge sharing among peers is informal yet another effective way of fostering the spread of any novel technology. As early adopters of MR tools can demonstrate the successful cost estimation applications to other collaborators, trust is established and encourages more project teams to embrace it (Liu et al., 2023). Akinradewo et al. (2025) emphasize the fact that the ad-hoc types of learning are not effective when it comes to maintaining adoption, hence measures such as peer-to-peer knowledge sharing, guided onboarding, and partnerships with tech vendors should be leveraged to bridge gaps where formal education systems lag.

2.2.4 *Financial Viability Factors*

The initial purchase price is not the sole detail of the financial consideration; the operating cost of software upgrades, maintenance, licensing charges and special training also add to the overall cost

of ownership (Prabhakaran et al., 2022). Perceived return on investment (ROI) is hence a vital factor. When the advantages are evident, i.e. the increase in the quality of cost estimation, better visualization of construction processes, fewer errors and rework, and more efficient project monitoring, organizations are more willing to use the MR technologies (Apinayan et al., 2023; Delgado et al., 2020). Companies that have a stronger financial base or have access to external resources are in a better position to take these initial costs and achieve long-term efficiency and productivity benefits (Aliu et al., 2025; Maqsoom et al., 2023). Research has shown that strong initial investment needs are one of the initial limitations to the adoption of advanced technologies in developing economies (Maqsoom et al., 2023; Oke et al., 2022). MR software license is another major financial obstacle. MR applications can be platform-dependent and demand dedicated license for systems that use BIM models, real-time rendering, and collaboration features. High licensing costs, often in foreign currencies, are frequent in developing nations, which adds additional financial burdens amid economic volatility, import duties, and constrained budgets of SMEs (Uwaegbulam, 2025; Akinradewo et al., 2025).

2.2.5 *Institutional Factors*

The adoption of MR technologies may be supported or hindered by institutional pressures, such as regulatory frameworks, industry standards, professional guidelines, and the organizational policies (Aliu et al., 2025; Oke & Arowoiya, 2022). Companies usually react to compulsive forces of state authorities or professional organizations that can force them to certain modern technologies or sustainable building concepts. Organizations located in jurisdictions that have favorable policies on the use of digital construction tools have higher chances of integrating MR into their work processes (Adebowale & Agumba, 2024; Prabhakaran et al., 2022). The perceived legitimacy of MR technologies is increased by institutional support, in the form of workshop programs, technical advice, and knowledge sharing platforms, which leads to increased adoption (Prabhakaran et al., 2022; Anireddy, 2020). Moreover, the cooperation among stakeholders would enable sharing of knowledge, collaborative research and development, curriculum design, and pilot projects (Kline & Ayer, 2023; Radianti et al., 2020). Also, public sector project requirements such as mandates, procurement specifications, or tender conditions are standing as factors capable of influencing the adoption of emerging technologies such as MR in construction. Government can hasten the diffusion of MR technology by controlling and purchasing innovative tools for government infrastructure through their high purchasing power and regulatory force (Maqsoom et al., 2023). Industry-wide advocacy in the form of professional associations, trade bodies, conferences, workshops, and thought-leadership campaigns is critical in increasing awareness, consensus, and normalization of the use of MR in construction. This advocacy generates momentum by spreading success stories, which offer evidence of the benefits of MR and refutes the perceptions of the technological immaturity or high risk (Maqsoom et al., 2023; Delgado et al., 2020).

3. METHODOLOGY

3.1 Research Design

For this research, an extensive review of literature was performed, after which a quantitative approach was employed to carefully evaluate the factors influencing the adoption of MR Technology for construction cost estimation. Quantitative research approach is a survey used to acquire information from subjects or study participants (sample) using self-report; objectively, the study population or participants respond to questions posed to them by the researcher (Leavy, 2017). This method enables systematic collection of data on individuals' attributes, behaviors, beliefs, and perceptions (Creswell & Creswell, 2018), thereby supporting the study's aim to explore observable patterns and relationships within a defined context (Saunders et al., 2019).

3.2 Research Population

The research population comprised Quantity Surveyors in registered consulting and construction firms in Lagos State, Nigeria. The reason for selecting Lagos State is because, as Nigeria's commercial hub with a high volume of construction projects, the state offers a rich environment to study new technologies such as MR for cost estimation. Its relative advanced technological adoption, strong

regulatory frameworks, and diverse construction landscape makes it an ideal case for broader national insights. A census sampling technique was applied, targeting all one hundred and seven (107) eligible QSs. The consulting firms were identified through the QSRBN 2025 directory, while the construction firms were identified through Google Business 2025 directory. One (1) respondent from each firm was selected to participate in this study. Table 1 below presents the population distribution across the two firm types.

Table 1: Research Population

Firm Type	Number of Firms	No. of QSs (Population)
Consulting Firms	53	53
Construction Firms	54	54

Source: QSRBN (2025); Author's Compilation (Google Business Directory, 2025)

3.3 Data Collection Instrument

A structured questionnaire was used as the data collection instrument for this study. The questionnaire was sectioned into two (2) parts: The first part was designed to obtain the demographic and background data of each respondent, which includes their qualifications, years of experience, type of firm, and areas of specialization. The second section focused on the factors influencing MR technology adoption for construction cost estimation. A 5-point Likert scale was used in rating the opinions, where 5 = very high, 4 = high, 3 = average, 2 = low, 1 = very low. The latent factors measured included Organizational Factors (ORGF), Infrastructural Factors (INFF), Training-Related Factors (TRF), Financial Viability Factors (FVF), and Institutional Factors (INSTF), each with four (4) observed indicators, totaling twenty (20) items.

3.4 Method of Data Analysis

Confirmatory Factor Analysis (CFA) was applied to examine the factors influencing MR adoption for construction cost estimation, to assess whether observed variables load appropriately on latent factors and whether the latent factors significantly predict the observed variables. An Exploratory Factor Analysis (EFA) was not conducted because the five latent constructs are drawn from established theoretical frameworks whose factor structure has been extensively validated (Venkatesh & Davis, 2000; Davis, 1989). The individual observed indicators, however, were newly developed for this study by adapting the broader TAM/UTAUT and TOE dimensions to the specific context of MR-based cost estimation (e.g., mobile support for MR applications, interoperability with BIM), since directly validated item sets for this technology-task combination were not available in prior literature. This is acknowledged as a limitation of the CFA-only approach, as the item-level structure had not been previously confirmed through exploratory analysis. CFA nonetheless remains appropriate for theory-driven constructs to confirm hypothesized measurement structures without prior exploratory analysis (Hair et al., 2019; Kline, 2016). The latent factors include ORGF, INFF, TRF, FVF, and INSTF, all measured using a 5-point Likert scale, with each latent factor having four (4) corresponding observed indicators, totaling twenty (20) observed indicators. The hypothesized CFA model specified that each latent factor is measured by its respective indicators. Each indicator was restricted to load on only one latent factor, and the latent factors were allowed to co-vary.

CFA requires the use of multiple indices to assess how well a proposed measurement model fits the data, as no single index is sufficient for evaluating model adequacy (Hair et al., 2019; Kline, 2016). Following best practice, this study used three major index families: Absolute Fit Indices (χ^2, χ^2/df, RMSEA, SRMR), Incremental Fit Indices (CFI and TLI), and Construct Validity Indices (R^2, standardized factor loadings, AVE, Cronbach's Alpha, and McDonald's Omega). Following the recommendations of Kline (2016), Byrne (2016), and Hair et al. (2019), acceptable thresholds of $\chi^2/df \leq 3$; CFI/TLI ≥ 0.90; RMSEA ≤ 0.08; SRMR ≤ 0.08 align with widely adopted CFA standards. Standardized factor loadings ≥ 0.50 (preferably above 0.70) were retained in accordance with Hair et al. (2019). Internal consistency was assessed using both Cronbach's Alpha (α) and McDonald's Omega

(ω), with reliability coefficients ≥ 0.70 deemed acceptable. Convergent validity was examined using AVE (≥ 0.50), following Fornell & Larcker (1981). Analysis was conducted using JASP software.

4. RESULTS AND DISCUSSION

4.1 Response Rate

Table 2 presents the breakdown of the return rate of the questionnaires sent out. Out of the One Hundred and Seven (107) questionnaires sent out to Quantity Surveyors in selected consulting and construction firms in Lagos State, Nigeria, a very high return rate was recorded (84.91% and 90.74% respectively) from each firm type. An overall return rate of 87.85% was recorded across both firm types.

Table 2: Response Rate of Respondents

Firms	Distributed	Retrieved	% Retrieved
Consulting Firms	53	45	84.91%
Construction Firms	54	49	90.74%
Total	107	94	87.85%

Author's survey (2025).

4.2 Respondents' Profile

Table 3 presents the demographic information of the Quantity Surveyors that were part of this research. The results show that 74.47% of respondents were Male and 25.53% Female. In the Academic Qualification category, most of the respondents possess only a First-degree certificate (B.Sc/B.Tech), with approximately 51.06% representing that group, followed by those who possess Master's degree (approximately 36.17%), and those with Higher National Diploma (HND) (approximately 12.77%). In the Years of Professional Experience category, the group with the highest percentage is 6–10 years (approximately 43.62%), followed by professionals with 11–15 years' working experience (approximately 30.85%), 1–5 years working experience (approximately 13.83%), and respondents with 16–20 years of professional working experience (approximately 11.70%). It is worth noting that most respondents fall into the group of professionals with less than 16 years' working experience, which establishes the non-redundancy of the sampled professionals to new technological trends. Lastly, in the primary area of specialization category, most of the respondents specialize in Infrastructural projects (approximately 48.94%), while approximately 24.47% specialize in Commercial projects, approximately 20.21% in Residential projects, and approximately 6.38% in Industrial projects.

Table 3: Respondents' Information

Variable	Classification	Frequency	Percentage (%)
Gender	Female	24	25.53
	Male	70	74.47
	Total	94	100.00
Highest Academic Qualification	HND	12	12.77
	B.Tech / B.Sc	48	51.06
	M.Tech / M.Sc	34	36.17
	Total	94	100.00
Years of Experience	1–5	13	13.83
	6–10	41	43.62
	11–15	29	30.85
	16–20	11	11.70
	Total	94	100.00
Primary Area of Specialization	Commercial	23	24.47
	Industrial Projects	6	6.38
	Infrastructure	46	48.94
	Residential	19	20.21
	Total	94	100.00

Author's survey (2025).

4.3 Model Fit Indices of the Factors Influencing the Adoption of MR Technology for Construction Cost Estimation

Table 4 shows the results of the model fit of the factors influencing MR adoption for construction cost estimation. The chi-square score ($\chi^2 = 204.017$, df = 160, $p < 0.05$) is statistically significant but the chi-square test is highly sensitive to sample size (Kline, 2016). In this case, the χ^2/df ratio is lower than the recommended value of 3 (Kline, 2016; Carmines & McIver, 1981), implying strong model fit with a moderate sample (N = 94). Additional model fit indices reflected in Table 4 show that the model fits the data well. The Comparative Fit Index (CFI = 0.973) and Tucker–Lewis Index (TLI = 0.968) are above the 0.95 cut-off, showing that it fits quite well. In addition, both the RMSEA (0.054) and SRMR (0.053) are below their respective thresholds of 0.06 and 0.08, which indicates that the covariance predicted by the model is in line with the observed variables. All in all, the measurement model can be deemed as acceptable.

Table 4: Model Fit Indices of the CFA for the Factors Influencing MR Adoption

Index	Value	Threshold
χ^2/df	1.28	≤ 3.0
Comparative Fit Index (CFI)	0.973	≥ 0.90
Tucker–Lewis Index (TLI)	0.968	≥ 0.90
Root Mean Square Error of Approximation (RMSEA)	0.054	≤ 0.08
Standardized Root Mean Square Residual (SRMR)	0.053	≤ 0.08

Note. **$\chi^2 = 204.017$, df = 160, p = .011. N = 94.**

4.4 R-Squared Values, Factor Loadings, AVE, and Reliability

The R^2 values presented in Table 5 are squared multiple correlations of the observed indicators, which denote the extent of variance in each indicator explained by its corresponding latent construct. The values fall between 0.469 and 0.844, which show moderate to strong measuring strength among the five constructs. According to Hair et al. (2019), R^2 values of 0.75, 0.50, and 0.25 may be described as strong, moderate, and weak, respectively. The Organizational factors represent strong indicator representation, specifically Management commitment ($R^2 = 0.784$) and Organizational willingness to invest in MR technology ($R^2 = 0.742$). The Infrastructural factors also exhibit high measurement strength with Availability of MR-capable hardware ($R^2 = 0.843$) and Mobile support of MR applications ($R^2 = 0.815$) showing the strongest explanatory power. The same can also be said about Training, Financial and Institutional factors that have R^2 values ranging between moderate and strong, suggesting that their indicators are sufficiently described by their latent constructs.

The factor loading values are all statistically significant at $p < .001$, which means that all the indicators have a significant contribution to their corresponding latent construct. The standardized factor loadings vary between about 0.68 and 0.92, all above the required minimum of 0.50 and the desirable level of 0.70 (Hair et al., 2019). The findings indicate excellent convergent validity of the model. The AVE values for all five constructs, ORGF (0.709), INFF (0.707), TRF (0.724), FVF (0.755), and INSTF (0.769), are greater than the recommended value of 0.50 (Fornell & Larcker, 1981), which confirms that over 50% of the variation in each set of observed indicators is attributed to its corresponding latent factor. This shows that the indicators are meaningfully convergent to measure their respective latent factor. The excellent internal consistency of all latent factors is also confirmed through the reliability results. The ORGF omega (ω) and alpha (α) coefficients of 0.905 each indicate that the indicators are quite consistent in their measurement of the same latent factor. INFF follows, with $\omega = 0.893$ and $\alpha = 0.902$. TRF is also highly consistent with $\omega = 0.911$ and $\alpha = 0.913$. FVF is even more reliable with $\omega = 0.924$ and $\alpha = 0.925$, while INSTF has the best construct-level reliability, with $\omega = 0.930$ and $\alpha = 0.928$. The constructs are highly reliable since all of them have coefficients that greatly exceed the widely recognized 0.70 threshold, and most of them exceed the 0.90 standard (Hair et al., 2019). The total scale reliability scores ($\omega = 0.990$ and $\alpha = 0.958$) further confirm that the overall measurement framework of the Influencing Factors is stable and internally consistent.

Table 5: R-Squared Values, Factor Loadings, AVE, and Reliability of the Influencing Factors

Factor	**Indicator**	**R^2**	**AVE**	**α**	**ω**
ORGF	Leadership support for MR technology adoption	0.656	0.709	0.905	0.905
	Innovation-friendly organizational culture	0.638			
	Management commitment	0.784			
	Organization's willingness to invest in MR technology	0.742			
INFF	Availability of MR-capable hardware and devices	0.843	0.707	0.902	0.893
	Mobile support for MR applications	0.815			
	Stable internet access	0.469			
	Interoperability with BIM	0.645			
TRF	Access to MR Technology training	0.721	0.724	0.913	0.911
	Training programs aligned with job roles	0.795			
	Peer knowledge sharing	0.767			
	Opportunities for hands-on practice using MR tools	0.632			
FVF	Affordability of MR hardware and related devices	0.841	0.755	0.925	0.924
	Availability of financing options for MR adoption	0.743			
	Perceived Return on Investment (ROI) of MR adoption	0.799			
	Affordability of MR software licenses	0.644			
INSTF	Collaboration with tertiary institutions and research bodies on MR standards	0.668	0.769	0.928	0.930
	Public sector project requirements pushing MR adoption	0.791			
	Regulatory frameworks supporting digital adoption in construction	0.770			
	Industry-wide advocacy for MR adoption	0.844			

4.5 Factor Covariances of the Factors Influencing MR Adoption

Table 6 presents the factor covariances, which indicate the strength and significance of the relationship among the five (5) latent factors. A positive and significant covariance means that an increase in one variable predicts an increase in the other variable, hence there is conceptual compatibility and interdependence between the variables. The covariances are all positive and statistically significant ($p < .001$) with estimates between 0.604 and 0.732. This shows that the variables have a moderate to a strong relationship, which proves that they are related concepts but not the same dimensions in the model. Particularly, ORGF demonstrates high positive covariances with all other latent factors; INFF (0.700), TRF (0.604), FVF (0.732) and INSTF (0.612). Additionally, INFF has significant correlation with TRF (0.672), FVF (0.668) and INSTF (0.684). On the same note, TRF has a substantial correlation with FVF (0.679) and INSTF (0.652). Lastly, FVF and INSTF also show positive and significant covariance (0.678). These findings imply that the five (5) latent factors are strongly associated, but each one of them is unique enough to reflect a different dimension of the model.

Table 6: Factor Covariances of the Influencing Factors

Covariance			Estimate	Std. Error	Z	p	95% CI
ORGF	↔	INFF	0.700	0.145	4.841	< .001	[0.417, 0.984]
ORGF	↔	TRF	0.604	0.122	4.942	< .001	[0.365, 0.844]
ORGF	↔	FVF	0.732	0.143	5.126	< .001	[0.452, 1.012]
ORGF	↔	INSTF	0.612	0.134	4.561	< .001	[0.349, 0.875]
INFF	↔	TRF	0.672	0.136	4.928	< .001	[0.405, 0.939]
INFF	↔	FVF	0.668	0.150	4.466	< .001	[0.375, 0.962]
INFF	↔	INSTF	0.684	0.152	4.516	< .001	[0.387, 0.981]
TRF	↔	FVF	0.679	0.132	5.125	< .001	[0.419, 0.939]
TRF	↔	INSTF	0.652	0.133	4.914	< .001	[0.392, 0.913]
FVF	↔	INSTF	0.678	0.146	4.649	< .001	[0.392, 0.963]

Note. CI = Confidence Interval. All covariances significant at $p < .001$.

4.6 Discussion of Findings

The adoption of MR technology for construction cost estimation is shaped by several factors. These factors are referred to as Influencing Factors (IF) in this study. These IF collectively determine organizational readiness and user acceptance. Findings from this study reveal that Organizational, Infrastructural, Training-Related, Financial Viability, and Institutional Factors are influencing factors to MR adoption for construction cost estimation.

4.6.1 *Organizational Factors (ORGF)*

There were four (4) observed indicators loaded on this latent factor, namely; Leadership support for MR technology adoption, Innovation-friendly organizational culture, Management commitment,

and Organization's willingness to invest in MR technology. All the four (4) indicators underscore the central role of organizational readiness in driving the adoption of emerging technologies such as MR for construction cost estimation. These indicators collectively reflect the degree to which an organization's internal environment enables or constrains technological innovation. This is a very important variable, because for technology to be fully embraced, organizational influence is huge. The high covariance between ORGF and other constructs, particularly FVF (0.732) and INFF (0.700), further confirms the interdependence of organizational capacity with financial and infrastructural readiness.

These findings align with Bamgbose et al. (2024), who reported that organizational leadership, culture, and resource commitment are primary determinants of technology adoption in the construction sector. The results also support the extended TAM proposition of Venkatesh and Davis (2000) and Hong and Yu (2018), where perceived strategic alignment and management endorsement reduce uncertainty and signal organizational priority. In the Nigerian context, where resource constraints and risk aversion are common, the role of organizational support in catalyzing MR adoption is even more decisive (Aliu et al., 2025; Oke et al., 2023).

4.6.2 *Infrastructural Factors (INFF)*

Four (4) observed indicators were also loaded on this latent factor. These indicators include Availability of MR-capable hardware and devices, Mobile support for MR applications, Stable internet access, and Interoperability with Building Information Modelling (BIM). All the four (4) indicators capture the fundamental role of technological infrastructure in shaping the feasibility and ease of using MR technology for construction cost estimation. Availability of MR-capable hardware and Mobile support for MR applications emerged as the strongest predictors within this construct, suggesting that access to specialized devices is the most immediate infrastructural barrier.

These findings are consistent with Akinradewo et al. (2025) and Oke and Arowoiya (2022), who identified limited broadband connectivity, unreliable power supply, and old hardware as the major infrastructural challenges to AR/VR/MR adoption in Nigeria. Adebowale and Agumba (2024) similarly reported that the level of MR technology application is substantially higher in countries with effective digital infrastructure, suggesting that bridging the infrastructure gap is a precondition for accelerating MR adoption in Lagos State.

4.6.3 *Training-Related Factors (TRF)*

There were four (4) observed indicators loaded on this latent factor, namely; MR technology training, Training programs aligned with job roles, Peer knowledge sharing, and Opportunities for hands-on practice using MR tools. These four (4) indicators capture the Training and Expertise dimension influencing MR technology adoption. They highlight the indispensable role of human capacity development in facilitating the adoption of MR technology for construction cost estimation. Training programs aligned with job roles emerged as the strongest predictor within TRF, suggesting that role-specific training is more impactful than generic digital literacy programs.

These findings are consistent with Akinradewo et al. (2025), who emphasized that the ad-hoc types of learning are not effective when it comes to maintaining adoption, and that peer-to-peer knowledge sharing, guided onboarding, and partnerships with tech vendors should be leveraged to bridge gaps where formal education systems lag. In contexts like Nigeria, the absence of institutionalized training on MR technology in curricula or industry workshops has slowed down diffusion, as corroborated by Liu et al. (2023) who demonstrated that organizations investing in structured digital training achieve higher productivity benefits and improved user commitment.

4.6.4 *Financial Viability Factors (FVF)*

There were four (4) observed indicators loaded on this latent factor, namely; Affordability of MR hardware and related devices, Availability of financing options, Perceived return on investment (ROI), and Affordability of MR software licenses. These indicators show that the cost of technology remains a major influence on MR adoption for cost estimation. Contextually, this means financial viability determines whether MR adoption is viewed as possible or out of reach. Affordability of MR hardware and Perceived ROI are the dominant indicators within this construct.

These results are supported by Maqsoom et al. (2023), who identified high upfront investment costs, coupled with perceptions of low immediate ROI and limited demand, as factors that suppress adoption momentum. Uwaegbulam (2025) and Akinradewo et al. (2025) corroborate these findings in the Nigerian context, noting that high licensing costs, often denominated in foreign currencies, impose additional financial burdens amid economic volatility, import duties, and constrained budgets of SMEs. The strong AVE and reliability coefficients reported in Table 5 further confirm the construct's internal coherence and the centrality of financial considerations in adoption decisions.

4.6.5 *Institutional Factors (INSTF)*

Also, four (4) observed indicators were loaded on this latent factor, namely; Collaboration with tertiary institutions and research bodies on MR standards, Public sector project requirements pushing MR adoption, Regulatory frameworks supporting digital adoption in construction, and Industry-wide advocacy for MR adoption. All the four (4) indicators show how the institutional environment shapes the perceptions of organizations and professionals about adopting MR technology for cost estimation. Industry-wide advocacy for MR adoption emerged as the strongest predictor. INSTF also recorded the highest AVE and the highest reliability coefficients among all five constructs.

These findings align with Aliu et al. (2025) and Oke and Arowoiya (2022), who highlighted that institutional pressures, including regulatory frameworks, professional norms, and peer expectations, are important determinants of MR technology adoption decisions. The findings also corroborate Maqsoom et al. (2023) and Delgado et al. (2020), who emphasized that industry advocacy generates momentum by spreading success stories and refutes perceptions of technological immaturity or high risk. In developing economies where formal digital construction policy structures are still emerging, institutional support becomes an even more critical lever for normalizing MR adoption across the sector.

5. CONCLUSION AND RECOMMENDATIONS

5.1 Conclusion

This study examined the factors influencing the adoption of Mixed Reality (MR) technology for construction projects' cost estimation among Quantity Surveyors in Lagos State, Nigeria. Using Confirmatory Factor Analysis (CFA), the measurement model comprising five latent constructs, Organizational Factors (ORGF), Infrastructural Factors (INFF), Training-Related Factors (TRF), Financial Viability Factors (FVF), and Institutional Factors (INSTF), demonstrated excellent model fit (CFI = 0.973; TLI = 0.968; RMSEA = 0.054; SRMR = 0.053), high convergent validity (AVE values exceeding both the 0.50 minimum threshold and the 0.70 desirable benchmark), and outstanding internal consistency (α and $\omega \geq 0.89$) across all constructs. The following conclusions were drawn:

1. Adopting MR for construction cost estimation is not driven by technology alone; it requires the intentional alignment of organizational support, infrastructural readiness, training and capacity development, financial viability, and institutional frameworks. When these Influencing Factors are addressed together, they translate professionals' awareness of MR into concrete adoption action.
2. The financial viability and infrastructure constructs had the highest individual indicator predictive power, indicating that they are likely the closest and most visible barriers to MR adoption in the construction context in Lagos.
3. The study also found that MR technology provides the greatest benefits in areas that require visualization, collaboration, and real-time decision-making. These findings provide practical direction for firms, QSs, and technology developers seeking to align MR deployment with the highest-impact estimation tasks.
4. Influencing Factors (IF), comprising organizational, infrastructural, training, financial, and institutional factors, are the most influential antecedents of MR technology adoption for

construction cost estimation. These factors significantly show that adoption success depends heavily on external readiness and contextual support within the construction environment.

5.2 Limitations of the Study

This study is subject to two main limitations. Firstly, the sample size (N = 94) is modest, compared to the measurement model (20 observed indicators and 5 latent constructs). Larger samples are generally recommended for CFA to provide stable parameter estimates; this should be taken into consideration when assessing the quality of the reported fit indices. Secondly, the study is limited to Lagos state and despite Lagos being chosen due to the high technological adoption of the technology and the high construction activity in the state, the results and recommendations might not necessarily apply to other states in Nigeria with varying technological adoption levels and institutional support. Larger and multi-regional samples are recommended for future studies to increase the generalizability of the findings.

5.3 Recommendations

The following recommendations were made in lieu of the research findings:

1. Construction and consulting companies need to show greater leadership in their digital transformation efforts by incorporating MR technology into cost estimation and project management processes. Senior management should establish clear policies, allocate resources and establish innovation-friendly environments to support experiments with MR applications and other innovative technologies.
2. Strategic partnership of universities, professional and regulatory organisations (e.g. NIQS, COREN) and MR technology developers should be fostered. These partnerships will foster local research, the adaptation of MR solutions to the local context, and the development of platforms for knowledge exchange and continued innovation in construction cost management.
3. Government agencies and industry regulators should develop digital adoption policies to promote the use of MR technology in the construction industry. Tax reliefs, research grants or public–private partnerships could lower the cost burden on companies and encourage them to increase their innovation in the cost estimation process.
4. Due to high costs and uncertain return on investment, construction companies should consider new models for financing, including leasing, technology sharing consortia and innovation funds. Digital innovation loans with a low interest rate can also be distributed by financial institutions to enable MR acquisition and implementation.
5. Industry associations are encouraged to conduct demonstration projects, small-scale studies and open house exhibits of the cost-saving and other practical value of MR in cost estimation. By documenting and sharing success stories and best practices, confidence will build, resistance to change will diminish, and best practices will be adopted broadly throughout construction.

5.4 Contribution to the Body of Knowledge

This study has provided empirical and theoretical contributions to knowledge on the adoption of MR technology for construction projects' cost estimation. It has demonstrated that MR, through its immersive and visualization capabilities, has strong potential to enhance the precision, accuracy, and communication efficiency of cost estimation processes in construction. Through the application of CFA, the research established and validated five latent constructs, Organizational, Infrastructural, Training-Related, Financial Viability, and Institutional Factors, as significant influencing factors of MR adoption among Quantity Surveyors in Lagos State. The validated measurement model, with excellent fit indices, convergent validity, and internal consistency, offers a replicable framework that future studies can adapt for other contexts and emerging digital technologies. Finally, this study contributes to the limited pool of local academic research on advanced construction technologies in Nigeria, providing a contextual foundation for future studies and implementation of immersive technologies within the construction cost management discipline.

5.5 Areas of Further Studies

From the research, some of the findings provided possible directions for further studies in the following areas:

1. Given the strong covariance observed between Organizational and Financial Viability Factors in this study, future research could specifically investigate the relationship between organizational readiness and financial commitment to determine whether strengthening one factor accelerates improvement in the other.
2. Future work can conduct cost–benefit analyses to assess the financial viability and return on investment (ROI) of MR adoption in cost estimation processes within different firm sizes and project types.
3. Lastly, further research should investigate the roles of regulatory bodies, professional institutions, and government agencies in supporting MR adoption, especially in relation to policy design, incentives, and training programs.

ABSTRACT
Drawing on an analysis of 85 studies in the period 2020-2026, this review examines how smart technologies are utilized for energy management in agriculture. This review uncovers current trends and future trajectories across six themes: farm energy monitoring made possible by IoT; the incorporation of renewables into agricultural operations; forecasting of energy needs for the storage and processing of crops; policy frameworks for agro-energy; the use of AI to optimise heavy-duty farming equipment; and blockchain for peer-to-peer energy trading on rural grids. Among the key findings is the capacity of AI to transform on-farm energy consumption through demand-response in livestock and irrigation facilities and a better integration of decentralised renewables in microgrids. At the same time, the study highlights several shortcomings, particularly regarding system scalability for farms of different sizes, the real-time demands of variable weather and crop cycles, and the computational limits encountered off-grid. A four-step methodology has been employed to bridge the divide between theoretical propositions and practical implementation challenges, thus providing a road map to a smart EMS that is both resilient and economical for agri-food value chains. In so doing the research puts forward a comprehensive framework for agricultural engineers, researchers and energy policymakers to build more sustainable farm energy systems and surmount the obstacles to field-level deployment that are peculiar to the rural environment.

Keywords: *Demand-Side Management; Smart Farming; Renewable Energy; Artificial Intelligence; Internet of Things; Energy Forecasting; Agricultural Electrification*

1. INTRODUCTION

The rapid increase in population, urbanisation, and climate change effects placed immense strain on global food systems. The world's population is estimated to reach 9 billion by 2037, with a significant proportion residing in urban centres (Gu *et al.*, 2021). A report released by the Food and Agriculture Organization (FAO) stated that there must be a significant increase in food production if this demand is to be met but this will also bring other challenges such as causing a rise in the emission of greenhouse gases (GHG), scarcity of water resources, and land degradation especially if farmers continue to use traditional farming technique (Emegha *et al.*, 2025). This has therefore warranted the need for innovative and sustainable farming methods with low environmental footprint and optimized operational efficiency.

Smart farming, which is also referred to as precision agriculture, digital farming, or Agriculture 4.0 integrates advanced technologies including the IoT, AI, robotics, and data analytics to optimise resource utilisation, increase yields, and enhance sustainability (Vardhan *et al.*, 2025). A modern smart farm consists of multiple technical fields such as precision agriculture, cyber-physical systems, and sustainable energy. The goal of smart farming is to optimise the water-energy-food nexus and includes highly mechanised, automated, and data-driven ecosystems. However, smart farming entails substantial energy consumption. About 30% of the world's energy consumption comes from activities related to the agri-food sector, and about one-third of the total GHG emissions from these systems are attributable to their energy use (Corigliano *et al.*, 2025). Energy consumption in agriculture varies substantially across production stages, with irrigation alone consuming between 12,173 and 23,781 MJ ha^{-1}. In controlled environment agriculture (CEA), particularly greenhouses, energy requirements are higher,

with lighting, heating, ventilation, and air conditioning (HVAC) systems consuming vast amounts of electricity to maintain optimal microclimatic conditions (Corigliano *et al.*, 2025).

Managing the water-energy-food nexus is a very complicated process in many developing regions, particularly in Sub-Saharan Africa. Challenges such as unstable grid, limited access to modern facilities and capital exacerbates these challenges. Some farmers therefore use diesel generators and other traditional systems to meet agricultural demands, thereby increasing operational costs and constraining productivity. The introduction of AI and other intelligent technologies offer potential solutions to these challenges and are poised to transform the agricultural sector especially in the area of energy and other resource management. These intelligent systems have the ability to process large datasets, recognize patterns, and predict future outcomes making them ideal for the complex and variable nature of agricultural activities. ML models have been widely used to forecast energy consumption, which enables better load management and scheduling of irrigation and climatic control operations. Reinforcement learning (RL) techniques have also been used to improve the optimal scheduling of microgrids and also deploy DSM response techniques. Other AI-based tools such as Artificial Neural Networks (ANN), genetic algorithms (GA), and fuzzy logic (FL) have also been used to solve optimisation problems relating to energy storage management, renewable energy integration, and load prioritization especially in smart farming (López-Pérez and Flores-Prieto, 2023).

Even with all the benefits of AI-based solutions for EMS, there are many limitations, especially when it comes to their application in the farming sector. In large scale farming, these systems can be very complex to use because there is large data to be processed from IoT sensors and smart meters. Many researchers have used EMS for many applications ranging from industrial to residential settings, but their adaptability and scalability in the farming sector are limited(Tirth *et al.*, 2023). The broad implementation of these cutting-edge farming techniques remains severely limited, not only by financial outlays for infrastructure but also by cyber threats, privacy issues, and poor rural connectivity. Farming operations are becoming more mechanised and therefore it is very important for that these challenges are solved which will enhance the use of intelligent systems in energy management especially in the farm (Zhang *et al.*, 2022). These challenges are summarized in Figure 1.1.

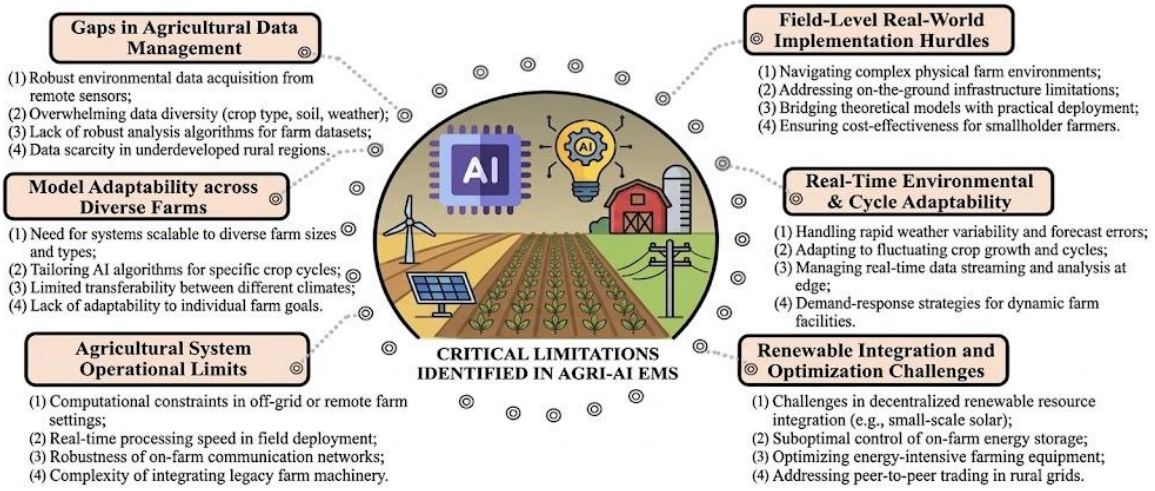

Figure 1.1: Critical Limitations Of AI-driven EMS Systems Deployed in The Agricultural Sector

This study therefore focuses on AI-driven DSM and energy management systems within the context of smart farming and agriculture by examining review papers published between 2020 and 2026. The most studied topics include irrigation optimisation, greenhouse climate control, and reinforcement learning, while scalability, blockchain applications in agriculture, and real-time adaptability remain underexplored. This review guided us to address these gaps and identify future directions for AI-driven DSM in smart farming. With a thorough analysis of what already exists in literature and their limitations, this research provides valuable insights in developing more efficient and robust EMS for applications in the agri-food sector. Figure 1.2 gives a brief overview of the strategy used in the systematic literature review which is inspired by the work done by Kim *et al.* (2021) and Rehman *et al.* (2025).

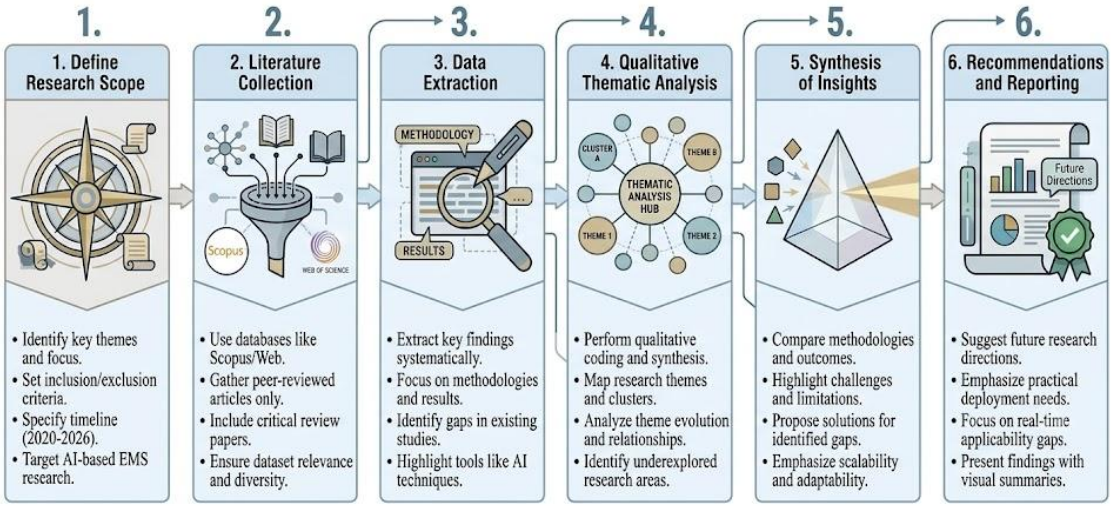

Figure 1.2: Review Strategy Adopted

1.1 Novelty of the Study

Many contributions have been given in the field of AI-driven DSM and energy management systems for smart farming from this study. With many researchers like Aguilar *et al.* (2021) focusing on the application of these technologies in smart buildings and large industries, this research focuses on the agricultural sector highlighting how intelligent energy managements systems can be applied in the entirety of smart farms from irrigation management and greenhouse climate control to renewable energy integration. This study conducts a qualitative thematic review of papers published between 2020 and 2026, which gives a more detailed and current insight into structures and trends specific to agricultural applications; bridging theoretical models with practical implementation in farming contexts.

2. RESEARCH METHODOLOGY

The methodological framework used in this research is summarised in this section.

2.1 Research Questions Formulation

To set the parameters for this review, we begin with a set of research questions (RQs) that will be put forward:

I. RQ1: In the period from 2020 to 2026, what sub-domains in farm-level energy optimisation and DSM have been the subject of the greatest scholarly interest, as opposed to those that are left wanting in funding or attention? What can one make of such publication trends with regard to the strategic imperatives at play and the operational obstacles that endure in agricultural power management?

II. RQ2: What role is being played by the tactical frameworks, machine-learning architectures and hybrid systems of an integrated nature in the governance of on-farm energy today, and to what extent they are able to put an end to the fundamental physical problems at hand?

III. RQ3: Do AI-driven DSM models in precision agriculture truly stand up to the rigours of deployment? The question is whether they can handle processing latency, dynamic responsiveness and scalability while also respecting the biological limits of crops that are determinants of yield and quality in the marketplace.

IV. RQ4: What methodological failings or other deficiencies have been put on record? One has to consider how such flaws stand in the way of a smooth transition from the confines of a trial to a working farm, all the more so in the case of rural agricultural economies with limited resources.

V. RQ5: What does the literature project by way of novel approaches, algorithmic advances or a rethinking of the system to do away with model bottlenecks?

2.2 Definition of Research Queries

For the purpose of this study, we made use of EEE Xplore, ScienceDirect, Web of Science, Google Scholar and Scopus as our principal digital sources. Structured query strings were put to them in order to turn up the publications of greatest relevance. A first pass was made with an assortment of keywords including “demand-side management”, “smart farming”, “precision agriculture”, “renewable energy”, “energy management”, “irrigation optimization”, “greenhouse climate control” as well as “AI”, “machine learning”, “IoT” and “agricultural electrification”.

2.3 Articles Inclusion and Exclusion Criteria

This method of retrieval yielded in excess of 100 publications. To narrow this to the final 85 studies, a rigorous screening process was applied. Inclusion criteria required papers to be peer-reviewed, published between 2020 and 2026, and directly focused on agricultural energy management. Papers were excluded if they focused solely on urban environments or lacked empirical or robust simulation data.

2.4 Results Synthesis and Analysis

In conclusion, the synthesized results were structured to systematically address each research question, yielding several key insights. A significant proportion of the studies focus on reducing energy consumption; however, there is a notable paucity of research regarding the dynamic, real-time adaptation of systems or the handling of biological loads from crops. Technologically, the literature frequently features methodologies such as LSTM networks, hybrid algorithms, gradient boosting and reinforcement learning; all are considered sound approaches to the problem of energy management in an agricultural setting.

3: SMART ENERGY MANAGEMENT SYSTEMS IN FARMING

3.1 Energy Management (EM)

EM involves the comprehensive process of planning, operating and monitoring the energy consumption and generation aim at optimizing the performance and also decreasing the cost of energy Asghar *et al.* (2023). The field of EM is a very broad one which consists of a number of processes or strategies which has been an area of interest for many. Mariano-Hernández *et al.* (2021) gave a review of EMS in buildings, showing the importance of DSM, predictive control, optimisation, fault detection and diagnosis. Energy efficiency can be enhanced in buildings by employing these strategies which will ensure the reliability of the system. Another area of focus is EM in microgrid operation. Energy Management is broadly classified into two major strategies that work together: Supply Side Management (SSM) and Demand Side Management (DSM).

3.1.1 Supply side management

SSM is refers to the set of methods, technologies and policies which are used by utility companies and grid operators in order to ensure that the generation of energy and its supply meets the energy demand. In the earlier days this was the primary strategy used to ensure that there is stability and it was focused on only large centralized energy generation systems like thermal and hydroelectric power plants (Cai *et al.*, 2022). While DSM is mainly focused on adjusting the time of use and the level of energy consumptions from the end user, SSM focuses on the producer and supplier’s side. The main objective is to ensure generation adequacy, maintain system reliability and to optimize the economic dispatch of the generating units (Cai *et al.*, 2022).

SSM has evolved from just a predictable exercise in fuel procurement to a more complex highly uncertain scheme caused by the need to decarbonize and also the integration of renewable energy sources (Aoun *et al.*, 2020). SSM problems are also divided into two; Unit Commitment (UC) and Economic Dispatch (ED). In UC the utility company or operator makes a decision on which generator

unit to turn ON or OFF during a specific period and ED involves deciding how much power each unit will supply to meet the demand most economically.

3.1.2 Demand side management

The concept of DSM emerged in the late 1970s. At that time, utility companies began looking for ways to influence how their customers used electricity (Abul Kalam *et al.*, 2024). Their primary goals were to reduce peak electricity demand and, as a result, postpone the need to build new power plants or infrastructure. By the 1990s, the understanding of DSM evolved to encompass a broader range of strategies. This refinement included approaches such as load shifting, which involves moving electricity consumption to off-peak hours, as well as electrification, promoting the use of electricity for processes previously powered by other energy sources, and fostering the strategic growth of power markets to better manage energy demand (Bogdanova *et al.*, 2023).

3.2 DSM Strategies and Demand Response Schemes

DSM programs are essentially a blend of two key strategies: enhancing energy efficiency and implementing active load management as seen in Figure 3.1. A widely accepted framework categorizes DSM into these two primary pillars: energy efficiency, which focuses on reducing overall energy consumption by upgrading or replacing less efficient equipment, and demand response, which involves strategically altering the timing of energy use (Nebey, 2024).

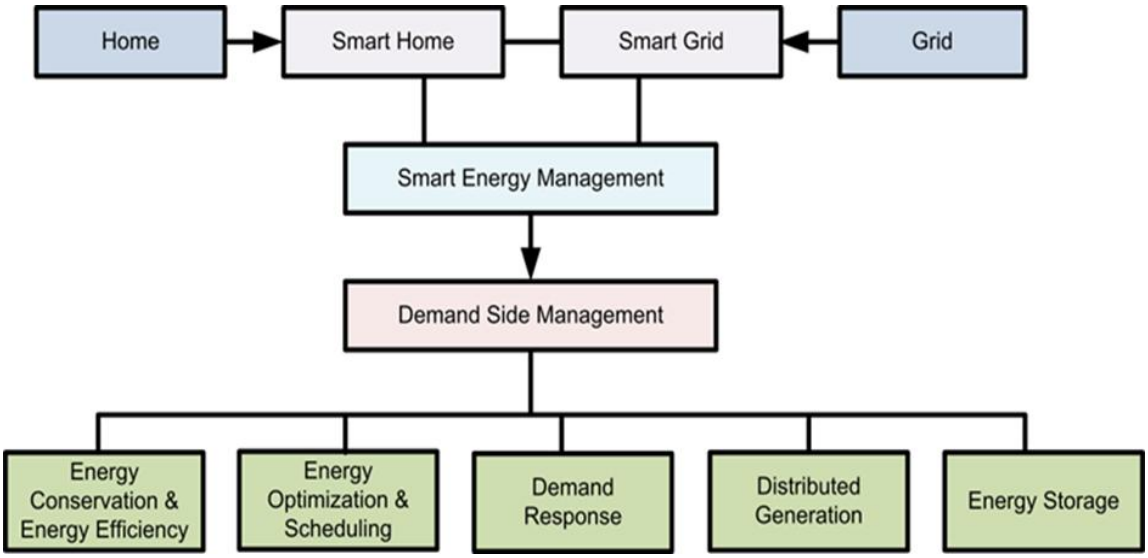

Figure 3.1: Energy management framework

Adapted from Iqbal *et al.* (2021)

Figure 3.2 visually represents the various functions of DSM techniques. Such functions involve managing electricity demand through peak shaving, increasing off-peak usage (valley filling), strategic energy conservation, load redistribution, and timing-based consumption shifts. Peak shaving and valley filling are direct methods of controlling electricity demand. Peak shaving aims to minimise energy usage throughout periods of highest demand, while valley filling seeks to increase consumption during periods of lowest demand. Strategic conservation, on the other hand, involves directly reducing overall energy demand on the consumer side. Both load shifting and time-shifting involve transitioning power consumption to off-peak intervals (Iqbal *et al.*, 2021).

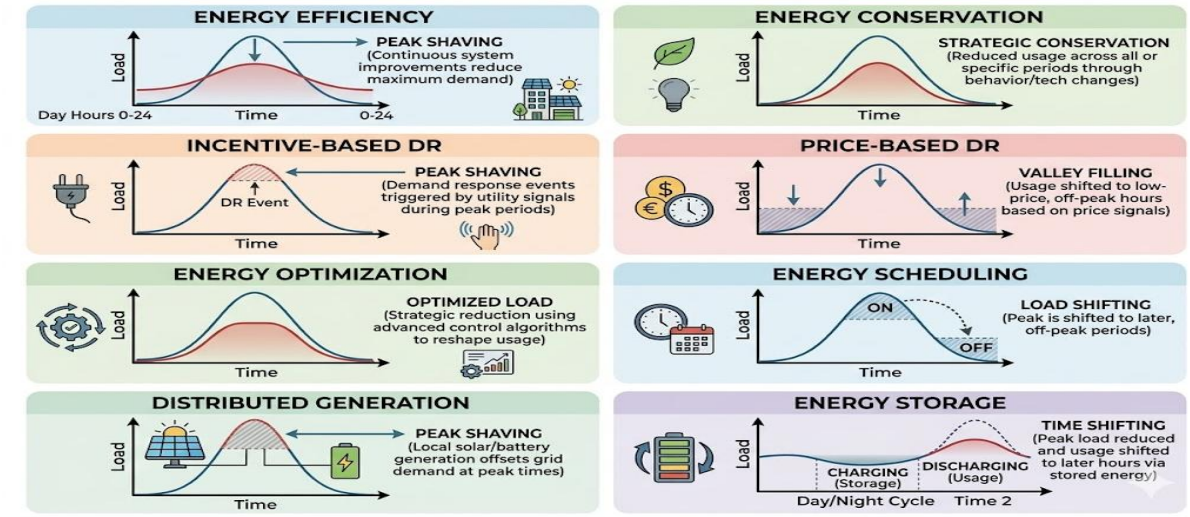

Figure 3.2: DSM Strategies

3.3 Theoretical Background of Smart Farming

A modern smart farm consists of many technical areas coming together including precision agriculture, cyber-physical systems, and sustainable energy engineering. Driven by the need to optimise the critical water-energy-food nexus, smart farming transitions agricultural operations from passive biological methods to highly mechanized, automated, and data-driven ecosystems (Azadi et al., 2021). To overcome grid unreliability and guarantee absolute biological safety, the modern smart farm's architecture has seen the integration of localized HRES with DSM schemes. As illustrated in Figure 3.3, this ecosystem relies heavily on the IoT to serve as a central nervous network. The architecture is structurally divided into three interconnected layers; the generation and storage layer which combines various energy generating and storage systems forming a resilient microgrid. This power is routed through a cyber-physical control layer, where an edge controller processes real-time data from a comprehensive sensor network monitoring various farming parameters such as soil moisture, temperature, and water levels. Finally, this intelligence governs the load layer, dynamically shifting or shedding deferrable agricultural loads based on environmental thresholds and battery state-of-charge without compromising overall crop health.

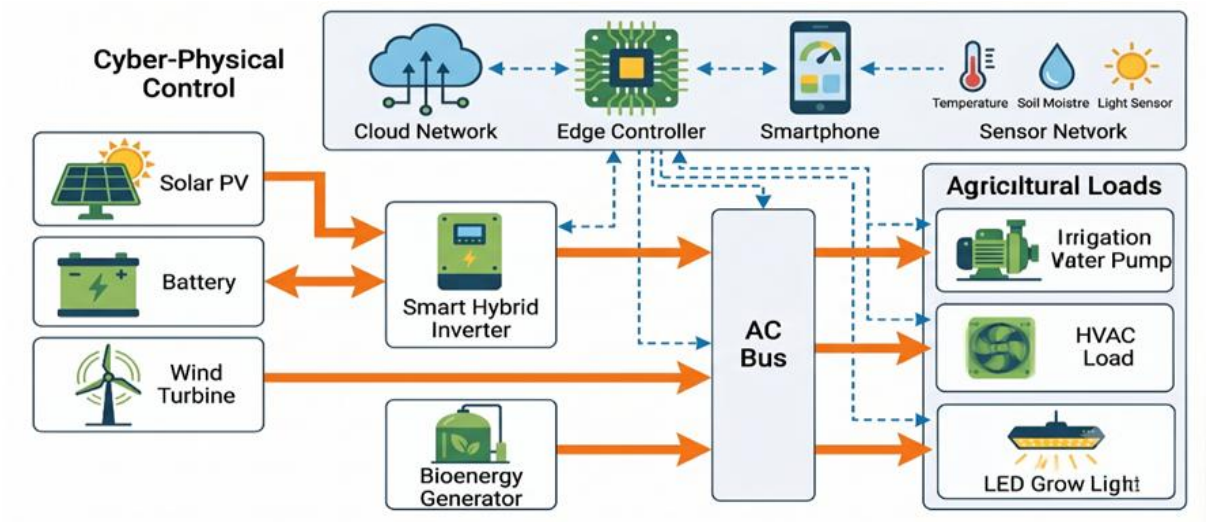

Figure 3.3: Architecture of a Modern Smart Farm

3.4 Energy Demands and Load Profiling in Smart Farms

Moving towards precision agriculture is one of the most important steps in ensuring global food production, which will alter the energy-water-food nexus (Iqbal *et al.*, 2026). Advanced smart farms, which include both open-field precision and controlled indoor farming, greatly depend on automated

and data-driven systems in order to increase their yields and also optimise the use of resources (Nirosha et al., 2024).

3.4.1 Irrigation and water pumping systems

Irrigation systems are a very important but highly variable electrical load in both open field and greenhouse agriculture. Factors that influence the electrical power which is needed to move the water from its source to its needed destination are fluid dynamics, the elevation, and the friction of the pump system (Mansoor *et al.*, 2025). In irrigation, the main metric used in determining the required electrical power is Water Horsepower (WHP), which is a representation of the mechanical energy needed to move a certain volume of water against a total dynamic head (THD) (Mushtaq et al., 2024). The mathematical representation is given in Equation 3.1:

$$WHP = \frac{GPM \times TDH}{3960} \tag{3.1}$$

where GPM represents the pumping rate in gallons per minute, TDH is the total dynamic head in feet, and the denominator 3960 serves as a universal conversion constant deriving from the weight of water and the definition of horsepower. Mechanical and electrical systems are prone to thermodynamic efficiency losses and this makes it very important to know the actual mechanical power that is needed at the shaft of the pump. This is called the Brake Horsepower (BHP) and it can be derived by considering the mechanical efficiency of the pump and the efficiency of the drive mechanism, given in Equation 3.2 where η_{pump} represents the mechanical efficiency of the pump, and η_{drive} represents the efficiency of the drive mechanism.

$$BHP = \frac{WHP}{\eta_{pump} \times \eta_{drive}} \tag{3.2}$$

By actively measuring these metrics, EMS controllers can engage in dynamic load profiling, prioritising energy dispatch precisely when mechanical efficiencies peak and water demands are critical.

3.4.2 Climate control and HVAC in controlled environments

Providing the optimal microclimate is one of the biggest consumers of energy in Controlled Environment Agriculture and greenhouses. About 30% of the energy used in these types of facilities is from powering heating, ventilation, and air conditioning (HVAC) systems which are used to regulate the internal environment against extreme weather variations (Çam *et al.*, 2025). Since temperature and humidity need to be continuously maintained, this creates a rigid base load that makes it very difficult to integrate renewable energy systems. In the Mediterranean, semi-arid, or tropical climate regions which are known for high solar irradiance, high heat is accumulated inside the greenhouse which requires constant operation of HVAC systems in order to prevent heat stress on the crops. This ventilation requirement can be expressed mathematically as seen in Equation 3.3.

$$Q_v = \frac{\tau \cdot R_{s,o-max} \cdot A}{\rho \cdot C_p \cdot \Delta T} \tag{3.3}$$

where Q_v is the required ventilation rate, τ is the greenhouse structural solar transmission coefficient, $R_{s,o-max}$ is the maximum outside solar radiation, A is the ground surface area, ρ is the density of the air, C_p is the specific heat capacity of air, and ΔT is the maximum permissible temperature difference between the indoor and outdoor environments.

3.5 IoT-enabled Farm Energy Monitoring and Smart Infrastructure

IoT is a wireless network that is incorporated with physical items like electronic devices, vehicles, structures, and other electronic devices (Konings *et al.*, 2022). It is a very important technology as it allows objects to obtain, analyze, process, control, and output the information remotely over the network by a computer-based system (Onike, 2025). It makes it possible for the user to control their system remotely over phone through the internet. As illustrated in Figure 3.4, which shows how

the interaction of multiple IoT devices is done as a cyber-physical system, it is a technology which has a wide range of applications in smart grids, smart buildings, and smart farms.

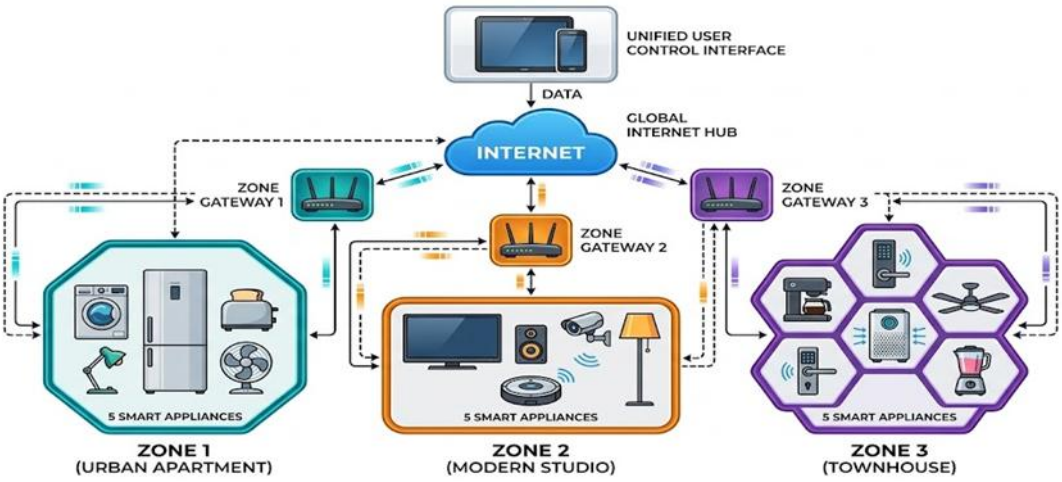

Figure 3.4: The Interaction Between IoT Devices

In modern agriculture, the way data is collected and processed is of paramount importance for ensuring operations are both accurate and as unencumbered as possible. There is scope for IoT to better monitor farm activities and pick up on any faults (Choudhary *et al.*, 2025). Research into agricultural energy has shown a marked interest in the use of IoT to manage irrigation; Al-Ali (2019) put forward an IoT solar system for smart irrigation by way of example. The design makes use of a single-board controller with its own Wi-Fi to link to the solar cells that furnish the power required. From the sensors in the field, it will take readings of soil moisture, temperature and humidity, then issue the actuation commands needed to run the irrigation pumps.

3.6 Renewable Energy Integration for Agricultural Operations

Adopting renewable energy is one of the key aspects for decarbonising agriculture to help tackle climate change, reduce dependency on fossil fuels and improve the economic viability of agricultural systems. Adetoro *et al.* (2023) performed techno-economic and environmental impact assessment of a hybrid renewable energy system with improved combined dispatching strategy for a north-central Nigeria dairy farm. Their best HRES design, made from 248 kW solar PV array, 2 kW wind turbine, 22 kW biogas generator and a diesel generator with nominal power of 92 kW + 658kWh battery storage gave LCOE $0.148/kWh and NPC $1.99 million. This LCOE is highly competitive when compared to Nigeria's current grid electricity tariffs and represents a significant cost reduction compared to the baseline of running diesel-only generators in off-grid rural areas. The Enhanced Combined Dispatch (ECD) strategy, which combines Load Following (LF) and Cycle Charging (CC) modes with six operation scenarios based on net load, battery state of charge (SOC), and energy balance forecasts was shown to perform considerably better than conventional dispatch methods. ECD provides significant reductions in CO_2 emissions (25% lower than CC, 14% lower than LF) as well as diesel consumption (from the base system of 84,351 L/year to only 3,110 L/year), demonstrating the environmental and economic advantages of optimized renewable integration.

The potential of biogas systems for agricultural energy applications has also received considerable attention due to the availability of organic waste streams on farms. Sanni *et al.* (2021) analysed the potential of off-grid solar PV/biogas power generation for a slaughterhouse in Ado-Ekiti, Nigeria, demonstrating that biogas from organic waste could provide reliable backup power to complement solar PV systems. The study utilised HOMER software for optimization and simulation, finding that incorporating biogas generation could reduce diesel consumption by 96% compared to diesel-only systems. The intermittent nature of solar and wind resources presents significant challenges for agricultural applications requiring continuous power supply. Studies by Rehman *et al.* (2024) addressed this challenge through the development of comprehensive frameworks integrating renewable energy resources with battery energy storage systems and precision robotics. Their work highlights the

importance of energy storage in enabling high renewable penetration in agricultural operations, noting that battery energy storage systems can increase the renewable fraction of agricultural microgrids from 20-40% up to 60-80% compared to standalone systems.

3.7 Energy Forecasting and Predictive Analytics

Accurate energy forecasting is critical for the management of an agricultural operation; it is what allows for the kind of proactive decisions that are needed in matters of demand response, storage and the dispatch of generation. In the studies at hand, the methodology is underpinned by an empirical approach to load profiling as opposed to the use of intricate digital twin simulations. The biological variables at play on a farm are too numerous for a conventional digital twin to put on the map with any precision, so a more robust way to do one's analytical forecasting is with targeted load profiling. Recent research has increasingly focused on hybrid machine learning architectures for this purpose in agriculture. In a 2025 study, Biswal *et al.* (2025) put forward a hybrid XGBoost-LSTM model to predict greenhouse energy demand; it makes use of Extreme Gradient Boosting to learn from static features and Long Short-Term Memory in order to recognise sequential patterns. With the addition of a priority-based DSM framework the model was able to cut average electricity costs by 17.3% and grid reliance by 7.1%, all with a MAPE of 5.3%. A comprehensive analysis of AI for power forecasting in renewable microgrids was conducted by Islam and Othman (2026) . They compared the likes of ANN, Fuzzy Logic and ANFIS with deep learning of a more advanced nature such as Transformer, TCN or LSTM. Using hourly data in the field from the King Saud University microgrid in Riyadh, they identified the SE+LSTM as the optimal model, recording an RMSE of 0.7015 kW and a 2.01% MAPE. This was well above what could be obtained from the traditional models or even the TCN (RMSE 0.765 kW, 3.92% MAPE) and standalone LSTM (0.783 kW RMSE, 3.91% MAPE).

3.8 Smart Agro-Energy Policies and Farmer Engagement

For AI-driven energy management to be implemented in the agricultural sector, one needs more than technological advances; there is a requirement for sound policy and ways of engaging farmers. The policy landscape for agricultural energy management is characterized by significant regional variation. For instance, Nigeria's Electricity Act of 2023 eliminates the requirement for a licence to construct or run an electricity distribution or generation facility so long as capacity limits are observed. The Act is open to anyone wishing to do so, particularly where renewable sources are concerned. Gelchu *et al.* (2023) emphasised the importance of policy frameworks in enabling DSM in agricultural contexts. Their analysis of autonomous solar PV-based mini-grids for Ethiopian farms revealed that the cost-effectiveness of DSM strategies depends significantly on tariff structures and regulatory frameworks. Household loads showed the highest DSM impact (45.8% LCOE reduction), followed by productive use with night-time loads (20.7% LCOE reduction), suggesting that policy interventions targeting these load categories could yield substantial benefits. Farmer engagement and adoption of smart energy technologies is a critical factor in the success of AI-based energy management systems. Nigussie *et al.* (2020) highlighted the importance of incorporating indigenous farming and expert knowledge, regional weather information, and crop and soil-specific characteristics into IoT-based irrigation management systems.

3.9 Global Trends in AI-driven EMS in Agriculture

At its core, AI is the discipline of developing and studying intelligent systems or agents. For the purpose of making computers that are truly intelligent, one has been able to draw on techniques like soft computing, statistical learning and knowledge-based systems going back to the 1950s. An examination of 85 studies is visually represented in Figure 3.5, illustrating the annual publication trends in AI-based EMS over the 2020-2026 period. One can see from the data a consistent rise in research output, with the number of studies climbing from 10 in 2020 to 22 by 2025; this is indicative of the heightened interest, both in academia and in practice, for the use of AI in agricultural energy management. The trend also reflects rapid advancements in such technologies as IoT and deep learning that are putting new forecasting and optimisation at the disposal of EMS. As to how these are put to use in DR and what classifications they fall under, Figure 3.6 classifies the various AI approaches

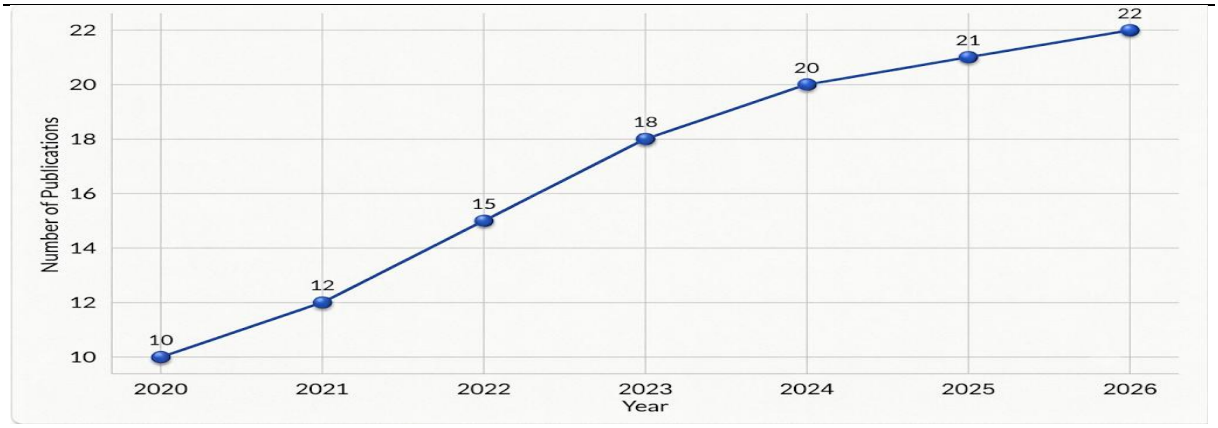

Figure 3.5: Rising research trend in AI-driven EMS for Agricultural Energy Management (Rehman *et al.*, 2025).

An analysis of global research into AI for agricultural energy management reveals notable patterns. In the last five years alone there has been a marked upturn in the number of papers produced in this area, which is testimony to an appreciation of what AI can do to solve the problems of agricultural energy. The bulk of the work on AI-driven agricultural EMS comes from a handful of places; China, Europe, the United States and India are the principal contributors by way of publications. However, developing regions are increasingly contributing to this research domain. Studies from these areas elucidate the particular opportunities and challenges to be had in resource-limited settings.

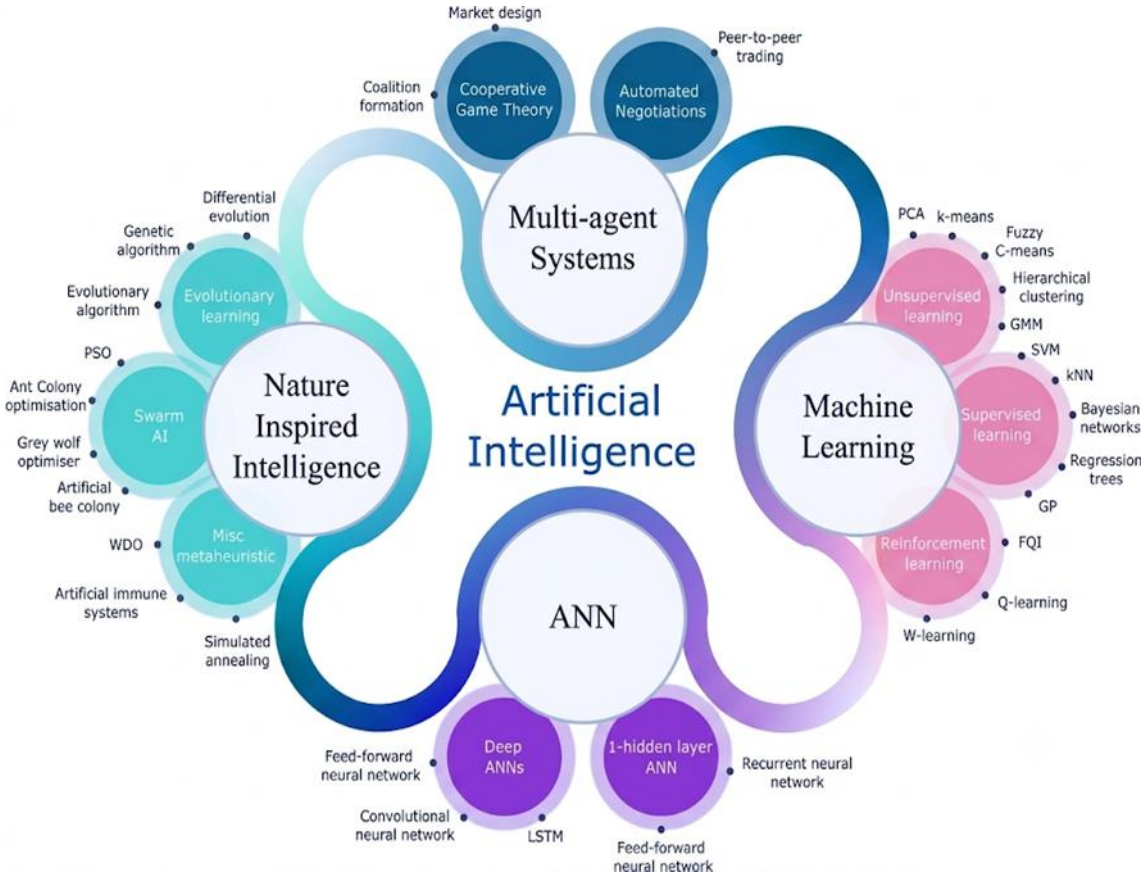

Figure 3.6: Classification of AI Techniques in Energy Management

Adapted from Antonopoulos *et al.* (2020)

4. OPTIMISATION TECHNIQUES FOR AI-BASED AGRICULTURAL ENERGY MANAGEMENT

4.1 Machine Learning for Agricultural Energy Optimisation

In the area of agricultural energy optimisation, ML has become integral to the field, providing the means to forecast, classify and optimise in a wide range of applications. One finds in its use supervised learning for prediction, unsupervised methods for clustering and pattern recognition, as well as reinforcement learning to handle adaptive control and make decisions. For the purposes of forecasting in agriculture, there is extensive recourse to supervised learning techniques such as ANNs, SVMs, random forests or XGBoost. Unsupervised learning has been applied to load profiling and the segmentation of customers within agricultural energy management. Priyanka *et al.* (2023) are one example; they made use of region-based clustering to see gains in energy efficiency from IoT agriculture networks and showed that with large scale deployments, the approach can do much to cut down on the communication overhead and energy used. Several studies have quantified the economic benefits to be had from ML-driven optimisation. In Sri Lanka, for instance, Witharama *et al.* (2024) found that 14.22% of electricity costs could be reduced through LightGBM forecasting given the present tariff system, and as much as 39.42% when market prices are time-varying.

4.2 Reinforcement Learning (RL) for Agricultural Demand Response

In the area of agricultural demand response, RL has demonstrated significant efficacy. It is the basis for adaptive energy management strategies which, through iterative learning, optimize how one makes operational decisions in a dynamic setting. RL algorithms are applied across various tasks in agricultural energy management: from the control of HVAC and irrigation scheduling to battery management. Q-learning, Proximal Policy Optimization (PPO), and Deep Q-Networks (DQN) are among the primary methods utilised. RL overcomes several limitations inherent in traditional rule-based methods when applied to this field. Abul Kalam *et al.* (2024) observe that an RL agent is able to adapt as conditions change and in so doing enhance its performance, learning the best control policies by way of engagement with the environment. The capacity of RL to optimize pricing strategies for service providers was shown by (Lu and Hong, 2019) in their work on an incentive-driven demand response framework for the smart grid, for which they made use of deep neural networks and reinforcement learning.

4.3 Swarm Intelligence for Renewable Energy Integration in Agriculture

The collective behaviour of social organisms is the source of inspiration for swarm intelligence (SI) algorithms, which have seen wide use in the integration of renewables on farms. With their capacity to tackle the kind of intricate optimisation issues that arise in agricultural energy systems, be it in the sizing, dispatch or scheduling of resources, SI algorithms are formidable instruments. Among them are Particle Swarm Optimization (PSO), Ant Colony and Artificial Bee Colonies (ACO, ABC) as well as the Grey Wolf Optimizer (GWO). A case in point is the work of Adetoro *et al.* (2023) who compared the performance of PSO, GA, and ABC in a Nigerian dairy farm to see how they would fare with HRES sizing. Ultimately, PSO demonstrated superior performance, delivering an LCOE of 0.162/kWh and an NPC of $2.05m. The authors attributed this advantage to the way PSO can search the design space and home in on the optimum without sacrificing its balance of exploration and exploitation.

4.4 Hybrid and Ensemble Modeling Approaches for Agriculture

In the field of agricultural energy management, hybrid and ensemble models are demonstrating considerable efficacy. By drawing on the strengths of a number of AI techniques, such approaches have much to offer; they mitigate the limitations of individual methods through complementary capabilities and in most instances outperform a model on its own. One finds that the pairing of machine learning with evolutionary optimization is especially well suited to agricultural energy applications. A novel class of hybrid modeling is also gaining prominence in the form of physical models being brought together with data-driven ML. As an example of what can be done by marrying forecasting models to system simulation for a full appraisal of renewable energy performance, Punyam Rajendran and Gebremedhin (2024) made use of EnergyPLAN software in their multi-energy microgrid analysis,

putting deep learning-based solar power forecasts to work in the process. Also, recent frameworks have successfully merged Extreme Gradient Boosting (XGBoost) for analysing static environmental features with Long Short-Term Memory (LSTM) networks for sequential pattern recognition. Biswal *et al.* (2025) demonstrated that this hybrid approach is highly effective in greenhouse demand-side management, achieving a Mean Absolute Percentage Error of just 5.3% while reducing grid reliance.

5. LIMITATIONS IN AI-DRIVEN OPTIMIZATION FOR AGRICULTURAL ENERGY MANAGEMENT

5.1 Limited Scalability Across Diverse Farm Sizes

Current research is constrained by the limited scalability of AI optimization across the different sizes of farm. One will find in most of the literature a concentration on particular scales or types of farms, and little way to validate the findings over the whole range of agricultural operations, be it a smallholder or a large commercial concern. Priyanka *et al.* (2023) put forward a region-based network design as a means of scaling, one that can take in an assortment of nodes; yet they confined their validation to what was simulated, not to any real-world deployment.

5.2 The Quality and Availability of Data

For AI to be of use in managing agricultural energy, there are fundamental limitations imposed by the data. The models need to be trained and validated on datasets of sufficient size and quality, which are scarce in the agricultural sector, in developing nations especially. In rural SSA for instance, Nigussie *et al.* (2020) pointed out that with so few weather stations researchers must rely on satellite data for irrigation purposes instead of measurements from the ground.

5.3 Computational Demands of Off-grid Environments

Deploying AI in off-grid agricultural settings presents significant technical challenges given the complexity of the algorithms and the paucity of power, connectivity and computing resources to be found in remote areas. Such algorithms are energy and processing intensive. Biswal *et al.* (2025) have shown how these constraints can be met by running ML models that have been properly optimised on a Raspberry Pi 3B+ controller via edge computing.

5.4 Not Enough Adaptability When Conditions Change

Currently utilized approaches are limited in their ability to adapt to dynamic on-farm conditions. Energy management systems must adapt in real-time to dynamic equipment loads or abrupt meteorological changes, but AI models, being based on historical data, will not always react to something new.

5.5 Dealing with Older Farm Infrastructure

Furthermore, integrating AI energy management with legacy infrastructure poses substantial challenges. Much of what is already in place has not been built for the purpose of digital control or to gather data. Implementing monitoring and control systems can be a capital-intensive process and at times not possible from a technical standpoint. At Maizube Farm, Adetoro *et al.* (2023) had to install actuators and sensors in order to monitor and control the diesel pumps and other processing and irrigation equipment since they were not designed for it.

5.6 Lack of Focus on Farmer-centric and Ethical Considerations

Research into AI for agricultural energy management frequently overlooks ethical and farmer-centric considerations. The emphasis has been on the technical merits of the system, its accuracy and efficiency, rather than what bearing it has on the farmer's livelihood or autonomy in making decisions. Abul Kalam *et al.* (2024) observe that such matters as worker displacement, bias in the algorithm and data privacy have not been given the attention they warrant in the published work.

6. DISCUSSION, RESEARCH GAPS, AND SOLUTIONS

6.1 Research Gaps

Although the integration of intelligent technologies into agricultural systems has advanced rapidly, critical research gaps remain across the six primary thematic clusters identified in this review:

I. IoT-Enabled Farm Energy Monitoring: Existing literature predominantly evaluates IoT telemetry and sensor topologies under controlled or simulated environments. A pronounced gap persists in long-term, empirical field validation under severe environmental conditions, intermittent rural connectivity, and sensor drift in open-field deployments.

II. Renewable Energy Integration in Agricultural Microgrids: While techno-economic assessments of basic solar-diesel systems are common, research lacks comprehensive dispatch models capable of coordinating multi-source generation (solar PV, wind, and bioenergy) with battery storage against the highly non-linear, seasonal demand profiles of agro-industrial operations.

III. Predictive Energy Forecasting for Crop Storage and Processing: Deep learning and hybrid architectures (such as XGBoost-LSTM) exhibit high predictive performance, yet their transferability is constrained by a severe scarcity of high-resolution, open-access agro-climatic datasets. Furthermore, current models rarely integrate biological growth stages directly into the load prediction loop.

IV. AI Optimisation of Farm Machinery and Operations: Most algorithmic frameworks assume modern, digitally controllable loads. There is limited investigation into retrofitting legacy agricultural equipment with intelligent edge controllers or mitigating the physical wear and electromechanical constraints of retrofitted motors and pumps.

V. Smart Agro-Energy Policies and Farmer Adoption: Energy management research frequently treats policy and regulatory mechanisms as static boundary conditions rather than dynamic variables. Few studies evaluate how decentralized energy policies (such as the Nigeria Electricity Act 2023) or localised tariff structures influence the financial viability of rural demand-side management.

VI. Blockchain and Peer-to-Peer (P2P) Energy Trading: Decentralized energy trading among rural agricultural producers remains largely conceptual. There is a lack of field-tested, lightweight consensus algorithms capable of operating within the low-bandwidth, low-computational-capacity constraints typical of off-grid rural distribution networks.

6.2 Solutions

To address the identified research gaps and advance the practical deployment of intelligent agricultural energy systems, a transition from simulated environments to physical testbeds and demonstration sites is paramount. Developing modular, low-voltage hardware prototypes utilizing robust edge-level microcontrollers, such as ESP32 architectures, can enable real-time, multi-tiered load prioritization and fault detection. This approach allows agricultural energy management systems to function reliably without depending on continuous cloud or rural broadband connectivity, making it possible to integrate intelligent control seamlessly with legacy farm machinery.

Furthermore, to overcome the severe meteorological variability inherent in open-field environments, future forecasting models must prioritize hybrid machine learning architectures. Combining temporal sequence processing, like LSTM networks, with gradient boosting algorithms, such as XGBoost, can highly optimize weather-based energy forecasting and predictive dispatch logic for hybrid agricultural microgrids. This advancement must be coupled with the establishment of open-access agro-climatic datasets and standardized protocols for data sharing, which are essential to accelerate model training and allow researchers to systematically evaluate algorithmic performance across diverse climates.

Ultimately, the development of Agricultural Energy Demand Side Management (AGDSM) systems requires a participatory, interdisciplinary approach that actively involves agricultural practitioners, engineers, and policymakers. Researchers must proactively engage with regulatory frameworks to test the economic viability of these AI models under localized tariff structures and decentralized energy policies. In the context of Nigeria's development priorities, these findings

highlight a critical pathway for the nation's growth. Aligning with the conference theme to 'Harness Engineering to Drive Nigeria's Growth,' deploying AI-driven hybrid renewable systems in rural farming directly supports national food security and rural electrification mandates, effectively mitigating the impacts of unstable grid infrastructure.

7. CONCLUSION

In this systematic literature review we have evaluated the role that artificial intelligence plays in energy management systems as they are applied in agriculture. An analysis of 85 studies over the period 2020-2026 was carried out. Six distinct thematic clusters were identified in the review: from IoT farm energy monitoring and the use of renewables in agricultural operations, to forecasting energy needs for crop storage and processing; smart policy frameworks for agro-energy; and AI optimisation of heavy farming equipment. These serve to illuminate what is trending, where there are gaps and what lies ahead.

The analysis reveals the capacity of AI to transform how an on-farm operation consumes energy, be it through better integration of decentralised renewables in a microgrid or the demand-response strategies one can put in place for livestock and irrigation. The review's key findings are that hybrid ML methods will outperform standalone ones in terms of forecasting accuracy, and swarm intelligence, PSO in particular, is well suited to HRES optimisation. There are considerable energy savings to be had when AI and IoT are combined.

While the convergence of AI with technologies like 5G, blockchain and IoT offers new avenues for managing agricultural energy, the literature rarely details fully integrated platforms combining multiple technologies. It is a priority to develop AI techniques that take into account the seasonality and biological constraints of the sector, and to align energy management with wider sustainability concerns like soil health and water conservation. To make the most of the opportunities for innovation there will be a need for policy support and continued investment in research. In tackling the gaps, we have identified the community can help bring about agricultural energy systems of greater efficiency and resilience. This review provides a basis for researchers and energy policymakers, as well as agricultural engineers, to move forward with sustainable farm energy systems and deal with the implementation issues peculiar to the rural environment.

ABSTRACT

Accurate measurement of liquid film thickness is important in process equipment because it supports heat- and mass-transfer calculations. In gas-liquid two-phase flow, film thickness is also required for estimating liquid film holdup. Twin-wire conductance probes have been shown to provide reliable measurements of liquid film height in air-water two-phase flows. In this work, probes were fabricated from 0.5 mm platinum wire of 99.95% purity in the student workshop at Imperial College London using standard machining procedures. The probes were mounted on a 32 mm pipe to measure liquid film height in air-water stratified and slug flows. The resulting measurements were accurate, instantaneous, and suitable for tracking changes in liquid film thickness. This paper falls within the sub-theme of sustainable engineering processes. The data and the correlations in this paper can be found useful in the prediction of slug flows for pipeline safety in Nigeria's oil and gas pipelines.

Keywords: *Liquid film holdup; twin-wire conductance probes; liquid film thickness*

1.0 INTRODUCTION

Flows containing more than one phase, commonly referred to as *multiphase flows*, are encountered in many chemical engineering applications. Examples include separation units, chemical reactors, nuclear reactors, tube-bundle heat exchangers, pipeline systems, and several other items of process equipment. Gas-liquid or vapour-liquid flows occur in oil and gas pipelines, condensers, evaporators, distillation columns, absorbers, and combustion systems. Liquid-liquid systems are found in processes such as liquid-liquid extraction and emulsification, while solid-liquid mixtures are frequently transported as slurries through pipelines. Improved understanding of multiphase flow is essential for the effective design and operation of such systems. This paper focuses specifically on measuring liquid film height in gas-liquid flow through horizontal pipes.

When two closely spaced, vertical, parallel wires are immersed in a conducting liquid, the length of wire in contact with the liquid can be inferred from the measured resistance between the wires. This arrangement provides an instantaneous measurement because of the rapid transmission of electrical signals. The method was particularly suitable for the present experiments because rapid response was required to capture fast-moving slug fronts, and because water provides sufficient electrical conductivity.

This work confirms that accurate, time-resolved measurement of liquid film thickness and holdup remains central to the analysis of gas-liquid two-phase flow. Modern studies have extended earlier conductance-probe approaches through interdigital and multielectrode conductance sensors for non-uniform film distributions, while wire-mesh sensors are increasingly used to obtain spatially resolved phase-fraction and flow-pattern information in industrial and laboratory pipe flows (Tompkins, C etal, 2018). Recent slug-flow modelling studies (Ehinmowo, etal (2025), Miao L, etal (2026), have also shown that reliable predictions of pressure gradient, translational velocity, slug liquid holdup, and film-region behaviour depend strongly on high-quality experimental measurements for validation. These developments demonstrate that conductance-based techniques, although well established, remain relevant because they provide fast local measurements that can support both experimental characterisation and the validation of contemporary mechanistic and numerical models of horizontal gas-liquid flow.

In the experiments reported here, conducted by MK Abdullahi (2013), twin-wire conductance probes were used to measure instantaneous liquid height at several positions along the test section. The probes were designed, fabricated, and installed on the Long Tube System (LOTUS), whose general layout is shown in Figure 1. Figure 2 shows the schematics of the probes mounted on the LOTUS test section, while Figure 3 presents a photograph of the twin wires inserted into a pipe section. Because the conductance between the two wires changes with liquid height, recording this conductance provides an instantaneous measure of the local film height. The conductance-time traces can also be used to determine the film height ahead of a slug and, when two probes are placed a known distance apart, to estimate the slug-front velocity. Twin-wire conductance probes therefore offer a convenient method for measuring local liquid film height when the liquid has sufficiently high electrical conductivity (Miya, 1970; Brown et al., 1978; Davies, 1992; Strand, 1993; Srichai, 1994; Manolis, 1995). The LOTUS facility used probes made from 0.5 mm diameter platinum wire of 99.95% purity. This work is within the sub-theme of sustainable engineering processes of this conference.

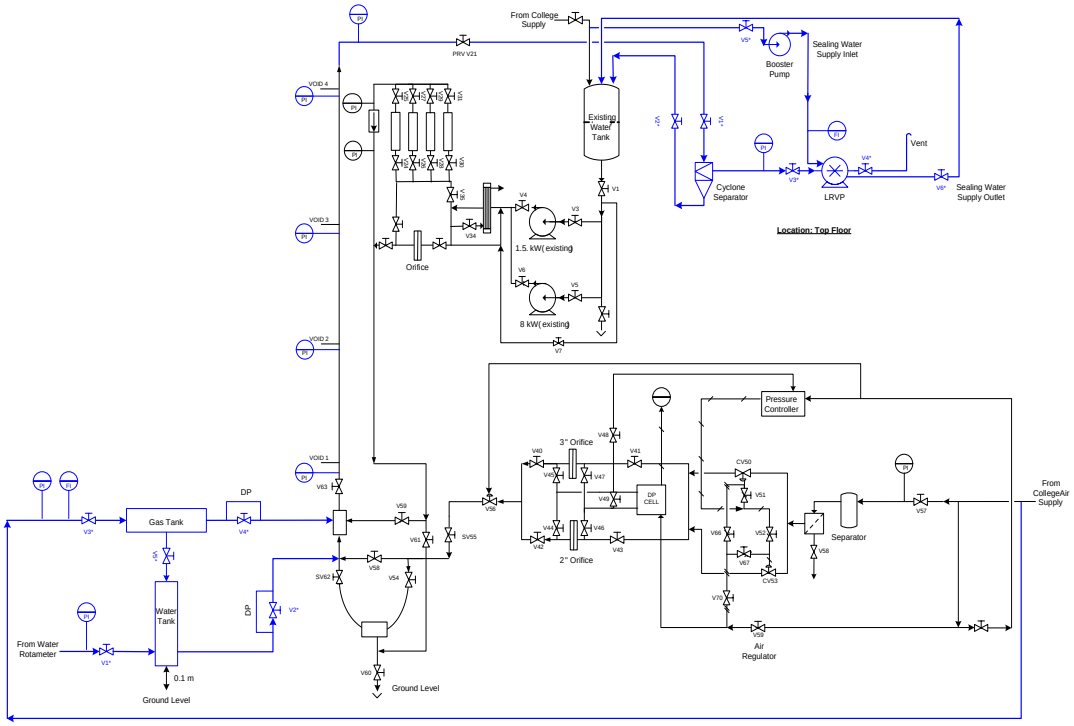

Figure 1: General schematic of the LOTUS Rig

2.0 CONSTRUCTION OF TWIN-WIRE CONDUCTANCE PROBES.

The conductance probes were constructed on pipe sections with an internal diameter of 32.8 mm. Figure 2 shows a schematic of the probe arrangement, with the twin wires positioned 2 mm apart. Four probes were manufactured in the student workshop at Imperial College London and subsequently mounted on the LOTUS test section. Selecting an appropriate wire diameter is important: the wire must be large enough to keep its electrical resistance low relative to that of the liquid, but small enough to avoid disturbing the flow. Two fluid-dynamic considerations govern this choice. First, the wire diameter must be sufficiently small that any wake generated by the wires is negligible. Second, interfacial effects around the wires must also remain insignificant (KOSKIE et al., 1989).

A saddle was attached to the outer surface of each probe assembly, and the wires were screwed to it to keep them straight and correctly positioned.

An equilibrium condition is established when two electrodes are placed in an aqueous medium. This condition results either in a zero net rate of charge transfer between similar metal electrodes or in a potential difference between dissimilar electrodes. When current passes between the electrodes, charge transfer occurs at the interface between the aqueous solution, or water film, and the metal electrodes. This transfer takes place through the movement of protons across the electrical double layers

of ions formed on the anode and cathode surfaces. The process requires activation energy, which is supplied by the potential difference maintained across the system (Glasstone, 1942). In most cases, the current through the double layer increases exponentially with over-voltage, defined as the additional potential difference across the double layer beyond that present when no net current flows. When an external potential is applied between electrodes immersed in an aqueous medium, the over-voltage does not change instantaneously; instead, it increases in a manner similar to the charging of a capacitor through a resistor (Coney, 1972). The double layer can therefore be represented as a capacitance in series with the resistance of the bulk solution.

When alternating current is applied, the influence of double-layer capacitance decreases as the AC frequency increases (Coney, 1972), so the total impedance approaches that of the bulk solution. A very high applied frequency is not necessarily required for the impedance to depend mainly on the bulk solution resistance, particularly when electrodes with high double-layer capacitance, such as platinum, are used.

3 CALIBRATION OF TWIN-WIRE CONDUCTANCE PROBES

Offline calibration was performed for all four probes. Two 1.0 m long pipe sections with an internal diameter of 32.8 mm were used: one fitted with probes CPR1 and CPR2, and the other with CPR3 and CPR4.

An offset run was first conducted with the pipe dry, and the corresponding data were recorded to establish the voltage at zero liquid film height. The pipe sections were then filled with water and sealed using a flange at one end and a cock at the other to retain the water. With the pipe positioned horizontally, the data acquisition system was operated to record the full-pipe reading, corresponding to the 32.8 mm pipe diameter. The liquid level was then reduced in stages, the pipe was kept horizontal, and further readings were taken to obtain voltages corresponding to different liquid levels.

Calibration data relating probe output to liquid height were therefore essential. Such data were obtained for the twin-wire probes used in the LOTUS experiments, as shown in Figure 4.

Figure 4 indicates that an approximately *linear* relationship is expected between probe conductance and liquid height. Early attempts to relate conductance directly to the liquid level observed from the side of the pipe showed deviations from linearity at low and high liquid heights. These deviations resulted from distortion of the interface image caused by the curvature of the pipe wall, which introduced error in locating the true interface position. A correction procedure was therefore developed to relate the apparent side-view level to the true level. Known volumes of water were introduced into a length of acrylic resin tube, which was then sealed and placed horizontally. The true water level was calculated from the known volume added and compared with the apparent level observed from the side of the tube. This comparison enabled correction of the apparent levels. After correction, plots of relative liquid height, defined as liquid height divided by pipe diameter, against data logger reading became close to linear for the four probes used in the LOTUS and LOWPRESS experiments. Some deviation remained at low film heights, probably because of uncertainty in identifying the interface position. It was therefore reasonable to assume a linear relationship when converting data logger output to liquid height. This assumption is convenient because film height can be obtained by linear interpolation between the empty-pipe and full-pipe conductance values, which were measured daily during testing.

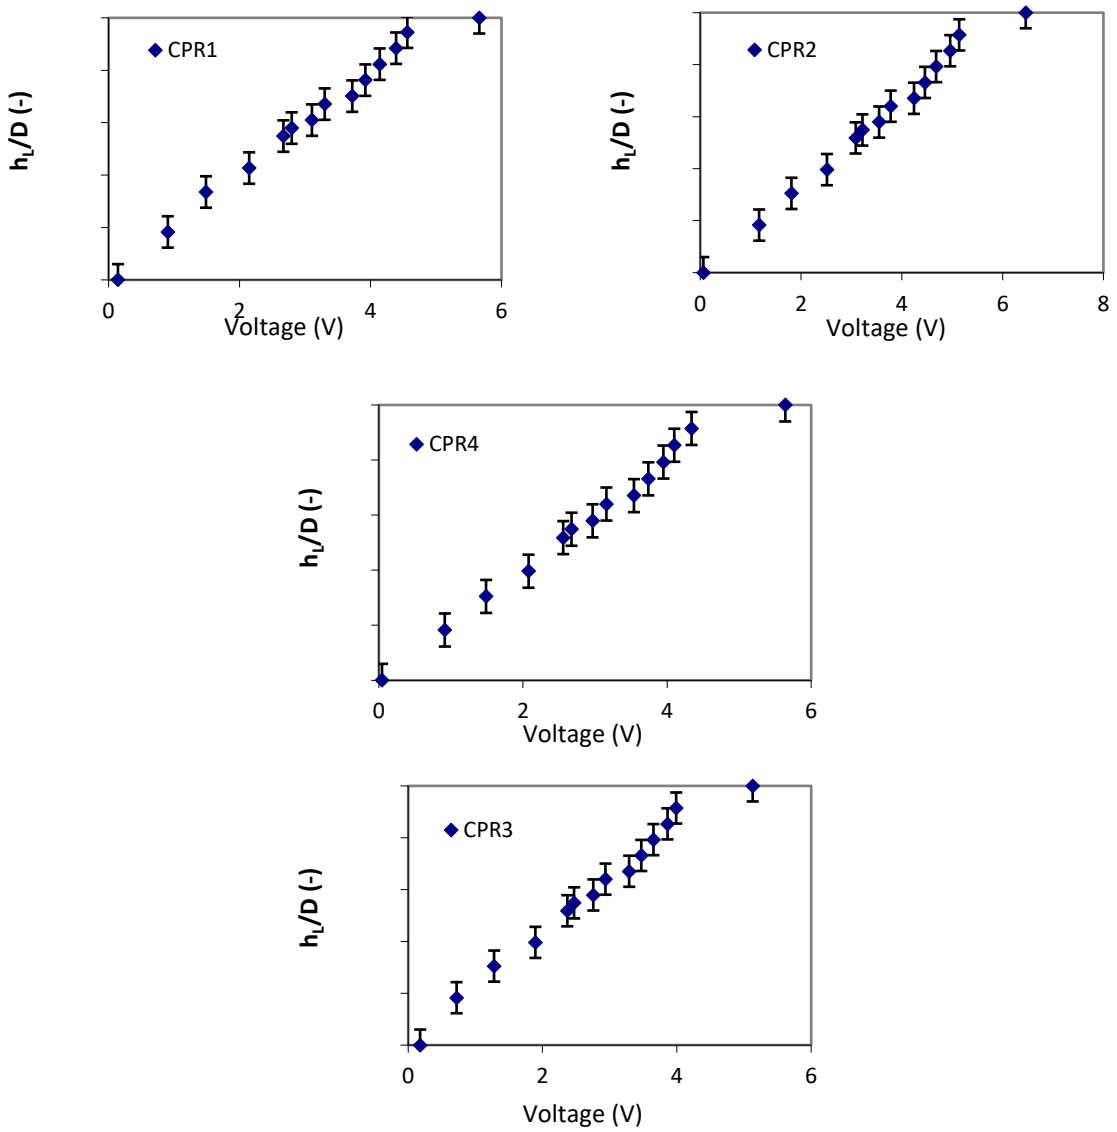

Figure 4: Variation of data logger reading (proportional to conductance) with non-dimensional liquid height for the four twin wire probes used in the LOTUS experiments

From these data, a correlation was derived for the measurement error. This took the form:

$$\varepsilon = -0.1836\left(\frac{h_L^M}{D}\right)^2 + 0.4165\left(\frac{h_L^M}{D}\right) - 0.1607\left(\frac{h_L^M}{D}\right) \quad (1)$$

It was then possible to correct the measured film heights by subtracting the error:

$$\frac{h_L}{D} = \frac{h_L^M}{D} - \varepsilon \quad (2)$$

The results of this correction process are shown in Figure 5. The data now follow the diagonal line to within their error bars (assumed to be +/- 1.5 mm).

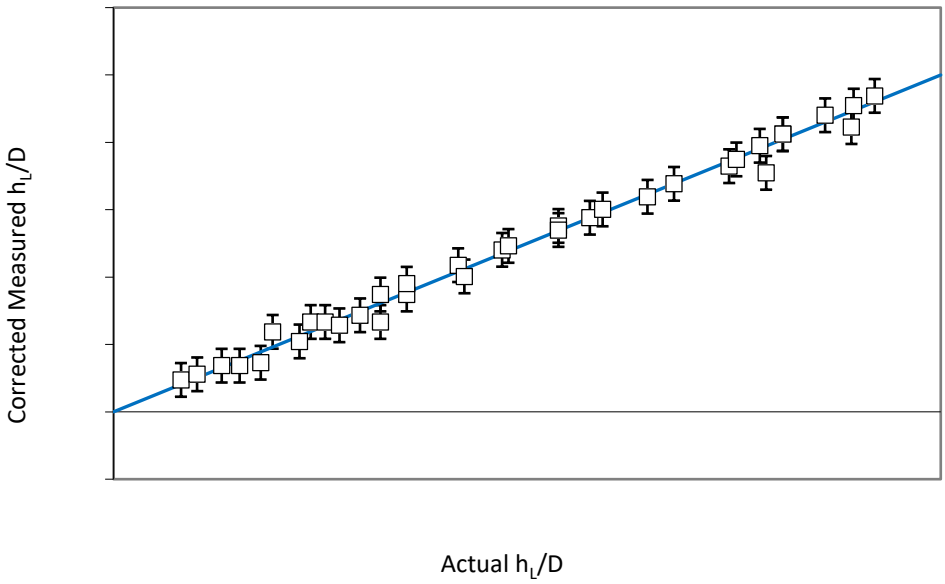

Figure 5: Corrected side-on h_L/D versus actual h_L/D

Each of these probes was constructed as shown in Figure 2. This design has the advantage that the two sets of probes are always at a known, fixed distance apart and so this test section has often been used for measuring slug translational velocities.

The liquid film holdup ε_{LF} can also be determined from the conductance probe measurements of $\frac{h_{LF}}{D}$ and computed using Eqn. (3).

$$\varepsilon_{LF} = \frac{1}{\pi}\left\{\pi - cos^{-1}\left(2\frac{h_L}{D} - 1\right) + \left(2\frac{h_L}{D} - 1\right)\sqrt{1 - \left(2\frac{h_L}{D} - 1\right)^2}\right\} \quad (3)$$

4 Experiments

A typical experiment began by establishing stratified flow in the 32.8 mm horizontal tube. The air and water streams used to create the stratified flow were supplied by the LOTUS rig and passed through a three-way ball valve, as shown in Figure 6. The third connection to this valve was linked to a water-filled vessel pressurised by air from the rig. In the LOTUS experiments, this vessel was a vertical 3 m long stainless-steel tube with an internal diameter of 76.2 mm. When the three-way valve was operated, water from the pressurised vessel entered the test section rapidly, and the rate of water ingress was measured using the venturi meter. The injected water travelled over the existing stratified layer as a pushed-in slug. At the same time, the feed supplying the initial stratified flow was shut off.

The fundamental principle of the experiments is illustrated in Figure 6 and 7 for the stratified flow case and push-in liquid slug respectively. In the case illustrated, the experiment starts with the setting up of a stratified flow in the pipe with the 3-way valve set for through flow as shown. The liquid flow rate in the stratified flow is $\dot{V}_{LF}$ and the liquid fraction in the stratified flow is ε_{LF}. In the experiments, the liquid height in the preceding film region h_{LF} is measured using the twin wire conductance probe system. Assuming that the interface is flat ε_{LF} is related to h_{LF} by the expression in Eqn. (3):

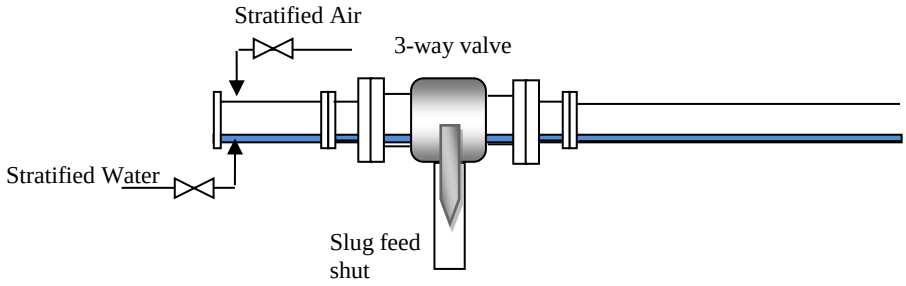

Figure 6: Stratified flow in horizontal test section

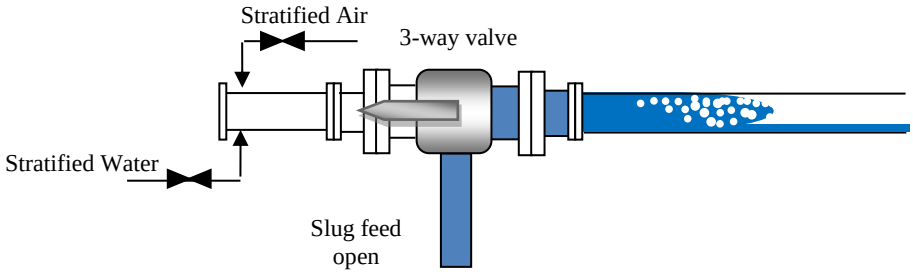

Figure 7: Slug flowing over stratified flow in horizontal test section

Figure 6 illustrates a typical arrangement for measuring liquid height with twin-wire probes positioned upstream of the three-way valve. With the stratified air and water valves open, stratified air-water flow was established in the test section. In the situation shown in Figure 7, the air and water feeds for the stratified stream were closed, and the pushed-in liquid slug moved over the existing stratified layer ahead of it.

5 Data acquisition and processing on LOTUS rig

Air flow rate was monitored continuously. Pressure transducers measured both the absolute pressure at the upstream tapping of the orifice plate, and the pressure drop across it. The upstream tapping was connected to a 0–10 barg absolute pressure transducer, which had been verified against a previously calibrated transducer and found to be accurate within ±4 mbar. The pressure-drop across the orifice plate was measured using a 0–1 bar differential pressure cell. A water-filled manometer was also connected in parallel to allow periodic accuracy checks.

Output signals from these transducers, together with the signal from the transducer mounted on the test line, were converted to digital form and stored on an Amstrad PC1512 (8088) personal computer. Analogue-to-digital conversion was performed using a Scientific Solutions Inc. Lab Master data acquisition unit, which can process up to 16 channels and can be configured for signal ranges of either −10 to +10 V or 0 to 10 V. In the experiments described here, the 0 to 10 V range was selected to match the transducer outputs. A Quick BASIC program written by Manolis (1995) controlled the conversion process and recorded the digitised data. To avoid reducing acquisition speed, only output voltage signals were stored during each run; these were later converted into pressures and air flow rates after completion of the test. For all LOTUS rig experiments, this system operated at a data acquisition frequency of 10 Hz.

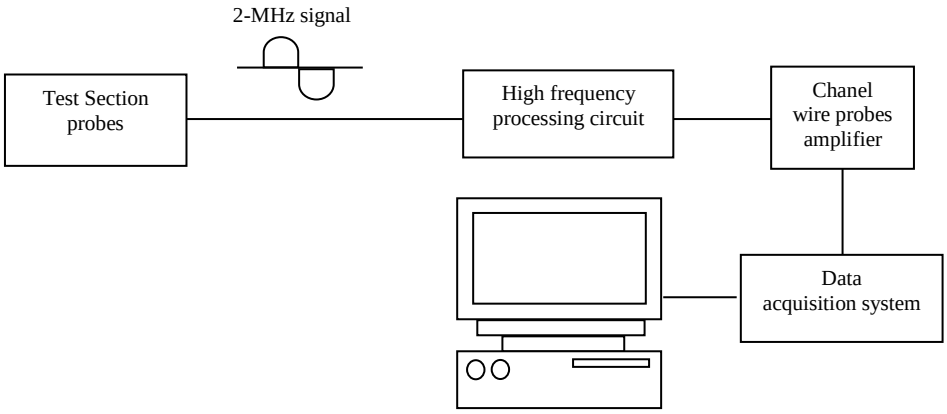
For more detailed pressure profiles and for recording conductivity-probe output signals, a faster data acquisition system could be connected in parallel. This system used an Amplicon-Liveline PC30AT analogue-to-digital conversion card installed in the expansion slot of a NAGA 80486 DX-33 personal computer. It enabled rapid acquisition from up to 16 channels. A Quick BASIC program controlled the conversion process and recorded the digitised data, allowing sampling frequencies between 0 and 1000 Hz to be selected.

In this experiment, a sampling frequency of 500 Hz was generally used as a compromise between the need for high sampling rates and the practical difficulty of handling very large data files. According to the sampling theorem (Lynn, 1982), the maximum frequency that can be adequately

represented by a sampled continuous signal depends on the sampling interval. For adequate representation of this frequency:

$$\vartheta_{\text{sample}} = \frac{1}{2t_{\text{dur}}} \tag{4}$$

Where $\vartheta_{\text{sample}}$, is the frequency of the sampled continuous signal and t_{dur} is the time duration between samples. A sampling rate of 500 Hz (t_{dur} = 0.002 s) corresponds to $\vartheta_{\text{sample}}$ = 250 Hz which should be sufficient for representing major system changes. Figure 8 is a block diagram of the data acquisition for the probe signals obtained in the LOTUS and LOWPRESS tests.



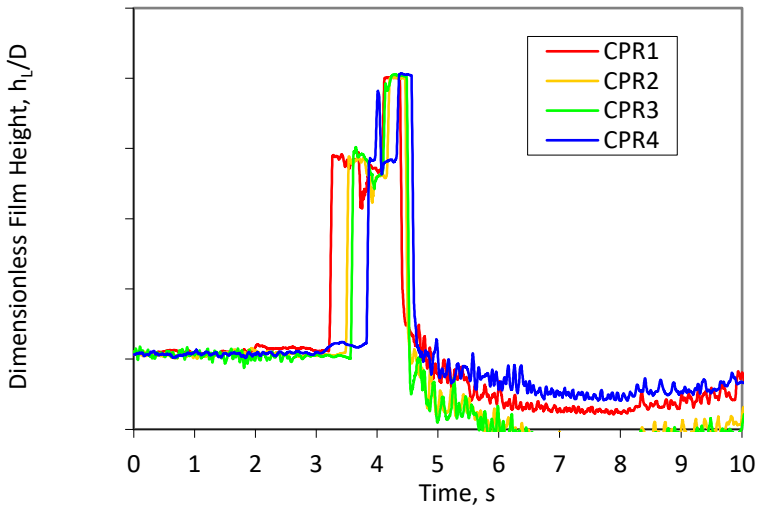


Figure 8: Block diagram of high-frequency probes signal processing system

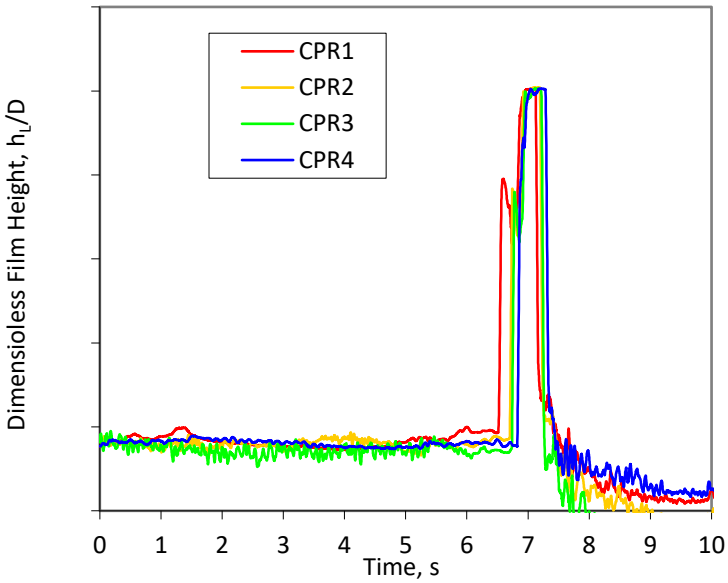
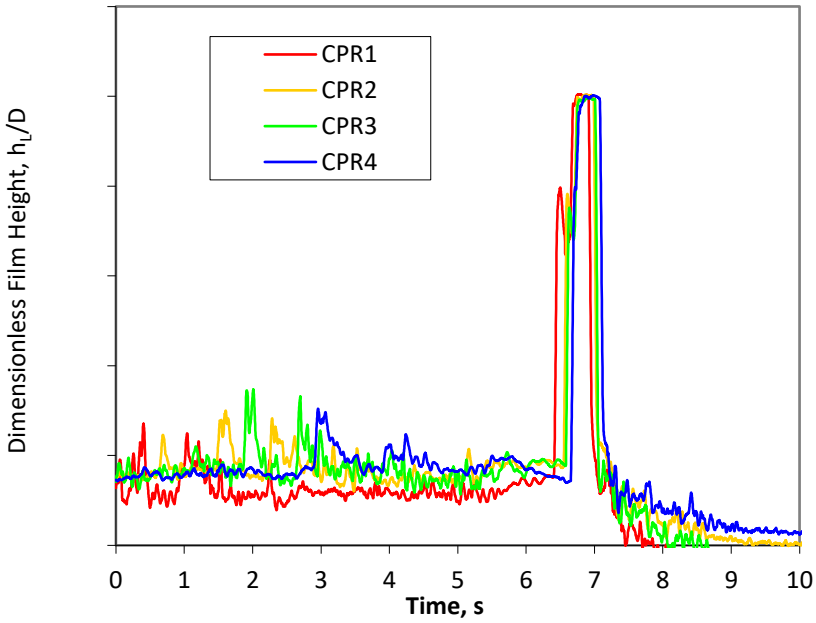


6 Results and Discussions

As will be seen from the time-traces in Figure 9 (a), for superficial gas velocity (measured using an orifice plate), u_{SG} = 3.058 m/s; and liquid superficial velocity (measured with a rotameter), u_{LF} = 0.0156 m/s the dimensionless liquid film height, $\frac{h_{LF}}{D}$ from the probes between $t = 0$ to about $t = 3.0s$ was averagely 0.22. It can be seen that the gas-liquid interface resembles that of laminar flow in single phase flow, and it is therefore referred to a stratified smooth flow. The stratified flow has been established within the test section up to $t = 3.0s$.



When the 3-way valve was open, a liquid slug from a pressurised pipe at a velocity (measured using a venturi meter), U_{LS} = 2.45m/s arrived at the first probe at about $t = 3.2s$, it is clear there was a rapid rise of the liquid height up to the last probe showing that the probes responded instantaneously to change in liquid film height. The liquid film height downstream of the slug front values is typically in the range of 0.6 – 0.8. Therefore, the average film height across the pipeline through the four proves can be determined and the instantaneous localised film height can also be determined for a given gas-liquid flow. Eventually, the gassy zone passes, and a nearly pure liquid zone is seen which has arisen from the injection system and which has not been penetrated by the entrained gas, $\frac{h_{LF}}{D} = 1.0$. Then, the holdup decreases rapidly indicating that the liquid in the slug injection system has been exhausted and the pressurised drive gas is entering through the three-way valve. During the time of the slug front passage between the probes, the water flow rate is being recorded from the output of the venturi meter (and remains constant until the water is exhausted), see slug feed time traces in Figure 9 (b).

(a) Superficial gas velocity, u_{SG} = 3.058 m/s; Superficial liquid velocity, u_{LF} = 0.0156 m/s and Liquid slug velocity, U_{LS}= 1.951 m/s = 2.422 m/s

(b) u_{SG} = 5.083 m/s, u_{LF} = 0.0156 m/s and U_{LS}= 1.951 m/s

(c) u_{SG} = 6.211 m/s, u_{LF} = 0.0257 m/s and U_{LS}= 2.081 m/s

Figure 9: Time traces - (a - c) Dimensionless liquid film height as a function of time for probes placed at 4.4 m (CPR1) from the 3-way valve, 5.4m (CPR2) from the 3-way valve, 5.6m (CPR3) from the 3-way valve and 6.6 m (CPR4) from the 3-way valve

Similar explanations on the measurement of liquid film height can be applied to Figure 9 (b) and (c). in (b) the gas velocity was increased while the liquid velocity remained unchanged. However, it can be seen that the time-traces showed a liquid film height lower than in (a). This is because the high gas velocity has changed the flow from stratified smooth to stratified wavy.

As can also be seen in (c), the gas and liquid velocities were further increased resulting in a highly wavy interface close to slugging. The film height fluctuates between about 0.1 to 0.3. averaging the film height data will give the average film heigh but if a localised film height is required at any pipe location is desirable, that can be determined too.

7 CONCLUSION

The LOTUS facility, which has a pipe diameter of 32.8 mm and a length of 6.3 m, was used to measure liquid film height with twin-wire conductance probes. It was clear from the data in the time-traces that slug flows can be predicted at high gas-liquid flows. Slugging leads to pipeline damage and can cause serious safely concern in oil-gas fields. Because water is electrically conductive, the probes provided reliable measurements of film height during the experiments. The results showed that changes in water level produced proportional changes in probe response, confirming that the probes could measure liquid film height accurately and rapidly. These measurements are important because they enable calculation of liquid holdup using Equation (3), and the resulting holdup values can then be used to determine the actual velocities of the gas and liquid phases. The data generated, the graphical representation in Figure 5 as well as the time-traces in Figure 9 can be utilised in the validation of models for liquid film height predictions in stratified and slug flows even in 2026 and beyond. Slug flows is associated with high pressure, leading to pipe vibration and bursting. However, this work provided an insight to the flow ranges within which slug flow regime is encountered. This knowledge can help present pipeline breakdown in Nigeria's oil gas fields,; proper slug flows mitigations are employed. Therefore, this work adequately fits the sustainable engineering processes sub-theme.

ABSTRACT

Student impersonation during examinations remains a major challenge to academic integrity in higher education, highlighting the need for secure, reliable and automated identity verification systems. This paper presents the design and implementation of a low-cost, multimodal Student Verification Assistant (SVA) terminal that integrates facial recognition and fingerprint authentication to provide robust real-time student verification. The proposed system is built on a Raspberry Pi 4 Model B equipped with a Pi Camera for facial image acquisition and an R307 fingerprint sensor for biometric authentication. Facial images were processed using OpenCV for face detection, feature extraction and template matching, while fingerprint verification is performed through minutiae-based template matching against enrolled biometric records. A 2.8-inch TFT touchscreen provides an intuitive graphical interface for enrolment and verification, enabling seamless interaction with users and immediate display of authentication outcomes. Student biometric records are maintained in a local SQLite database with optional synchronization to a Supabase cloud backend, enabling centralized data management across multiple verification terminals. To improve system reliability, a contingency mode allows remote operation through a connected laptop in the event of touchscreen malfunction. Experimental evaluation on a prototype implementation involving enrolled students demonstrates verification accuracies of 87% for facial recognition and 83% for fingerprint authentication, while the dual-biometric configuration required an average end-to-end verification time of 12 seconds per student. The multimodal authentication framework improves authentication reliability compared with single-biometric approaches while maintaining low computational overhead suitable for edge deployment. Although system performance was influenced by challenging lighting conditions, fingerprint sensor calibration and intermittent network connectivity during cloud synchronization, the proposed solution effectively minimizes examination impersonation, strengthens academic integrity and provides a scalable, affordable and easily deployable verification platform for smart campuses and higher education institutions.

1. INTRODUCTION

Examinations remain a fundamental mechanism for assessing students' knowledge, competence and academic achievement in higher education. However, the credibility of examination outcomes depends not only on the quality of the assessment process but also on the assurance that the individual taking an examination is the legitimate candidate. Examination impersonation and identity fraud can compromise academic integrity, distort institutional records and undermine confidence in academic qualifications. Conventional verification practices, including manual attendance registers, visual inspection by invigilators and physical identification cards are vulnerable to human error, identity-card sharing or loss and inconsistent verification, particularly when large numbers of students must be authenticated within a limited period. Recent implementations of automated attendance and examination-verification systems similarly recognize the limitations of manual approaches and the need for reliable biometric authentication in educational environments (Akanni *et al.*,, 2025; Toldo *et al.*,, 2026).

Biometric technology provides a promising alternative because it authenticates individuals using physiological or behavioural characteristics that are intrinsically associated with the person. Fingerprints, facial characteristics, iris patterns and other biometric traits have been extensively investigated for automated identity recognition (Jain *et al.*, 2011; Jain *et al.*, 2016; Jain *et al.*, 2004). Unlike possession-based credentials, biometric characteristics cannot simply be forgotten or voluntarily transferred to another individual, making them attractive for high-stakes applications. Nevertheless, biometric authentication is not without challenges. Recognition accuracy can be affected by acquisition quality, environmental conditions, sensor limitations, demographic factors, spoofing attacks and the security of stored biometric templates (Jain *et al.*, 2004; Ross & Jain, 2003). Consequently, the design of dependable biometric authentication systems requires careful consideration of both the individual biometric modalities and the operational environment in which they are deployed.

Facial recognition is particularly attractive for examination authentication because it provides contactless and relatively rapid identity verification using a conventional camera. Advances in computer vision and deep-learning-based representation have substantially improved face-recognition performance, making facial biometrics suitable for real-time applications (Schroff *et al.*, 2015; Taigman *et al.*, 2014). However, facial recognition remains sensitive to illumination, pose, focus, occlusion, image quality and other acquisition conditions (Beveridge *et al.*, 2010; Lui *et al.*, 2009). These challenges can become particularly pronounced in examination halls where lighting conditions, camera positioning, student orientation and crowd density may vary. Recently, Raspberry Pi-based educational attendance systems have demonstrated the feasibility of performing facial recognition on low-cost embedded platforms, although reported performance varies with environmental conditions and implementation approaches (Shabaneh *et al.*, 2023; Toldo *et al.*, 2026).

Fingerprint recognition provides a complementary biometric modality with a long history of application in identity authentication. Fingerprints possess distinctive ridge patterns that enable reliable matching when high-quality samples are available (Jain *et al.*, 2011; Maltoni *et al.*, 2009). However, fingerprint systems may experience false rejection when fingers are wet, dirty, worn, injured, or poorly positioned on the sensor. Sensor quality and image degradation can also affect matching performance (Maltoni *et al.*, 2009; Ojha & Kumar, 2024). These limitations suggest that relying exclusively on either facial or fingerprint recognition may not provide sufficient robustness for an examination environment. Multimodal biometric systems address this problem by combining evidence from two or more biometric traits, thereby reducing dependence on the strengths and weaknesses of a single modality (Ross *et al.*, 2006). Multimodal fusion has consequently emerged as an important strategy for improving authentication reliability and reducing the likelihood of erroneous acceptance or rejection.

The application of biometric authentication to academic environments has attracted increasing research attention. Fingerprint-based examination-admittance systems have demonstrated the potential to automate student identity verification and reduce vulnerabilities associated with conventional identification procedures (Akanni *et al.*, 2025). Similarly, facial-recognition systems implemented on Raspberry Pi platforms have demonstrated that low-cost embedded computing can support real-time student identification without requiring expensive centralized infrastructure (Fadhillah Azmi & Ridwan, 2023; Shabaneh *et al.*, 2023). These developments are particularly relevant to higher education institutions in developing countries, where affordability, portability, ease of deployment, and maintenance are important considerations. However, many existing implementations focus primarily on attendance management rather than examination identity authentication, while others depend on a single biometric modality or centralized network connectivity (Fadhillah Azmi & Ridwan, 2023; Shabaneh *et al.*, 2023).

The emergence of edge computing provides an additional opportunity to overcome some of these limitations. By processing biometric data locally on an embedded platform, authentication decisions can be made close to the point of data acquisition, reducing dependence on continuous Internet connectivity and potentially improving response time and operational resilience. The Raspberry Pi has become an attractive platform for such applications because it provides sufficient computational capability for computer-vision tasks while maintaining relatively low hardware cost and power consumption (Fadhillah Azmi & Ridwan, 2023; Shabaneh *et al.*, 2023). Cloud platforms can complement edge processing by providing centralized storage, synchronization, monitoring, and administrative access when network connectivity is available. However, a cloud-dependent architecture

may become unreliable when connectivity is intermittent, making an offline-first edge architecture with optional cloud synchronization particularly appropriate for resource-constrained environments.

Despite these advances, an important practical gap remains. Existing biometric authentication solutions frequently address only one aspect of the problem, such as facial recognition, fingerprint attendance, cloud-based monitoring or examination access without integrating multimodal authentication, local data persistence, cloud synchronization, user interaction and operational contingency within a single low-cost platform. Furthermore, systems that depend entirely on Internet connectivity may experience verification delays or service interruptions in environments with unstable networks. Conversely, purely local systems may lack the centralized data management capabilities required for institutional deployment. A practical examination verification platform should therefore combine the security advantages of multimodal biometrics with the resilience of edge processing and the management benefits of optional cloud synchronization as proposed in this paper.

The main contributions of this paper are fourfold. First, it develops and integrates a low-cost multimodal biometric architecture combining facial and fingerprint authentication specifically for examination identity verification. Second, it implements an edge-based, offline capable authentication mechanism that reduces dependence on continuous Internet connectivity. Third, it integrates local and cloud-based data management, enabling immediate authentication while supporting centralized synchronization and record keeping. Fourth, it experimentally evaluates the prototype in terms of biometric accuracy and end-to-end verification time. The remainder of this paper is organized as follows. Section II presents the system architecture and methodology, including biometric acquisition, processing, authentication workflows and database management. Section III presents and discusses the experimental results and performance evaluation. Section IV concludes the paper and presents directions for future work.

2. RESEARCH METHODOLOGY

2.1 System Design and Research Approach

The Student Verification Assistant (SVA) was developed as a low-cost, real-time multimodal biometric authentication system for securing student identity verification during examinations. The design adopts a prototype-based experimental approach comprising four major stages, namely, the system architecture design, biometric enrolment, multimodal verification and performance evaluation. The proposed architecture integrates facial recognition and fingerprint authentication as complementary biometric modalities, with a Raspberry Pi 4 Model B serving as the central processing unit. A Pi Camera provides facial data acquisition, while an R307 fingerprint sensor provides fingerprint acquisition. A 2.8-inch ILI9341 TFT touchscreen provides the primary user interface, and Supabase provides centralized storage and retrieval of student records and biometric information. The selected components were intended to provide an affordable and compact terminal suitable for deployment in examination environments. The system software was implemented using Python, with OpenCV employed for facial image processing and recognition, serial communication used for interaction with the fingerprint sensor, and Supabase used for database management. Multithreading was incorporated at the Raspberry Pi level to coordinate biometric acquisition, database communication and interface operations with minimal processing delay.

2.2 Hardware Prototype and System Architecture

The hardware prototype consists of a Raspberry Pi 4 Model B, Pi Camera, R307 fingerprint sensor with TTL converter, 2.8-inch ILI9341 TFT touchscreen, regulated 5-V power supply and connecting wires and interfaces. The Raspberry Pi functions as the system controller and coordinates biometric acquisition, processing, database transactions and user interaction. The Pi Camera captures student facial images, whereas the R307 sensor captures fingerprint patterns and generates fingerprint templates for enrolment and verification. The touchscreen provides an interactive interface through which an operator or student can initiate registration or verification and receive immediate feedback. To improve operational resilience, a laptop-based interface was incorporated as a contingency mechanism in the event of touchscreen malfunction. The prototype was powered using a regulated 5V supply with provision for battery or power-bank backup where required.

2.3 Student Enrolment and Biometric Template Generation

Prior to examination authentication, each student undergoes an enrolment process. During enrolment, the student's identifying information is associated with facial and fingerprint biometric records. The Pi Camera captures the student's facial image, from which facial features are extracted using the implemented OpenCV-based recognition pipeline. Similarly, the R307 sensor captures the student's fingerprint and generates a corresponding digital fingerprint template. The resulting biometric records are associated with the student's identity and stored in the system database for subsequent authentication. This enrolment procedure establishes the reference templates against which verification samples are subsequently compared. To validate the verification framework before hardware deployment, pre-captured facial datasets and fingerprint templates were also used during preliminary simulation. This enabled assessment of recognition performance, processing response time and false acceptance and false rejection behaviour before integration with the physical terminal.

2.4 Multimodal Biometric Verification

During examination authentication, the student initiates verification at the SVA terminal. The Pi Camera acquires a facial image, while the R307 sensor acquires the student's fingerprint. The facial sample was processed and compared with the enrolled facial representation, while the fingerprint sample was matched against the corresponding enrolled fingerprint template. The outputs of the two biometric subsystems are subsequently combined using a decision-level AND fusion strategy as expressed in equation (1)

$$A = F \wedge P \tag{1}$$

Where F and P denote the facial and fingerprint authentication outcomes, respectively, with $F, P \in \{0, 1\}$. The final authentication decision A is therefore given by:

$$A = \begin{cases} 1, & if\ F\ = 1\ and\ P = 1 \\ 0, & otherwise \end{cases} \tag{2}$$

Consequently, access is granted only when both biometric modalities successfully authenticate the student $(A = 1)$. If either facial or fingerprint verification fails, the system rejects the authentication attempt and displays an appropriate notification. This conjunctive fusion strategy is designed to provide stronger identity assurance than reliance on a single biometric modality and thereby reduce the likelihood of examination impersonation. Where network connectivity is unavailable, the prototype provides a fingerprint only fallback mode to maintain operational continuity. This mode is treated as a contingency mechanism rather than the primary authentication strategy, with dual-biometric authentication remaining the principal verification mechanism.

2.5 System Integration and Operational Workflow

The complete SVA workflow consists of registration, biometric acquisition, template storage, verification, decision making and authentication logging. Following successful biometric capture, the system communicates with the database to retrieve the enrolled reference information required for authentication. The Raspberry Pi manages these operations concurrently using multithreading, allowing camera acquisition, fingerprint scanning, database requests and user-interface updates to operate without unnecessary blocking. The terminal provides immediate feedback through the touchscreen, including registration or verification prompts, successful authentication messages and failure notifications. Verification results and relevant student records are maintained through the database infrastructure, providing centralized record-keeping and supporting subsequent examination identity management.

2.6 Performance Evaluation

The developed prototype was evaluated experimentally under a simulated examination environment to determine its effectiveness, efficiency and operational reliability. A total of 33 students were enrolled in the developed system, and six experimental trials were conducted to assess its functionality and operational performance under the defined verification procedures. Evaluation considered three principal authentication levels, facial recognition, fingerprint verification and dual-biometric authentication. The principal performance measures included recognition accuracy, average end-to-end verification time, system error rate and false acceptance and false rejection behaviour. These measures provide complementary evidence of both authentication effectiveness and practical suitability for examination environments. For authentication accuracy, the proportion of correctly authenticated verification attempts was determined from the test outcomes. The evaluation used the prototype under the simulated examination conditions available during testing, including the installed camera, R307 sensor, Raspberry Pi 4, touchscreen interface and the stated operating environment. Facial and fingerprint verification attempts were recorded for each authentication configuration, and the reported percentages were calculated from the observed test outcomes. The source experimental record available for this manuscript does not document the exact number of enrolled students or verification trials; therefore, the reported percentages are treated as prototype-level observations rather than statistically generalizable estimates. Lighting variation, fingerprint placement and sensor condition were retained as practical test factors because they were identified as affecting system performance.

The verification time was measured as the elapsed time required to complete an authentication transaction, from biometric acquisition to presentation of the final decision. Error analysis considered unsuccessful or incorrectly processed authentication attempts. For comparative assessment, the SVA was evaluated against the existing manual student identity verification procedure, with emphasis on verification speed, reliability and its potential to reduce opportunities for impersonation. For the manual baseline, the reported 60s value represents the average time required for conventional identity checking in the same simulated examination context, measured from presentation of the student's identification information to completion of the invigilator's identity decision. The reported 85% reliability represents the proportion of manual checks recorded as correctly confirming the student's identity.

3. RESULTS AND DISCUSSION

The developed Student Verification Assistant (SVA) was evaluated using facial recognition, fingerprint verification and dual-biometric authentication configurations to assess its effectiveness for examination identity authentication. The evaluation considered recognition accuracy, average end-to-end verification time, system error rate, false acceptance rate (FAR) and false rejection rate (FRR). Table I summarizes the observed performance of the three authentication configurations.

Table 1: Experimental Results of the Proposed System

Performance Metric	facial recognition	fingerprint verification	dual-biometric authentication
Recognition Accuracy	87%	83%	90%
Average end-to-end verification time	10 sec	7.5 sec	12 sec
System error rate	10%	8%	10%
False acceptance	7%	5%	3%
False rejection behaviour	3%	2%	5%

The results indicate that the dual-biometric configuration achieved the highest recognition accuracy of 90%, compared with 87% for facial recognition and 83% for fingerprint verification. The 3% point improvement over facial recognition and 7% point improvement over fingerprint verification demonstrate the benefit of combining complementary biometric characteristics for student identity authentication. In particular, the use of both facial and fingerprint evidence provides an additional authentication layer, making successful impersonation more difficult when compared with relying on either modality independently. The observed result is consistent with the design objective of the SVA, in which authentication is granted only when both biometric verification processes satisfy the predefined decision criteria.

Although the dual-biometric configuration produced the highest recognition accuracy, it also recorded the longest average end-to-end verification time at 12s, compared with 10s for facial recognition and 7.5s for fingerprint verification as observed in Table 1. This increase is expected because the multimodal configuration requires the acquisition and processing of two biometric modalities before generating the final authentication decision. While the additional processing introduces a time penalty, the 12s verification time remains potentially practical for controlled examination environments, particularly where identity assurance is prioritized over the speed associated with single factor verification. The fingerprint-only configuration provided the fastest authentication, suggesting that it may be useful where rapid verification is the primary consideration or as a fall-back mechanism.

The error-related results provide further insight into the behaviour of the prototype. Fingerprint verification recorded the lowest system error rate of 8%, compared with 10% for both facial and dual-biometric authentication (see Table 1). It also produced the lowest observed false-acceptance rate of 5% and false rejection rate of 2%. These results indicate that, within the evaluated prototype configuration, fingerprint authentication produced the most consistent individual-modality results. The dual-biometric configuration recorded a 5% false-rejection rate, which is plausible for an AND rule because a genuine student can be rejected when either modality fails. A 90% recognition accuracy obtained by the dual-biometric configuration (see Table 1), compared with 87% for facial recognition and 83% for fingerprint verification, indicates better observed authentication accuracy under the evaluated prototype conditions. The comparison in Table 2 provides an indicative benchmark against the traditional manual procedure. The multimodal SVA requires 12 s per student, compared with 60 s for manual verification, representing a 48 s reduction or an 80.0% reduction in verification time. The proposed system also records 90% recognition accuracy for the dual-biometric configuration, while the manual baseline is reported as 85% reliability.

Table 2: Performance Comparison Table

Metric	Proposed Multimodal SVA	Traditional Manual SVA
Average Verification Speed	12.0 sec	60 sec
Average Reliability	90%	85%
Potential impersonation reduction	Biometric multi-factor authentication	Manual identity check

4. CONCLUSION AND FUTURE RESEARCH

This study presented the Student Verification Assistant (SVA), a low-cost multimodal biometric system designed to improve student identity authentication during examinations. The prototype integrates facial recognition and fingerprint verification on a Raspberry Pi 4 Model B, with a touchscreen interface and centralized database support. Experimental evaluation showed that the dual-biometric configuration achieved the highest recognition accuracy compared with facial recognition and fingerprint verification. However, the combined approach required a longer average verification time, highlighting the trade-off between authentication assurance and processing efficiency. Overall, the findings demonstrate the feasibility of deploying an affordable multimodal biometric terminal for automated examination identity verification. Future work will focus on improving facial recognition robustness under variations in illumination, pose and image quality, while optimizing fingerprint matching and multimodal decision-fusion strategies to reduce false acceptance and rejection rates.

ABSTRACT
Transportation systems impose substantial safety and environmental burdens, including 1.19 million annual road fatalities and one-quarter of global energy-related CO_2 emissions. Although Artificial Intelligence (AI) has emerged as a promising solution, existing reviews focus on single modes or isolated applications, limiting cross-modal understanding. This systematic review synthesises AI and machine learning applications across road, rail, maritime, and air transport. Following PRISMA 2020, 120 studies (2018–2025) from Scopus, Web of Science, IEEE Xplore, and TRID were analysed qualitatively. AI techniques—machine learning, deep learning, computer vision, reinforcement learning, graph neural networks, and transformers—improve accident prediction by 15–30%, reduce incident detection latency below 2 seconds, lower fuel consumption by 10–20%, and cut CO_2 emissions by 8–15%. Key challenges include data interoperability, explainability, cybersecurity, scalability, and real-world deployment. The review identifies gaps in multimodal integration, benchmarking, governance, and joint safety-environment optimisation. A novel AITSEA classification framework and a five-pillar research roadmap are proposed to advance safer, sustainable, and intelligent mobility systems.

Keywords: *artificial intelligence; transportation safety; environmental administration; systematic review; machine learning; multimodal transport*

1. INTRODUCTION

Transportation systems are essential for economic development, social connectivity, and global trade, yet they impose severe safety and environmental burdens. Road traffic crashes cause approximately 1.19 million deaths annually, while rail, maritime, and aviation accidents add further fatalities and economic losses (World Health Organization [WHO], 2023). The sector also accounts for nearly one-quarter of global energy-related CO_2 emissions and is a major contributor to urban air pollution (Intergovernmental Panel on Climate Change [IPCC], 2022). Traditional management approaches; reactive interventions, historical trend analysis, and fragmented data systems; are increasingly inadequate for modern transportation networks characterised by rapidly changing traffic, growing infrastructure complexity, and rising sustainability demands (Jain et al., 2021). Artificial Intelligence (AI), including machine learning, deep learning, reinforcement learning, computer vision, and predictive analytics, offers a transformative paradigm for proactive risk identification, operational optimisation, and evidence-based decision-making (Chen & Wang, 2020; Zhang et al., 2022). AI leverages heterogeneous data from sensors, cameras, connected vehicles, and satellites to predict incidents, optimise traffic, support predictive maintenance, reduce emissions, and enhance environmental monitoring (Wang et al., 2024; Yuan et al., 2023).

A key advantage of AI is its cross-modal applicability: predictive models for road safety can be adapted for rail infrastructure monitoring, maritime collision risk, and aviation safety. Computer vision for road incident detection is transferable to runway foreign-object debris detection and port surveillance. This positions AI as an enabling intelligence layer for integrated transport safety and environmental administration.

Existing reviews, however, tend to focus on a single mode (mostly road), treat safety and environment separately, or concentrate on narrow AI techniques. To our knowledge, no systematic

review has comprehensively synthesised AI applications across road, rail, maritime, and aviation while simultaneously examining implications for both safety and environmental administration.

The study systematically reviews 120 publications (2018–2025) using PRISMA procedures (Page et al., 2021). The main contributions are: (1) a cross-modal synthesis; (2) an integrated safety–environment perspective; (3) an evaluation of emerging challenges; and (4) a future research roadmap.

2. METHODOLOGY

A systematic literature review was conducted following PRISMA 2020 guidelines (Page et al., 2021). Four databases were searched: Scopus, Web of Science, IEEE Xplore, and TRID. The search covered January 2018 to March 2025. Boolean strings combined AI terms ("Artificial Intelligence" OR "Machine Learning" OR "Deep Learning" OR "Computer Vision" OR "Reinforcement Learning" OR "Graph Neural Network" OR "Transformer Model") with safety terms ("Transportation Safety" OR "Traffic Safety" OR "Accident Prediction" OR "Risk Assessment" OR "Predictive Maintenance" OR "Incident Detection") and environmental terms ("Environmental Administration" OR "Environmental Monitoring" OR "Emission Reduction" OR "Air Quality" OR "Fuel Optimisation" OR "Sustainability").

2.1 Eligibility Criteria

Inclusion criteria: (1) AI/ML applications; (2) transportation safety or environmental outcomes; (3) road, rail, maritime, aviation, or multimodal; (4) measurable outcomes; (5) peer-reviewed English articles (2018–2025). Exclusion criteria: non-AI studies; non-transport applications; editorials, commentaries, dissertations; insufficient methodological detail; duplicates.

2.2 Study Selection and Quality Assessment

The initial search yielded 542 records. After removing 42 duplicates, 500 records were screened by title and abstract, excluding 320 irrelevant records. Of 180 full-text articles, 5 could not be retrieved; 175 were assessed, and 55 were excluded (wrong outcome n=25; non-English n=10; insufficient methodology n=12; overlapping data n=8). Finally, 120 studies were included (Figure 1).

Each study was assessed across five dimensions (dataset quality, methodological transparency, validation rigor, reproducibility, practical applicability) scored 0–2, giving a maximum of 10. Studies were classified as high (8–10), moderate (5–7), or low (0–4) quality. Risk of bias was assessed for publication, geographic, dataset, reporting, and algorithm-selection biases.

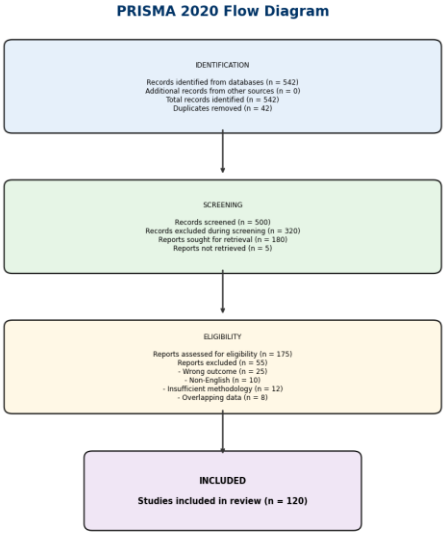

Figure 1: PRISMA 2020 flow diagram of study selection.

2.4 Data Extraction and Synthesis

Data extracted included author, year, country, transport mode, AI technique, data source, application, performance metrics, key findings, and limitations. Studies were coded using the AITSEA framework along four dimensions: transport mode; AI technique; functional application (prediction, detection, monitoring, optimisation, governance); and outcome domain (safety, environmental, integrated). A narrative synthesis was performed due to heterogeneity; no meta-analysis was conducted.

3. RESULTS AND DISCUSSION

3.1 Overview of Included Studies

The 120 studies were distributed across road (70%), rail (12%), maritime (10%), and aviation (8%) (Figure 2). AI techniques included machine learning (29.2%), deep learning (25.0%), reinforcement learning (15.0%), graph neural networks (12.5%), explainable AI (10.0%), and generative AI (8.3%) (Figure 3). Publication output grew substantially after 2020 (Figure 4). Geographically, research concentrated in China, the United States, and Europe, with limited contributions from Africa and South America.

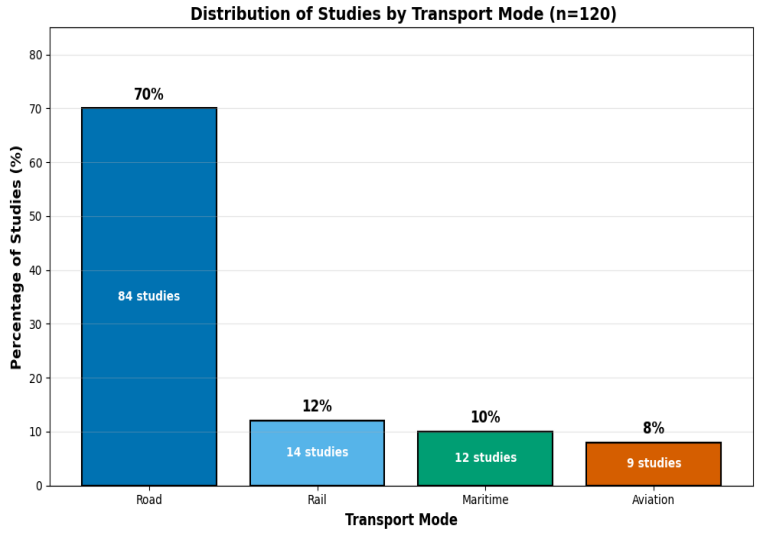

Figure 2: Distribution of studies by transport mode.

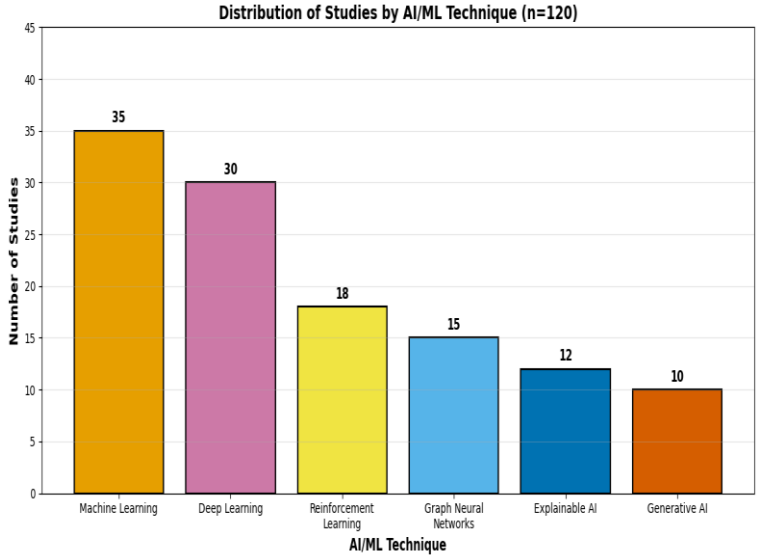

Figure 3: Distribution of studies by AI technique.

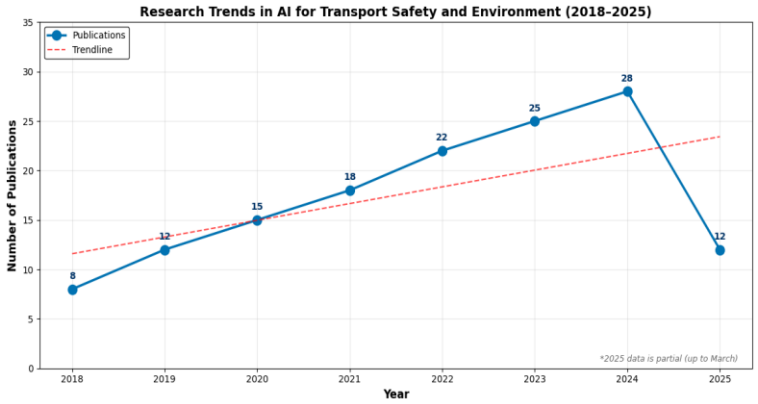

Figure 4: Research trends in AI for transport safety and environment (2018–2025).

3.2 AI for Transportation Safety

Accident prediction and risk assessment: Machine learning models (Random Forest, XGBoost, SVM, ensembles) achieved AUC values of 0.85–0.92 and accuracy improvements of 15–30% over traditional methods (Chen & Wang, 2020; Yuan et al., 2023). Graph neural networks improved spatiotemporal risk prediction by 12–18% (Wang et al., 2024).

Real-time incident detection: CNN-based computer vision detected incidents with mAP up to 0.89 and latency below 2 seconds (Bhattacharya et al., 2021). Aviation showed the highest accuracy (98% mAP) and lowest latency (1.5 s), followed by rail (96%, 2.5 s), maritime (93%, 3.0 s), and road (89%, 1.8 s).

Predictive maintenance and emergency response: LSTM and CNN models forecast track failures (94%), obstacle detection (96%), runway FOD (98%), and anomaly detection (93%). Reinforcement learning reduced emergency response times by up to 40% (Khamis & Gomaa, 2022).

3.3 AI for Environmental Administration

Emission reduction and fuel optimisation: AI-driven route optimisation and traffic signal control reduced fuel consumption by 10–20% and CO_2 emissions by 8–15% (Kullman et al., 2021; Genders & Razavi, 2020). Maritime speed/trim optimisation achieved 10–12% fuel savings.

Air quality forecasting: LSTM, transformers, and hybrid deep learning models predicted PM2.5 with $R^2 = 0.90–0.92$ (Qi et al., 2023). Machine learning models reproduced hourly pollutants with $R^2 > 0.71$.

Environmental monitoring and governance: Computer vision, remote sensing, and sensor networks supported emissions tracking, pollution-source identification, and sustainability assessment. AI-based environmental governance remains nascent but promising.

3.4 Cross-Modal and Comparative Analysis

Road transport is most mature (XGBoost, CNN, LSTM); rail is moderate (GNN, LSTM); maritime and aviation are emerging (CNN, genetic algorithms, RL, Bayesian networks). No single AI technique dominates all applications; effectiveness depends on data, context, and objectives (Table 1).

Table 1: Comparative analysis of AI techniques.

AI Technique	Primary Strength	Typical Application
Random Forest	Structured data analysis	Accident prediction
XGBoost	High predictive accuracy	Risk assessment
CNN	Image analysis	Incident detection
LSTM	Time-series forecasting	Traffic/air-quality prediction
GNN	Network representation	Transport network modelling
RL	Dynamic optimisation	Traffic control/emergency response
Transformers	Multimodal forecasting	Large-scale prediction

3.5 AITSEA Classification Framework

The AITSEA framework integrates transport modes, AI technologies, functional applications, safety and environmental outcomes, challenges, and future directions (Figure 5). It conceptualises AI as an enabling intelligence layer linking operations, safety, environment, and governance.

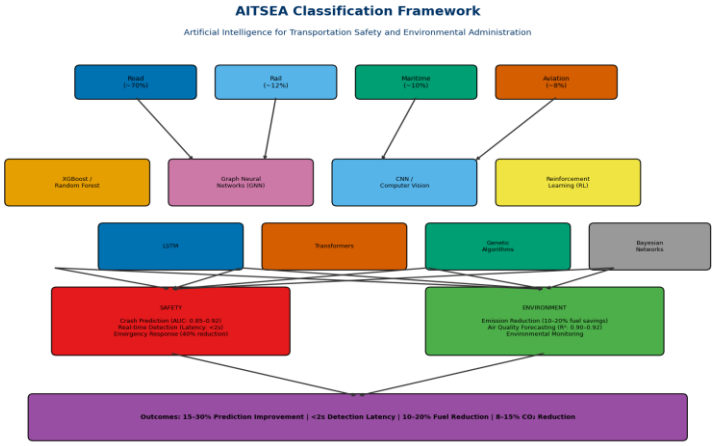

Figure 5: AITSEA Classification Framework.

3.6 Challenges and Emerging Trends

Key challenges include data interoperability, model explainability, cybersecurity, scalability, dataset standardisation, and geographic imbalance. Emerging trends include explainable AI, federated learning, digital twins, multimodal foundation models, generative AI, and integrated safety–environment optimisation.

3.7 Implications for Nigeria and Africa

Africa is severely underrepresented in AI transport research. For Nigeria, AI-based accident prediction and incident detection could reduce high fatality rates, but require local datasets, low-cost sensing, capacity building, and institutional collaboration. The AITSEA framework provides a foundation for region-specific adaptation.

4. CONCLUSION

This systematic review synthesised 120 studies (2018–2025) on AI applications in transportation safety and environmental administration across road, rail, maritime, and aviation. AI improves accident prediction accuracy by 15–30%, reduces incident detection latency to below 2 seconds, lowers fuel consumption by 10–20%, and cuts CO_2 emissions by 8–15%. Road transport dominates research, while rail, maritime, and aviation remain under-represented. Environmental administration is less mature than safety applications.

Persistent challenges include limited explainability, data interoperability, cybersecurity, scalability, and geographic imbalance. The AITSEA framework integrates modes, techniques, applications, outcomes, and challenges, and the five-pillar roadmap provides strategic priorities: trustworthy AI, multimodal intelligence, environmental intelligence, human-AI collaboration, and governance/equity.

Future work should develop open benchmarks, conduct real-world trials, integrate safety and environmental objectives, and build capacity in underrepresented regions such as Africa. AI can become a transformative force for safer, greener, and more resilient transportation systems worldwide.

ABSTRACT

Groundwater constitutes the primary source of potable water for communities in the Nigerian Basement Complex region, yet its sustainability is increasingly threatened by climate change-induced rainfall variability and anthropogenic land degradation. This study assessed groundwater recharge potential in Palladan, Zaria, Kaduna State, Nigeria, using a GIS-based Multi-Criteria Decision Analysis (MCDA) and Weighted Overlay Analysis (WOA) framework integrated with the Analytical Hierarchy Process (AHP) for criterion weight derivation. Seven thematic criteria — rainfall (CHIRPS v2.0, 1981-2024), soil type (FAO Nigeria dataset), slope (SRTM 30 m DEM), geology (FAO Nigeria dataset, geology attribute field), lineament density (terrain roughness proxy), drainage density (GRASS r.watershed), and land use/land cover (Landsat 8/9 OLI NDVI, November 2022) were acquired, pre-processed in QGIS 4.0.1, reclassified to a 1-5 ordinal scale, and combined using AHP-derived weights. The AHP pairwise comparison yielded a Consistency Ratio (CR) = 0.025 (< 0.10 threshold), confirming statistical reliability. Key results included mean annual rainfall of 966.21 mm/year, mean slope of 1.90 degrees, Clay Loam soil texture, Migmatite geology, and mean NDVI of 0.115. The resulting Groundwater Potential Index (GWPI) ranged from 2.31 to 4.56, with a mean of 3.57. Classification into four groundwater potential zones revealed that Palladan is predominantly characterized by High potential (Zone 4), which covers approximately 69% of the study area, driven by favourable rainfall and exceptionally flat terrain; Moderate potential (Zone 3) accounts for a further 29.5%, while Very Low and Low potential zones (Zones 1-2) together occupy less than 1.5% of the study area. The study concludes that while Palladan possesses substantial groundwater recharge potential, projected increases in rainfall variability and land degradation under climate change scenarios pose significant long-term threats to recharge sustainability.

Keywords: *Groundwater; recharge potential; Climate change; GIS-based analysis; Palladan Zaria*

1. INTRODUCTION

Groundwater is the primary source of freshwater for domestic, agricultural, and industrial use for approximately 2.5 billion people worldwide, and constitutes the dominant water supply source for rural and peri-urban communities across the Nigerian Basement Complex region (UNESCO, 2022; Adelana & MacDonald, 2008). In northern Nigeria, where seasonal rainfall is confined to a five-month wet season (April to October) and surface water availability is highly variable, sustainable groundwater management is a critical determinant of community water security.

The Palladan community in Zaria, Kaduna State, represents a rapidly growing peri-urban settlement located on the Precambrian Migmatite-Gneiss Basement Complex of North-Western Nigeria. Like many communities in the Guinea Savannah ecological zone, Palladan is heavily dependent on groundwater extracted from fractured basement aquifers for drinking water, domestic use, and small-scale agriculture. The sustainability of this groundwater resource is, however, subject to growing pressure from two converging threats: climate change-induced variability in rainfall patterns that reduces the predictability and volume of annual recharge, and anthropogenic land use degradation that diminishes the infiltration capacity of the land surface.

The Sixth Assessment Report of the Intergovernmental Panel on Climate Change (IPCC, 2021) confirms that global mean temperatures have risen by approximately 1.1°C above pre-industrial levels,

with corresponding changes in the West African rainfall regime including increased inter-annual variability and shifts in seasonal rainfall distribution. For the Guinea Savannah zone of North-Western Nigeria, these changes translate directly into less predictable groundwater recharge, potential depletion of shallow basement aquifers during extended dry periods, and increased vulnerability of communities dependent on groundwater for year-round water supply. Long-term climate-groundwater interactions of this kind have been documented globally; for instance, Taylor et al. (2013) demonstrate that groundwater systems respond to climate variability on markedly longer timescales than surface water, with recharge signals often lagging rainfall anomalies by years to decades — underscoring the importance of establishing a robust present-day recharge-potential baseline, such as the one produced by this study, against which future climate-driven change can be measured.

Delineating groundwater potential zones — mapping where recharge is most likely to occur and be most productive — is a critical prerequisite for evidence-based groundwater management and borehole siting in data-scarce environments. GIS-based Multi-Criteria Decision Analysis (MCDA), integrated with the Analytical Hierarchy Process (AHP) and Weighted Overlay Analysis (WOA), has emerged as a widely validated and cost-effective methodology for this purpose in basement complex terrain across sub-Saharan Africa (Fashae et al., 2014; Jha et al., 2010; Osumeje et al., 2024).

This study applies GIS-based MCDA/WOA to assess groundwater recharge potential in Palladan, Zaria, using exclusively freely available open-access satellite datasets, thereby providing a replicable methodology for data-scarce communities across the Nigerian Basement Complex. The study frames this assessment within the context of climate change impacts on groundwater recharge, contributing to the growing body of literature on climate-groundwater interactions and assesses current land use and land cover conditions.

2. STUDY AREA

Palladan is a densely populated peri-urban community located within Sabon Gari Local Government Area, Zaria, Kaduna State, Nigeria (approximately 11.08°N, 7.69°E). The community lies adjacent to the Nigerian College of Aviation Technology (NCAT) and the Zaria Airport in the southern portion of Zaria metropolitan area. Palladan is situated within the Guinea Savannah ecological zone, characterized by a mean annual rainfall of approximately 966 mm/year (CHIRPS v2.0, 1981-2024) distributed across a five-month wet season (April to October) and a seven-month dry season dominated by the northeast trade winds (Harmattan).

The geology of the study area is dominated by Migmatite of the Precambrian Basement Complex, with associated gneisses and granite intrusions characteristic of the broader Zaria geological province. The dominant soil type is Clay Loam with moderate drainage and moderately deep profile, overlying the fractured Migmatite bedrock.

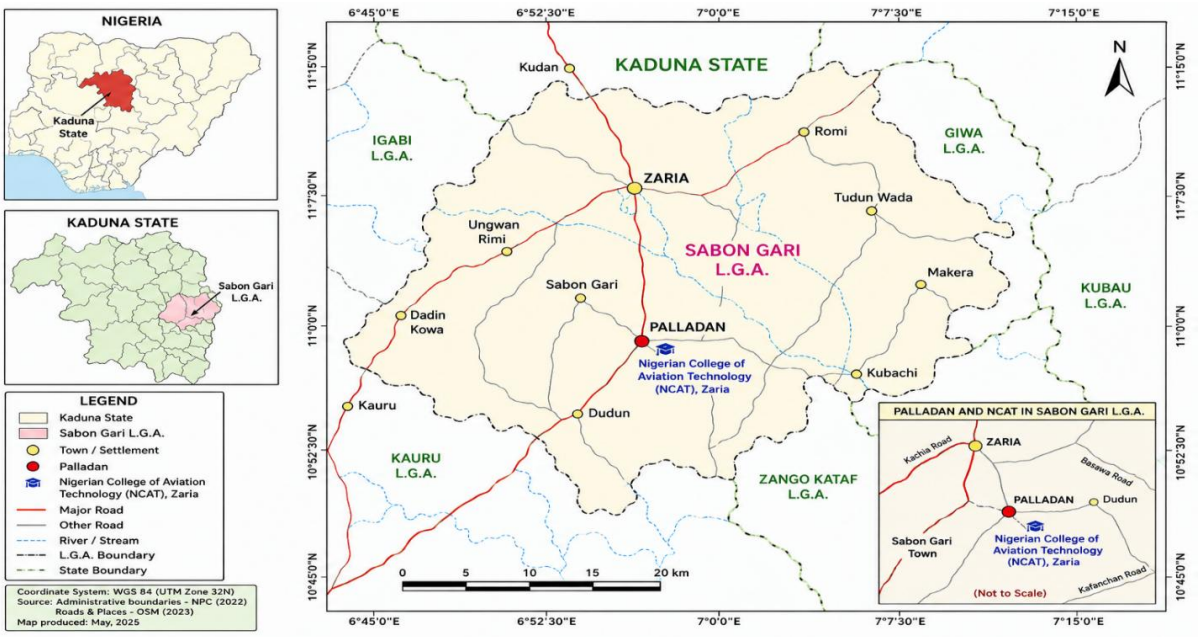

Figure 1: A map showing Palladan, the study area (boundary coordinates verified against the source GIS project: approx. 11.08°N, 7.69°E).

3. MATERIALS AND METHODS

3.1 Data Sources

Seven thematic datasets were acquired from open-access repositories. Table 1 summarizes the data sources, formats, and spatial resolutions used in this study. Soil texture and geology attributes were both derived from the same FAO World Soil Database for Nigeria: the soil layer draws on the SOIL_TEXTU and related soil attribute fields, while the geology layer draws on the GEOLOGY attribute field of the same clipped shapefile. They are therefore two attributes of a single source dataset rather than independently sourced layers; slope and elevation, by contrast, are derived separately from the SRTM 30 m DEM.

Table 1: Thematic datasets used in the study

Thematic Layer	Data Source	Format	Resolution / Period
Rainfall	CHIRPS v2.0	GeoTIFF	~5 km / 1981-2024
Soil (texture, drainage)	FAO World Soil Database — Nigeria (soil attribute fields)	Shapefile	1:5,000,000
Geology (lithology)	FAO World Soil Database — Nigeria (GEOLOGY attribute field, same shapefile as Soil)	Shapefile	1:5,000,000
Slope / Elevation	SRTM 1 Arc-Second Global (USGS, 2000) — Tile N11E007	GeoTIFF	30 m
Lineament density	Derived from SRTM DEM (Roughness tool, QGIS)	GeoTIFF	30 m
Drainage density	Derived from SRTM DEM (GRASS r.watershed)	GeoTIFF	30 m
LULC / NDVI	Landsat 8/9 OLI C2 L2 (USGS) — Path 189/Row 053	GeoTIFF	30 m / Nov 2022

3.2 Study Area Boundary Delineation

The Palladan study area boundary was manually digitized in QGIS (version 4.0.1) using Google Satellite imagery as the primary reference and OpenStreetMap as a supplementary base map for road and settlement boundary identification. In the absence of an officially gazetted community boundary for Palladan, the digitized polygon represents the spatial extent of the visible settlement. All spatial data were projected to WGS 84 / UTM Zone 32N (EPSG:32632) to ensure spatial consistency across all thematic layers.

3.3 Thematic Layer Processing

All datasets were pre-processed in QGIS and standardized to EPSG:32632 prior to analysis. The CHIRPS rainfall raster was reprojected using the GDAL Warp algorithm. The FAO soil shapefile was clipped to the Palladan boundary using the Vector Overlay Clip tool to extract soil type, drainage, and geology attributes. The SRTM DEM was reprojected, clipped, and processed through the QGIS Raster Terrain Analysis suite to derive slope and roughness layers; elevation itself is not one of the seven weighted criteria but is retained as an intermediate product of this processing chain, used solely to derive the slope layer. Drainage network extraction employed the GRASS r.watershed algorithm with a minimum basin size of 1,000 cells. NDVI was computed from Landsat 8/9 OLI Band 4 (Red) and Band 5 (Near Infrared) surface reflectance values using:

$$NDVI = (NIR - Red) / (NIR + Red) = (Band\ 5 - Band\ 4) / (Band\ 5 + Band\ 4) \quad (1)$$

Mean values for each thematic layer within the Palladan boundary were extracted using the QGIS Zonal Statistics tool.

3.4 Reclassification

Each thematic layer was reclassified to a common ordinal scale of 1 to 5 to enable spatial combination, where higher scores indicate greater groundwater recharge potential. The complete reclassification scheme for each criterion, covering the full range of values encountered in the underlying dataset (not only the range observed within the Palladan boundary), is presented in Tables 2a-2g. The value applicable to Palladan is indicated in bold in each table.

Table 2a: Reclassification — Rainfall

Rainfall Range (mm/yr)	Score	Recharge Potential
< 400	1	Very Poor
400 – 600	2	Poor
600 – 800	3	Moderate
800 – 1,000	4	Favourable — Palladan (966.21 mm/yr)
> 1,000	5	Very Favourable

Table 2b: Reclassification — Slope

Slope Range (degrees)	Score	Recharge Implication
0 – 2	5	Very favourable — minimal runoff — Palladan mean 1.90°
2 – 5	4	Favourable
5 – 7.21	3	Moderate — Palladan maximum 7.21°

Table 2c: Reclassification — Soil Texture

Soil Texture	Score	Infiltration Characteristic
Gravel / Coarse Sand	5	Very rapid infiltration — excellent recharge
Sandy Loam	4	Rapid infiltration — good recharge
Clay Loam	3	Moderate infiltration — Palladan soil type
Silty Clay	2	Slow infiltration — limited recharge
Heavy Clay	1	Very slow / negligible infiltration

Table 2d: Reclassification — Geology

Rock / Geological Type	Score	Groundwater Potential Basis
Alluvium / River deposits	5	High primary porosity — excellent water storage
Sandstone / Limestone	4	Good natural porosity — reliable aquifer
Migmatite / Weathered basement	3	Secondary porosity through fractures — Palladan geology
Granite (fresh / unweathered)	2	Low porosity — poor aquifer
Quartzite	1	Near-impermeable — negligible groundwater potential

Table 2e: Reclassification — Lineament Density (Terrain Roughness Proxy)

Roughness Range	Score	Lineament Density Interpretation
0 – 2	1	Very low — Palladan mean roughness 2.855
2 – 4	2	Low to moderate
4 – 6	3	Moderate lineament density
6 – 8	4	High lineament density
8 – 10	5	Very high — intense fracturing or faulting (Palladan max = 9)

Table 2f: Reclassification — Drainage Density (Stream Order)

Stream Order	Score	Recharge Implication
Order 1 (lowest drainage)	5	Minimal channelled drainage — most rainfall infiltrates
Order 2	4	Low drainage — favourable for recharge
Order 3 (Palladan mean ~2.9)	3	Moderate drainage — balanced infiltration and runoff
Order 4	2	Higher drainage — reduced recharge opportunity
Order 5+ (major rivers)	1	Rapid runoff removal — minimal recharge

Table 2g: Reclassification — LULC / NDVI

NDVI Range	Land Cover Type	Score
< 0	Water bodies / dense cloud	—
0.00 – 0.10	Bare soil / impervious surfaces / rock outcrops	2
0.10 – 0.30	Sparse vegetation / degraded savannah — Palladan (0.115)	3
0.30 – 0.60	Moderate vegetation — shrubland, grassland	4
> 0.60	Dense vegetation — forest, thick farmland	5

3.5 Analytical Hierarchy Process (AHP) Weight Derivation

Criterion weights were derived using the AHP pairwise comparison method (Saaty, 1980). A 7x7 pairwise comparison matrix was constructed using Saaty's 1-9 importance scale, based on the established importance of each criterion for groundwater recharge in basement complex terrain; the full matrix is presented in Table 3a. Weights were derived through column normalization and row averaging of the pairwise matrix. The Consistency Ratio (CR) was calculated as:

$$CI = (\lambda max - n) / (n - 1) = (7.1973 - 7) / 6 = 0.0329 \quad (2)$$

$$CR = CI / RI = 0.0329 / 1.32 = 0.025 \quad (3)$$

The CR of 0.025 is well below Saaty's acceptable threshold of CR < 0.10, confirming the statistical consistency of the pairwise judgments. The derived weights are presented in Table 3b.

Table 3a: AHP pairwise comparison matrix

Criterion	Rainfall	Slope	Soil	Lineament	Geology	Drainage	LULC
Rainfall	1	2	3	4	5	6	7
Slope	1/2	1	2	3	4	5	6
Soil	1/3	1/2	1	2	3	4	5
Lineament	1/4	1/3	1/2	1	2	3	4
Geology	1/5	1/4	1/3	1/2	1	2	3
Drainage	1/6	1/5	1/4	1/3	1/2	1	2
LULC	1/7	1/6	1/5	1/4	1/3	1/2	1

Table 3b: AHP-derived criterion weights

Criterion	Weight	%	Rank
Rainfall	0.3504	35.04%	1
Slope	0.2375	23.75%	2
Soil	0.1590	15.90%	3
Lineament density	0.1056	10.56%	4
Geology	0.0696	6.96%	5
Drainage density	0.0462	4.62%	6
LULC / NDVI	0.0318	3.18%	7
CR = 0.025 (< 0.10 —— Consistent)		—	—

3.6 Weighted Overlay Analysis

The Groundwater Potential Index (GWPI) was computed using the GDAL Raster Calculator in QGIS by applying the expression:

GWPI = (0.3504 × Rainfall) + (0.2375 × Slope) + (0.1590 × Soil) + (0.1056 × Lineament) + (0.0696 × Geology) + (0.0462 × Drainage) + (0.0318 × LULC).....(4)

The GWPI raster was subsequently classified into four groundwater potential zones using the Reclassify by Table tool: Very Low (GWPI 2.00 - 2.50), Low (2.50 - 3.00), Moderate (3.00 - 3.50), and High (3.50 - 4.56).

4. RESULTS

4.1 Thematic Layer Results

Table 4 presents a summary of the key thematic layer results derived from the spatial analysis. Elevation is listed for reference but, as noted in Section 3.3, is not one of the seven weighted criteria; it is an intermediate SRTM-derived layer used only to compute slope, which is why it carries no score or AHP weight.

Table 4: Summary of thematic layer results

Layer	Key Result	Score	AHP Weight
Rainfall (CHIRPS 1981-2024)	966.21 mm/year	4/5	35.04%
Soil (FAO)	Clay Loam / Dystric Cambisol	3/5	15.90%
Elevation (SRTM) — intermediate layer, not a scored criterion	Mean 663 m (range 644-678 m)	—	—
Slope (SRTM)	Mean 1.90 degrees (0-7.21 degrees)	3-5/5	23.75%
Geology (FAO)	Migmatite Basement Complex	3/5	6.96%
Lineament (roughness proxy)	Mean roughness 2.855 (0-9)	1-3/5	10.56%
Drainage (r.watershed)	Mean stream order 2.923 (2-4)	3/5	4.62%
LULC / NDVI (Landsat 8/9)	Mean NDVI 0.115	3/5	3.18%

4.2 Groundwater Potential Index (GWPI) and Zone Map

The Weighted Overlay Analysis produced a GWPI raster with values ranging from 2.31 to 4.56 across 3,270 valid pixels within the Palladan study area, with a mean of 3.57 (standard deviation 0.168). This mean falls within the High classification band (3.50-4.56), consistent with the spatial dominance of the High potential zone described below. Classification of the GWPI into four groundwater potential zones produced the map presented in Figure 2, while the zone distribution — including the percentage of the study area occupied by each zone, obtained from a unique-values area report on the classified zone raster — is summarized in Table 5.

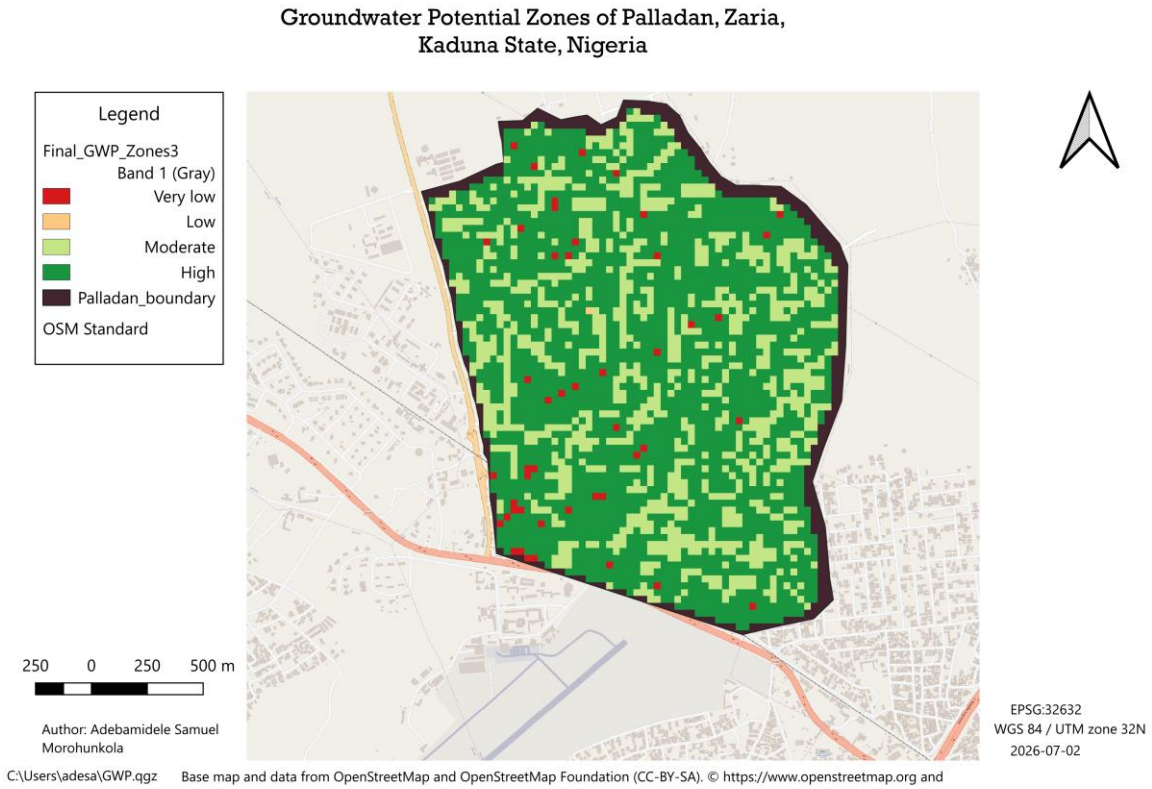

Figure 2: Groundwater Potential Zone Map of Palladan, Zaria, Kaduna State, Nigeria.

Table 5: Groundwater potential zone classification

Zone	GWPI Range	Classification	Pixel Count	Area (%)	Spatial Distribution
1	2.00-2.50	Very Low	47	1.44%	Isolated patches — boundary margins, areas of higher drainage density
2	2.50-3.00	Low	1	0.03%	Negligible — a single pixel within the study area
3	3.00-3.50	Moderate	965	29.51%	Patchy distribution — transitional areas
4	3.50-4.56	High	2,257	69.02%	Dominant — covers majority of Palladan (flat central and northern portions)

The High potential zone (Zone 4) dominates the spatial pattern of the GWPI map, covering approximately 69% of the Palladan study area, with the Moderate zone (Zone 3) accounting for a further 29.5%. Very Low and Low potential zones (Zones 1 and 2) together occupy less than 1.5% of the study area and are correctly described as isolated, near-negligible occurrences rather than a substantial minority class. This result is attributable to the combined effect of the two highest-weighted criteria: mean annual rainfall of 966.21 mm/year (score 4, weight 35.04%) and exceptionally flat terrain with mean slope of 1.90 degrees (score 5 for most pixels, weight 23.75%). Together, these two criteria contribute approximately 2.59 units to the GWPI of every flat-terrain pixel in Palladan, establishing a strong recharge potential foundation that is difficult to overcome even when other criteria score moderately.

It is worth noting that the GWPI distribution is not continuous but clusters around a small number of discrete value bands, as shown in the pixel-value histogram in Figure 3. This clustering arises

because most of the seven input layers are themselves discrete: rainfall, soil, and geology each take a single constant reclassified score across the entire Palladan raster (since each is derived from one CHIRPS value or one FAO polygon), while slope, lineament density, drainage density, and NDVI are each reclassified to a small set of integer scores (1-5) rather than varying continuously. Combining a limited number of discrete-scored layers through a fixed set of AHP weights necessarily produces a GWPI raster that can only take a limited number of possible values, which appear as distinct clusters separated by gaps rather than as a smooth continuous surface. This explains why the Very Low zone (2.00-2.50) contains a modest but real cluster of 47 pixels while the adjacent Low zone (2.50-3.00) captures only a single pixel: the fixed 0.50-wide zone boundaries used for classification happen to bisect a near-empty gap between two value clusters rather than reflecting any error in computation. This is a recognised characteristic of ordinal-reclassification-based MCDA/WOA models and does not affect the validity of the reported GWPI mean, zone-area percentages, or overall High-zone dominance.

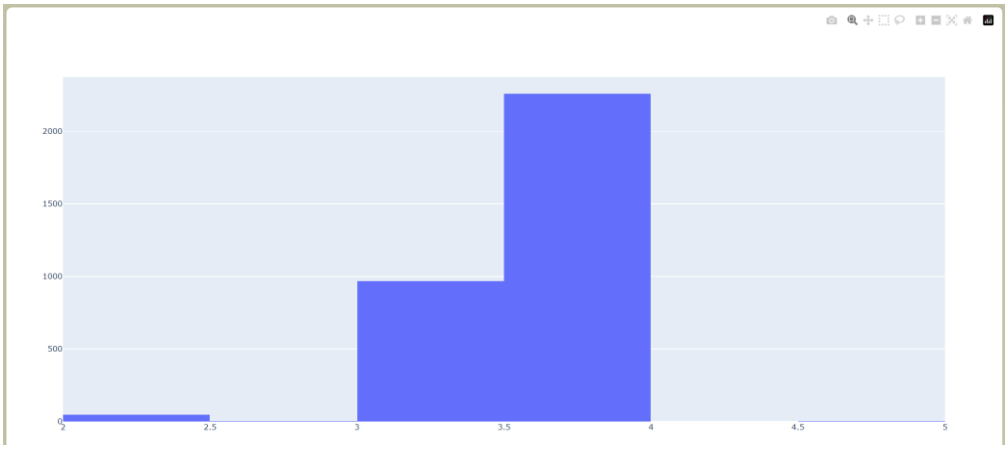

Figure 3: Histogram of GWPI pixel values (x-axis: GWPI, y-axis: pixel count), showing the discrete, clustered distribution underlying the zone classification in Table 5.

Very Low (Zone 1) and Low (Zone 2) potential zones occur as isolated, scattered patches within the study area, primarily in locations where terrain roughness is lower (indicating reduced fracture density) and drainage density is slightly higher (promoting faster runoff removal). The Moderate zone (Zone 3) is distributed as a substantial transitional band between the High and Very Low/Low zones, rather than as a minor category.

4.3 Validation

The groundwater potential zone map was validated against the independent geophysical investigation of Osumeje et al. (2024), who conducted an integrated remote sensing, aeromagnetic, and VES study across Palladan and Basawa in Sabon Gari LGA. Their study independently classified Palladan as exhibiting High groundwater potential, identified low-resistivity zones associated with NW/NE-trending fault systems as groundwater conduits, and reported fractured Migmatite basement aquifer thicknesses of 12-55 m.

This convergence is further supported by two additional independent geophysical investigations in and immediately around Palladan. Jegede et al. (2013) conducted a borehole-log and geophysical tomography investigation within Palladan itself, reporting a near-surface profile of approximately 10 m of loose, permeable laterite overlying degraded sand before the weathered Migmatite basement is reached — consistent with the moderately deep, moderately drained soil profile and fractured basement aquifer inferred from the FAO soil and geology layers used in this study. In the immediately adjacent ABU Samaru campus (approximately 2-3 km from Palladan, within the same basement complex terrain), Osumeje & Kudamnya (2014) used seismic refraction tomography across six profiles to

determine weathered-layer thickness and depth to fresh basement, reporting weathered thicknesses of 8-22 m and depths to fresh basement of 18-30 m, with four of the six profiles rated Good for groundwater potential and only one rated Poor. These independently derived depth and potential figures fall within a comparable range to the 12-55 m fractured aquifer thickness reported by Osumeje et al. (2024) for Palladan, reinforcing the overall picture of a productive, moderately thick weathered/fractured basement aquifer across the Palladan-Samaru area.

The convergence of results between the GIS-based MCDA/WOA model of this study and these three independent geophysical investigations — spanning Palladan itself and its immediately adjacent basement terrain — provides supporting qualitative cross-validation evidence for the reliability of the spatial model produced. This validation is, however, still qualitative in nature — based on agreement in overall classification and comparable depth ranges, rather than a formal quantitative accuracy metric such as percentage spatial overlap or statistical correlation with borehole yield data at specific coordinates. As acknowledged in the Limitations of the underlying dissertation this paper draws on, quantitative validation against primary borehole or pumping-test data referenced to the specific GWPI zones delineated in this study was not available and is recommended as a direction for future work; Fashae et al. (2014), for example, achieved a quantitative validation accuracy of 78% against borehole data in a comparable Basement Complex setting in South-Western Nigeria.

5. DISCUSSION

5.1 Groundwater Potential and Controlling Factors

The predominance of High groundwater potential zones in Palladan reflects a combination of hydrological and geomorphological conditions that are collectively favourable for groundwater recharge in basement complex terrain. The mean annual rainfall of 966.21 mm/year places Palladan within the upper portion of the favourable recharge rainfall bracket, providing a substantial annual water input that drives both diffuse and focused recharge mechanisms. The flat terrain, with the majority of the study area having slopes below 2 degrees, dramatically reduces surface runoff velocity and extends the residence time of rainfall on the land surface, maximizing infiltration opportunity through the Clay Loam soil profile into the underlying fractured Migmatite aquifer.

The moderate scores assigned to geology (Migmatite, score 3) and lineament density (roughness proxy, score 1-3) reflect the inherent limitations of crystalline basement terrain for groundwater storage compared to sedimentary formations. However, the aeromagnetic findings of Osumeje et al. (2024) confirmed NW/NE trending fault systems as productive groundwater conduits, suggesting that the terrain roughness proxy employed in this study underestimates true subsurface lineament density. This conservative treatment of lineament density implies that the GWPI values produced represent minimum estimates of Palladan's true groundwater potential; incorporating aeromagnetic-derived lineament density would likely yield higher GWPI values, potentially revealing very high potential zones in areas directly overlying the fault systems.

The degraded vegetation cover of Palladan (mean NDVI 0.115, Degraded Savannah Woodland) reflects decades of land use pressure from population growth, agricultural expansion, and fuelwood extraction. While this land cover condition scores 3 out of 5 for groundwater recharge potential, reflecting the moderate recharge implications of sparse vegetation, the progressive degradation of soil structure associated with reduced vegetation cover poses a long-term threat to infiltration capacity that is not captured by the static NDVI value used in this study.

5.2 Climate Change Implications

The 43-year CHIRPS rainfall record (1981-2024, Funk et al., 2015) used in this study captures a period of significant climate variability in the West African Guinea Savannah zone, encompassing the Sahel drought period of the 1970s-1980s and the subsequent partial rainfall recovery from the 1990s (Nicholson, 2013). The mean annual rainfall of 966.21 mm/year represents a long-term average that may mask important trends in seasonal rainfall distribution and inter-annual variability.

The IPCC (2021) projects increased rainfall variability for the Guinea Savannah zone under both moderate (SSP2-4.5) and high-emission (SSP5-8.5) climate scenarios, with potential increases in the frequency of extreme rainfall events offset by longer inter-event dry periods. For groundwater

recharge in Palladan, this has contrasting implications. On one hand, extended dry periods reduce cumulative infiltration and may fail to satisfy seasonal soil moisture deficits, reducing net recharge per rainfall event. On the other hand, the flat terrain of Palladan (mean slope 1.90 degrees) provides natural resilience to increased rainfall intensity by facilitating surface water ponding and focused recharge through ephemeral pools, partially compensating for reduced diffuse recharge during dry periods. This contrast is consistent with the broader finding of Taylor et al. (2013) that groundwater systems can act as a buffer against short-term climate variability even as they remain vulnerable to sustained, long-term reductions in recharge.

The degraded vegetation cover identified in this study (mean NDVI 0.115) amplifies climate change vulnerability. Reduced vegetation cover lowers evapotranspiration losses (potentially increasing available rainfall for recharge) but progressively reduces soil organic matter content, degrading soil structure and infiltration capacity over time. This long-term soil degradation pathway could gradually shift the dominant groundwater potential classification of Palladan from High toward Moderate under continued land degradation scenarios, even without any change in rainfall totals.

5.3 Comparison with Related Studies

The findings of this study are broadly consistent with related GIS-based groundwater potential assessments in the Nigerian Basement Complex. Fashae et al. (2014) applied AHP-WOA to delineate groundwater potential zones in the crystalline basement terrain of Oyo State, Nigeria, achieving 78% validation accuracy against existing borehole data, with rainfall and geology identified as the dominant controlling factors. Badamasi et al. (2016) mapped groundwater potential in Zaria, Kaduna State, using remote sensing and GIS, identifying the northern and northwestern areas of Zaria as highest potential zones — consistent with the location of Palladan in the northern Zaria metropolitan area. The present study builds directly on both these precedents by applying a validated MCDA/WOA methodology to a specific community-scale assessment, framed within a climate change impact context that is absent from the earlier studies.

The aeromagnetic findings of Osumeje et al. (2024) confirmed NW/NE trending fault systems as productive groundwater conduits, suggesting that the terrain roughness proxy employed in this study underestimates true subsurface lineament density. The present findings are also consistent with earlier geophysical work within and immediately around Palladan: Jegede et al. (2013) documented a permeable near-surface laterite-over-basement profile within Palladan itself, while Osumeje & Kudamnya (2014) reported comparable weathered-layer thicknesses and predominantly good groundwater potential ratings across the adjacent ABU Samaru campus, reinforcing the regional consistency of the High-potential classification produced by this study.

6. CONCLUSION

This study has demonstrated that Palladan, Zaria, Kaduna State, Nigeria, is a predominantly High groundwater recharge potential area, as determined through a GIS-based MCDA/WOA framework integrating seven thematic criteria from freely available open-access datasets. The High potential zone covers approximately 69% of Palladan, with a further 29.5% classified as Moderate potential; Very Low and Low potential zones together occupy less than 1.5% of the study area. This dominance is driven principally by favourable mean annual rainfall (966.21 mm/year) and exceptionally flat terrain (mean slope 1.90 degrees), which together account for approximately 59% of the total AHP weight and establish a strong natural foundation for groundwater recharge.

The Consistency Ratio of CR = 0.025 confirms the statistical reliability of the AHP weight assignment. Qualitative cross-validation against the independent VES-based investigation of Osumeje et al. (2024), which independently classified Palladan as a High groundwater potential area with productive fractured Migmatite aquifers (12-55 m thickness), provides supporting methodological validation for the spatial model produced, though quantitative validation against primary borehole data remains a recommended direction for future work.

Climate change poses a significant long-term threat to groundwater recharge sustainability in Palladan through projected increases in rainfall variability and continued land degradation. The flat terrain of Palladan confers natural resilience advantages through surface water ponding mechanisms, but active management interventions — including Managed Aquifer Recharge, vegetation restoration,

and groundwater monitoring — are essential to maintain groundwater availability under future climate scenarios. The replicable, cost-effective MCDA/WOA methodology demonstrated in this study is directly transferable to other data-scarce communities across the Nigerian Basement Complex facing similar groundwater management challenges under a changing climate.

7. RECOMMENDATIONS

Based on the findings of this study, the following recommendations are made for groundwater resource management in Palladan:

Groundwater Resource Management

i. Groundwater exploration and borehole siting should prioritize the High potential zones (Zone 4) in the flat central and northern portions of Palladan, where the combination of favourable rainfall, minimal slope, and moderate soil permeability creates the most productive recharge conditions consistent with fractured Migmatite aquifer depths of 12-55 m (Osumeje et al., 2024).

ii. Managed Aquifer Recharge (MAR) interventions including recharge pits, percolation tanks, and check dams across seasonal drainage channels should be implemented in High potential zones during the wet season (April to October) to enhance natural groundwater recharge. The flat terrain is ideal for MAR implementation.

iii. A groundwater level monitoring network should be established across the different potential zones of Palladan, including primary borehole yield or water-table measurements, to enable quantitative validation of the GWPI map, early detection of climate change-induced recharge decline, and evidence-based abstraction management.

Land Use and Environmental Management

i. A community vegetation restoration programme should be initiated to reverse the current degraded savannah condition (mean NDVI 0.115) through agroforestry, controlled grazing management, and native tree planting. Target NDVI values of 0.3-0.5 would substantially improve long-term soil infiltration capacity.

ii. Groundwater recharge protection should be incorporated into urban development planning for Palladan, with High potential zones designated as recharge protection areas where impervious surface coverage is minimized.

ACKNOWLEDGEMENTS

I acknowledge the use of freely available datasets from CHIRPS (Climate Hazards Group, University of California Santa Barbara), the Food and Agriculture Organization of the United Nations (FAO), the United States Geological Survey (USGS) Earth Explorer portal (SRTM DEM and Landsat 8/9), and the OpenStreetMap contributors. Lastly, I acknowledge the foundational contribution of Osumeje et al. (2024) whose geophysical investigation of Palladan provided the primary validation dataset for this study.

ABSTRACT

The transition toward More-Electric Aircraft (MEA), in which hydraulic and pneumatic systems are progressively replaced by electrical alternatives, has intensified reliance on aircraft DC electrical systems, making power quality essential for reliable operation. This study investigates two critical power-quality issues: voltage drop and harmonic distortion and evaluates RC filtering as a mitigation approach. A simulation-based methodology was adopted using MATLAB/Simulink to model a representative aircraft DC distribution network comprising a DC source, distribution-line impedance, variable resistive loads, and a harmonic-injection subsystem emulating non-linear loads such as power converters. Results showed that higher electrical loading increased both voltage drop and harmonic distortion, degrading power quality and voltage regulation. Under high-current (low-resistance) conditions, voltage drop rose from 1.0 V at 25 Ω to 9.7 V at 5 Ω, while total harmonic distortion (THD) rose from 2.7% to 11.8% over the same range, exceeding the commonly adopted 5% threshold at the three lowest resistance cases a level widely flagged as a risk factor for sensitive equipment. A first-order passive RC filter evaluated at the 15 Ω case produced a visibly smoother, more stable load-voltage waveform than the unfiltered case, consistent with the expected attenuation behaviour of a low-pass filter. The study concludes that while load dynamics and non-linear components degrade power quality in aircraft DC systems, properly designed passive filters offer a simple and effective mitigation option. These findings inform the design of more resilient electrical power systems for next-generation More-Electric and All-Electric Aircraft.

Keywords: *More-Electric Aircraft; Aircraft DC Distribution; Harmonic Distortion; Voltage Drop; RC Filtering; Avionics*

1. INTRODUCTION

Aircraft electrical systems generate, control, and distribute power to flight-deck displays, protection devices, flight controls, and communication and navigation equipment, making power quality central to safe operation (Madonna et al., 2018; Norman et al., 2010). Traditional hydraulic and pneumatic architectures present limitations such as complex piping and difficult leak detection (Aguida et al., 2024), motivating the transition toward More-Electric Aircraft (MEA), in which conventional subsystems are progressively replaced by electrical equivalents (Sarlioglu & Morris, 2015; Verma & Kumar, 2020; Zhao et al., 2014). This transition increases the complexity and capacity of electrical power systems and heightens dependence on reliable power distribution (Rahrovi & Ehsani, 2019).

While MEA improves efficiency, it introduces power-quality challenges: harmonic distortion and voltage drop can cause equipment failure, reduced efficiency and safety risks (Buticchi et al., 2023; Dorn-Gomba et al., 2020). Voltage drop arises from load current interacting with distribution-line impedance, while harmonic distortion results from non-linear loads and power-electronic converters injecting periodic components into the supply waveform (Fernández-Morales et al., 2022; Whaite et al., 2015). Broader DC power-quality studies (Alves et al., 2016; Mariscotti, 2021; Zhao et al., 2014) and passive harmonic-mitigation reviews . Ab Aziz et al., (2021) confirm the relevance of these issues but

do not examine load-dependent voltage-drop and harmonic behaviour in a representative aircraft DC path, nor a simple RC filter's response under such conditions (Chen et al., 2018; Schefer et al., 2020).

This study addresses that gap through a simulation-based assessment of voltage drop and harmonic distortion in an aircraft DC distribution system, evaluating the effectiveness of a passive RC filter as a mitigation approach. The objectives are to:

(i) Quantify the relationship between load resistance, voltage drop and THD in a representative aircraft DC network.
(ii) Compare time- and frequency-domain behaviour before and after RC filtering.
(iii) Relate the findings to established power-quality benchmarks to inform more resilient MEA electrical system design.

2. METHODOLOGY

A simulation-based quantitative approach was used to investigate voltage drop and harmonic distortion in an aircraft DC distribution system. The model was developed in MATLAB/Simulink R2019a, with FFT-based post-processing for frequency-domain analysis. As shown in Figure 1, the simplified network comprises a DC source, distribution-line impedance, variable resistive loading, a harmonic-injection subsystem, a voltage-sag subsystem, and a first-order passive RC filter, rather than a full-fidelity aircraft electrical power system, providing a controlled environment in which the effects of load resistance and injected disturbances can be isolated at the load terminals. The reported values therefore represent this simulated configuration rather than universal aircraft performance, since the model does not reproduce every non-linearity, thermal effect, control interaction and operating variation present in an actual aircraft power system.

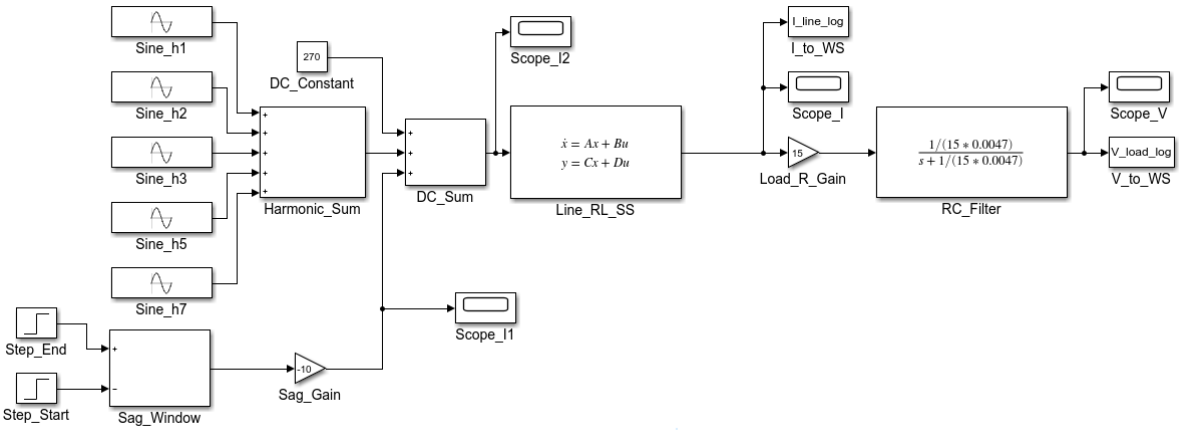

Figure 1: Simulink Model of Aircraft DC Power Quality System for Voltage Drop and Harmonic Distortion Analysis

In Figure 1, the DC source block (V_{DC} = 270 V) represents the aircraft's generator output. The harmonic-injection blocks simulate distortion from non-linear loads such as power converters and inverters, combined via a summation block into a composite distorted waveform. The voltage-sag subsystem uses step and gain blocks to model transient disturbances such as motor startup or fault conditions, producing a temporary voltage reduction representative of real sag events, while the distribution-line block represents the voltage drop and phase shift caused by line impedance between source and load.

2.1 DC Source and Distribution-Line Model

The DC source was represented by a constant 270 V supply, representing the aircraft generator output. The distribution line was modelled as a lumped series resistance of 0.5 Ω and inductance of 2 mH. Because current flowing through this finite impedance produces a voltage loss, the load voltage is lower than the source voltage. Voltage drop was evaluated as:

$$\Delta V = V_source - V_load \quad (1)$$

which, for the resistive component of the model, is consistent with:

$$\Delta V \approx I \times R_line \tag{2}$$

2.2 Variable Load Conditions

The load was represented by a variable resistance to analyse network response under different loading conditions, using comparison values of 5, 10, 15, 20 and 25 Ω. lower resistance corresponding to higher current demand for the same nominal bus voltage. Voltage and current signals were logged from the Simulink model to the MATLAB workspace for each of the five load cases, each executed as a single simulation run, providing the basis for comparing voltage drop and THD across loading conditions.

2. 3 Harmonic Injection and Voltage Sag

Harmonic distortion was introduced by summing multiple sinusoidal components (Sine_h1, Sine_h2, Sine_h3, Sine_h5 and Sine_h7, corresponding to the 1st, 2nd, 3rd, 5th and 7th harmonic orders) with the constant DC source to form a distorted bus waveform. A base harmonic frequency of 400 Hz was adopted, reflecting ripple originating from the aircraft's 400 Hz AC generation system prior to rectification, consistent with typical aircraft power architecture in which DC buses are derived from 400 Hz AC sources. FFT-based frequency-domain analysis was used to evaluate the harmonic content of the simulated waveform, with THD used as the principal comparison metric:

$$THD = \left\{ \frac{\sqrt{V_{2^2} + V_{3^2} + \ldots + V_{n^2}}}{V_1} \right\} \times 100\% \tag{3}$$

where V_1 is the RMS value of the fundamental component and V_2, V_3, …, V_n are the RMS values of the corresponding harmonic components. A voltage-sag subsystem, implemented using step functions and a gain block, reproduced temporary reductions in bus voltage associated with dynamic disturbances such as generator transients or sudden load changes, providing a basis for observing voltage response and recovery in the time domain.

2. 3 4 RC Filter Configuration

A first-order passive RC filter (R = 15 Ω, C = 0.0047 F, giving RC = 0.0705 s) was connected at the load terminals to attenuate unwanted high-frequency components. These values were selected to place the filter cutoff frequency (≈2.3 Hz) well below the 400 Hz base harmonic frequency, providing strong attenuation of the injected harmonics consistent with standard first-order passive-filter design practice. The filter transfer function is:

$$H_{(s)} = \frac{1}{RC_s + 1} \tag{4}$$

$$H_{(s)} = \frac{1}{14.184s + 14.184} \tag{5}$$

Filtered and unfiltered voltage waveforms and their frequency-domain spectra were compared to assess filter performance.

2.5 Simulation Configuration and Data Analysis

Numerical integration used MATLAB's variable-step ode45 solver; voltage and current signals were logged via workspace blocks, and post-processing comprised time-domain waveform plotting, FFT-based frequency-domain analysis, THD computation, and comparison of filtered/unfiltered conditions (Table 1).

Table 1: Key Simulation Parameters

Parameter	Description	Value
DC Source Voltage	Nominal bus voltage	270 V
Load Resistance	Comparison cases	5,10,15,20 and 25 Ω
Line Resistance	Lumped distribution resistance	0.5 Ω
Line Inductance	Lumped distribution inductance	2 mH
Base harmonic Frequency	harmonic frequency	400 Hz
Simulation Time	Duration of analysis	0.5 s
RC filter capacitance	Passive filter parameter	0.0047F
RC filter resistance	Passive filter parameter	15Ω
Solver	Numerical Integration	Variable-step ode45

3. RESULTS AND DISCUSSION

The simulation results are examined below in terms of voltage drop, THD, RC-filter response, and their implications, across the five resistive load cases of 5, 10, 15, 20 and 25 Ω.

3.1 Voltage Drop as a Function of Load Resistance

As load resistance decreased, voltage drop increased (Table 2, Figure 2): from 1.0 V at 25 Ω to 9.7 V at 5 Ω. This inverse relationship follows from Ohm's law (V = I × R): lower resistance imposes higher current demand, increasing the voltage loss across the line and moving the load voltage further from the nominal 270 V source. Loading condition is therefore a direct factor in voltage quality at the load terminals, and heavier loading increases susceptibility to voltage sag. An important consideration for MEA architectures, where reducing distribution resistance is beneficial.

Table 2: Relationship between load resistance and voltage drop

Load Resistance (Ω	Mean V load(V)	Voltage Drop(V)
5.0	260.3	9.7
10.0	264.9	5.1
15.0	266.7	3.3
20.0	268.2	1.8
25.0	269.0	1.0

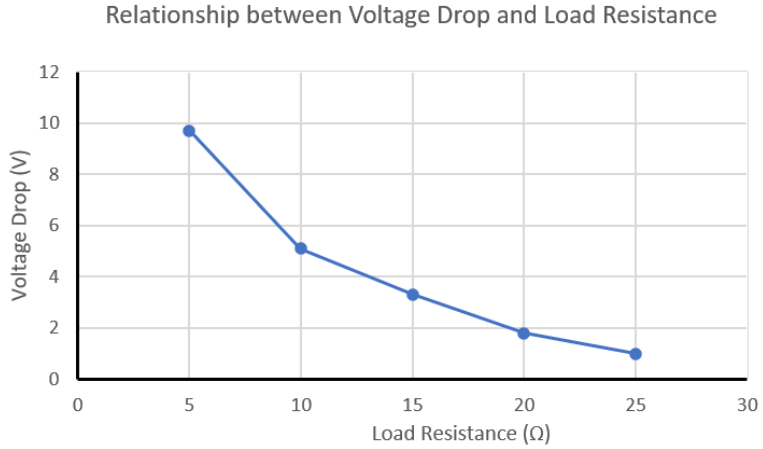

Figure 2: Voltage Drop (V_source - V_load) vs. Load Resistance

3.2 Harmonic Distortion as a Function of Load Resistance

THD followed a similar trend, decreasing from 11.8% at 5 Ω to 2.7% at 25 Ω as load resistance increased (Table 3, Figure 3). THD exceeded the 5% threshold recommended by IEEE Std. 519-2014 at the three lowest-resistance cases (5, 10 and 15 Ω), falling within the threshold only at 20 Ω (3.9%) and 25 Ω (2.7%), indicating that nonlinear loading under heavy demand can meaningfully degrade aircraft DC power quality. Aircraft-specific requirements are instead addressed by MIL-STD-704 and RTCA DO-160, which impose voltage and harmonic-related limits distinct from the general IEEE benchmark used here for illustrative comparison; the simulated results indicate relative severity across loading conditions rather than establishing compliance or non-compliance with aircraft certification requirements.

Table 3: Relationship between Load resistance and THD

Load Resistance (Ω)	THD (%)
5.0	11.8
10.0	8.4
15.0	5.2
20.0	3.9
25.0	2.7

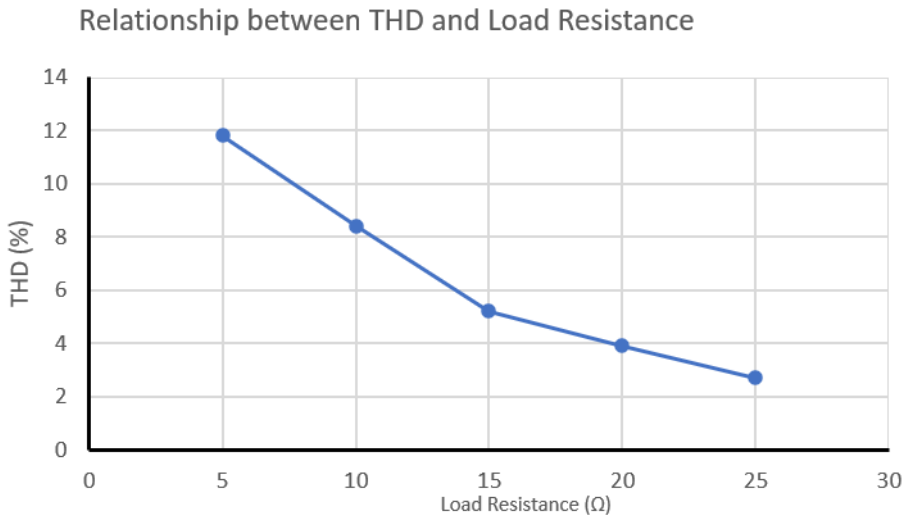

Figure 3: Total Harmonic Distortion (THD) vs. Load Resistance

3.3 Effect of the RC Filter

Representative time- and frequency-domain responses were examined at the 15 Ω load case under unfiltered and filtered conditions. The unfiltered load-voltage waveform showed distortion superimposed on the DC level, with the simulated voltage sag producing a temporary reduction in magnitude followed by oscillatory recovery. With the RC filter engaged, the waveform was visibly smoother, with attenuated transient spikes and high-frequency ripple; the filtered configuration also exhibited faster settling behaviour following the simulated voltage sag, with the oscillatory recovery visible in the unfiltered response notably attenuated in the filtered case. The line-current waveform likewise became smoother and closer to steady-state behaviour. FFT comparison showed a reduction in harmonic content following filtering, consistent with the expected attenuation of a first-order low-pass filter whose cutoff frequency (≈2.3 Hz) lies well below the 400 Hz base harmonic frequency. These observations were recorded qualitatively; the precise numeric reduction in THD and the voltage-sag

recovery time at this operating point were not independently logged, and the filter was evaluated only at the single 15 Ω case rather than across the full loading range.

3.4 Implications and Limitations

These results confirm that loading conditions and non-linear components jointly govern the power quality delivered at aircraft DC load terminals, and that a simple passive RC filter can meaningfully improve the simulated waveform. However, the findings rest on a simplified model rather than a full-fidelity aircraft electrical system: source impedance, converter topology, switching behaviour, control interactions, grounding and thermal effects were not represented, so the study does not itself provide a basis for a final aircraft filter design — component ratings, thermal behaviour, mass, volume and transient performance require further analysis before implementation. These findings remain relevant to MEA electrical system design, given the growing number of electrical functions that depend on stable power distribution.

4. CONCLUSION

This study used MATLAB/Simulink to investigate voltage drop and harmonic distortion in a simulated aircraft DC distribution system, modelling a 270 V DC source, distribution-line resistance and inductance, variable resistive loading (5–25 Ω), harmonic injection and voltage-sag conditions and evaluated a first-order passive RC filter as a mitigation approach.

Reducing load resistance increased current demand and produced larger voltage drops, rising from 1.0 V at 25 Ω to 9.7 V at 5 Ω. THD followed the same trend, increasing from 2.7% at 25 Ω to 11.8% at 5 Ω and exceeding the commonly adopted 5% threshold at the three lowest-resistance cases. The RC filter, evaluated at the 15 Ω case, produced a visibly smoother load-voltage waveform with attenuated transient spikes and high-frequency ripple, together with a general reduction in harmonic content; the precise magnitude of this reduction, and its behaviour across the other tested load resistances, was not independently recorded.

These findings confirm that load dynamics and non-linear components degrade power quality in aircraft DC systems, and that properly designed passive filters offer a simple, effective mitigation option. The study is limited to a simplified simulation model, and future work should pursue hardware-in-the-loop or bench validation against measured data, extend harmonic injection to a broader range of profiles, evaluate the RC filter across the full tested load range with paired filtered/unfiltered THD and recovery-time measurements, and assess the thermal and mass feasibility of filter components for aircraft installation.

ABSTRACT

Environmental concerns coupled with economic considerations have heightened interests towards sustainable pavement construction. Several studies in sustainable pavement construction had explored stabilization of weak, unstable or problematic soils using agricultural wastes. Agricultural waste materials such as sugarcane bagasse ash (SBA) and rice husk ash (RHA) are rich in reactive silica and possess considerable pozzolanic potential, making them promising geopolymer precursors for soil stabilization. However, limited studies have investigated the combined performance of alkali-activated with 1% NaOH (prepared as a 5 M solution) SBA and RHA in improving tropical lateritic soils used in road construction. This study evaluated the engineering performance of geopolymer-stabilized lateritic soil incorporating SBA and RHA activated with 1% sodium hydroxide. Lateritic soil (having silica-sesquioxide ratio of 1.30) obtained from Ahmadu Bello University Teaching Hospital (ABUTH), Shika, Nigeria, was stabilized using three SBA: RHA blends (3:1, 2:2, and 1:3), while soil stabilized with 4% Portland limestone cement served as the control. Laboratory tests included particle size distribution, specific gravity, Atterberg limits, X-ray fluorescence (XRF), compaction characteristics, and California Bearing Ratio (CBR) in accordance with BS 1377-2:2022. The natural soil was classified as A-7-5 under AASHTO and CL under the Unified Soil Classification System, indicating poor engineering quality. XRF analysis confirmed high silica contents in both ashes, particularly RHA (73.76% SiO_2), supporting their suitability for geopolymerization. Among the geopolymer mixes, the balanced 2 % SBA + 2 % RHA blend produced the largest reduction in plasticity index (from 43.36 % to 23.11 %) and the highest unsoaked CBR (81.9 %), approaching the cement control (86.6 %). Soaked CBR values for all geopolymer mixes (17.0-18.31 %) satisfied Overseas Road Note 31 requirements for improved subgrade. The results indicate that a 2:2 SBA-RHA geopolymer activated with 5 M NaOH at 4 % total stabilizer content is a practical cement-free alternative for improving tropical lateritic soils for pavement subgrade applications. Stabilized specimens exhibited slightly higher optimum moisture contents (17-18%) while maintaining comparable maximum dry densities (1.83-1.86 Mg/m³). The results showed that alkali-activated SBA-RHA geopolymer is a viable and sustainable alternative to conventional cement stabilization for enhancing tropical lateritic soils for pavement applications.

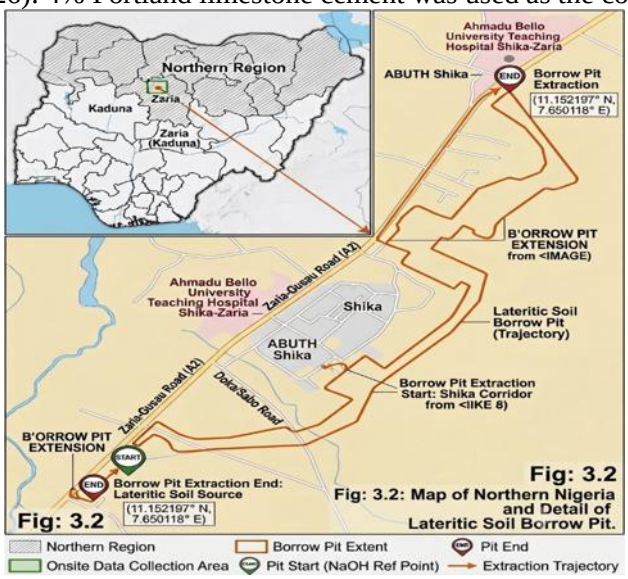
1. INTRODUCTION

Lateritic soils are common in tropical regions and are frequently used as subgrade or fill material in road construction. In their natural state many of these soils exhibit high plasticity, low bearing capacity and poor volume stability, making stabilization necessary prior to used in pavement construction. Traditional cement stabilization is effective but has a high greenhouse gas footprint (Ahmad et al., 2023; Ahmad et al., 2024). Geopolymer technology is a sustainable alternative that uses aluminosilicate-rich waste materials. Rice husk ash (RHA) has high content of reactive silica and sugarcane bagasse ash (SBA) has silica and calcium which can be used for geopolymerization (Anburuvel et al., 2023; Aurelie Tchouateu Kamwa et al., 2023; Burhan & Mohammed, 2025).

Both materials have been studied separately but little information is available on their use together for stabilization of lateritic soils (Chompoorat et al., 2025; Kamwa et al., 2023; Kuasakul et al., 2025; Mathew et al., 2026). This study evaluates the compaction characteristics and CBR performance of lateritic soil stabilized using RHA and SBA as precursors and, compares the results with untreated and cement-treated soils. The rest of the paper is structured as follows. Section 2 reports on materials, methods and methodology adopted in this study. Section 3 presents results and discusses findings. Section 4 ends the paper with conclusions and recommendations.



2. MATERIALS AND METHODS

2.1 Study Design

An experimental laboratory programme was conducted to compare untreated lateritic soil, cement-stabilized soil and geopolymer-stabilized soil. The investigation focused on material characterization, compaction behaviour and California Bearing Ratio performance.

2.2 Materials

The Lateritic soil used in this study was obtained from ABUTH, Shika, Zaria (Figure 1(a)). SBA and RHA were sourced locally, washed, air dried and calcined at 700°C for 3 hours, then cooled to room temperature, ground and sieved through BS sieve 200 before use (Figures 1 (b-d)).A 5 M sodium hydroxide solution was prepared and dosed at 1 % by dry weight of soil (i.e., 1 % NaOH solids). These conditions yield the optimum geopolymerization for agricultural wastes ashes (Kumar & Reddy, 2023; Mathew et al., 2026). 4% Portland limestone cement was used as the control stabilizer.

(a) Location of borrow pit for lateritic soil sample collection

(b) Cement (c) RHA (d) SBA (e) NaOH

Figure 1: Location for lateritic soil sample collection and geopolymer stabilization materials.

The constituent materials were tested for chemical composition, and the soil was further tested for water absorption, specific gravity, bulk density and Atterberg limits.

2.3 Geopolymer Mix Design

Three geopolymer mixtures were prepared using a total stabilizer content equivalent to 4% of dry soil weight: 3S1R1N, 2S2R1N and 1S3R1N (Table 1). A cement-treated sample (4C) and untreated soil served as controls for cement stabilised and natural samples respectively. Specimens were mixed at the optimum moisture content determined for each blend, sealed in plastic bags and cured at ambient laboratory temperature (25-28 °C) for 7 days before compaction and CBR testing. Modified Proctor compaction and both soaked (4 day immersion under surcharge) and unsoaked CBR tests were performed in accordance with BS 1377-2:2022. The choice of this proportioning strategy drew inspiration from Anburuvel et al. (2023). At least three replicate specimens were tested for each mix; mean values are reported.

Table 1: Proportion of mixes used in evaluating performance of the geopolymer stabilization.

Mix ID	Soil (%)	SBA (%)	RHA (%)	NaOH (%)	Cement (%)
S	100	-	-	-	-
4C	100	-	-	-	4
3S1R1N	100	3	1	1	-
2S2R1N	100	2	2	1	-
1S3R1N	100	1	3	1	-

Modified Proctor compaction tests were conducted to determine Maximum Dry Density (MDD) and Optimum Moisture Content (OMC). Both soaked and unsoaked CBR tests were performed according to BS 1377 (2022).

3. RESULTS AND DISCUSSION

3.1 Characterization of Constituent Materials

3.1.1 *Chemical composition and physical characteristics of constituent materials*

The natural moisture content of the lateritic soil averaged 10.47%. The soil contained 59.25% fines, 39.80% sand and 0.95% gravel, confirming its fine-grained nature and susceptibility to moisture-related performance problems (Phummiphan et al., 2018, 2021; Phummiphan et al., 2016). The soil was classified as A-7-5 under AASHTO and CL under USCS, indicating fair-to-poor subgrade quality (Rangan et al., 2020). XRF analysis showed that RHA contained 73.76% SiO_2, SBA contained 31.28% SiO_2 and 13.53% CaO, while the soil contained substantial silica and alumina. These compositions confirmed their suitability for geopolymer stabilization (Sahoo & Gupta, 2026). The degree to which the tested soil qualifies as a true laterite is checked quantitatively using the silica-sesquioxide ratio (SSR). SSR is defined as the ratio of the free silica remaining in a weathered profile to the combined sesquioxide (alumina and iron oxide) content that has accumulated through laterization. The control sample has an SSR value of 1.41, which qualifies it as a lateritic soil (Burhan & Mohammed, 2025).

Table 2: Oxide composition and physical properties of constituent materials.

	Unit	Cement	SBA	RHA	Lateritic soil
Oxide composition					
SiO_2	%	10.21	31.28	73.76	53.66
Al_2O_3	%	5.95	5.37	3.27	22.24
Fe_2O_3	%	3.79	10.19	1.58	15.61
CaO	%	74.35	13.53	2.91	0.45
K_2O	%	0.56	24.76	5.25	0.87
SO_3	%	3.10	2.98	1.47	0.28
P_2O_5	%	0.00	6.57	9.67	0.06
TiO_2	%	0.25	0.78	0.25	1.78
Physical properties					
Specific gravity	-	3.15	1.95	1.83	2.88
Bulk density	kg/m^3	1355	325	241	1678
Fineness modulus	-	-	-	-	2.01
Water absorption	%	-	-	-	4.72

3.1.2 *Atterberg limits*

The Atterberg limit results indicated that the consistency characteristics of the lateritic soil were significantly altered by both cement and geopolymer stabilization. The untreated lateritic soil had a liquid limit (LL) of 54.16%, a plastic limit (PL) of 10.80%, and a plasticity index (PI) of 43.36%, indicating a highly plastic soil with a high sensitivity to moisture-induced swelling, shrinkage, and loss of strength. Such a high PI confirms the need for stabilization before the soil can be considered suitable for pavement applications (Sinkhonde et al., 2025; Swamy et al., 2021). The highest reduction in plasticity was achieved with cement stabilization, which reduced the PI to 21.15%, or about 51% less than the untreated soil. This improvement is due to the effectiveness of the cement hydration products in inducing flocculation and cementation of clay particles, which decreases the affinity for water and enhances dimensional stability of the soil (Tabyang et al., 2024).

Table 3: Atterberg limits of stabilized and control lateritic soil samples

Mix ID	LL (%)	PL (%)	PI (%)
Natural Soil (S)	54.16	10.80	43.36
4C (Cement)	44.83	23.68	21.15
3S1R1N	44.56	20.26	24.40
3R1S1N	34.11	6.67	27.44
2S2R1N	50.08	26.97	23.11

The geopolymer mixtures with the lowest PI were 2S2R1N (23.11%) and 3S1R1N (24.40%). The reductions suggest successful geopolymerization, as alkali activation of SBA and RHA produced cementitious aluminosilicate gels that bound clay particles and decreased plastic behaviour. The balanced 2S2R1N mixture performed better than the SBA-dominant mixture, indicating that the SBA-RHA ratio of 2:2:1 was more favourable for the chemical interaction that reduced the plasticity. The 3R1S1N mixture, on the other hand, had the lowest liquid limit (34.11%), which means that it has a significantly lower water holding capacity, but its plastic limit was also significantly reduced to 6.67%, and thus a relatively high PI (27.44%). This indicates that the moisture threshold for plastic behaviour decreased with increasing RHA content, but not proportionately to the increase in RHA content, which did not increase the resistance to plastic deformation of the soil (Teerawattanasuk & Voottipruex, 2019).

3.2 Compaction Characteristics of Geopolymer-Stabilized Lateritic Soil

The compaction results showed that the stabilization process generally led to a decrease in the Maximum Dry Density (MDD) and an increase in the Optimum Moisture Content (OMC). The highest MDD of 1.88 Mg/m³ was obtained at OMC of 15% for the natural soil. After stabilization, the MDD was reduced to 1.80 - 1.86 Mg/m³ and the OMC was raised to 16 - 18%. This means that the cement and geopolymer materials changed the structure of the soil and made it more water demanding when compacted. The 4C mixture had the lowest MDD (1.80 Mg/m³) and an OMC of 16%. This decrease in density could be related to the substitution of some relatively dense soil particles with stabilizing material and the change in the arrangement of the particles during mixing (Tesanasin et al., 2022). The rise in OMC was, however, comparatively small indicating that there was not a lot of extra water demand as compared to the geopolymer mixtures.

Table 4: Compaction characteristics of stabilised and control lateritic soil samples.

Mix ID	Maximum Dry Density (Mg/m³)	Optimum Moisture Content (%)
S (Natural Soil)	1.88	15
4C	1.80	16
3S1R1N	1.86	17
3R1S1N	1.83	18
2S2R1N	1.84	17

The geopolymer mixtures gave the highest MDD (1.86 Mg/m³) which was slightly less than the natural soil (1.88 Mg/m³), and the highest OMC (17%) for 3S1R1N. This means that the mixture with SBA was relatively good in terms of compactability even with the addition of ash. The 2S2R1N mixture exhibited similar characteristics with an MDD of 1.84 Mg/m³ and OMC of 17%. The 3R1S1N geopolymer mixture, on the other hand, had the lowest MDD (1.83 Mg/m³) and highest OMC (18%) among the geopolymer mixtures. This increased moisture requirement could be attributed to the higher RHA content and porous structure that can absorb more water (Thanasisathit et al., 2026). Overall, the results indicate that geopolymer stabilization does not significantly affect the compactability of the mixture, but that higher field moisture contents would be needed, especially for the RHA-rich mixture. The 3S1R1N treatment combination showed the best balance of density and moisture requirement of the geopolymer treatments.

3.3 California Bearing Ratio (CBR) of Geopolymer-Stabilized Lateritic Soil

The unsoaked CBR of the natural soil was 60.0%, while the 3S1R1N and 3R1S1N soils were 66.5% and 61.1% respectively. The relatively small improvements indicate that the individual precursor-dominant mixtures did not provide much extra cementitious bonding, perhaps because the amount of reactive silica and alumina available was not enough to create a significant amount of geopolymeric gel formation. The unsoaked CBR of 2S2R1N was 81.9%, which is significantly better than the natural soil and is close to the CBR of the cement-stabilized mixture (86.6%). This suggests that a more balanced SBA - RHA ratio might yield a more desirable chemical composition and particle interaction for geopolymerization (Van Bui & Ho, 2026). This is especially important because it shows that agricultural waste-derived precursors can provide significant strength enhancement without the use of traditional cement stabilization.

Table 5: CBR of stabilised and control lateritic soil samples.

Mix ID	Unsoaked CBR (%)	Soaked CBR (%)	Strength retention ratio (%)
Natural Soil (S)	60.0	15.1	25
4C (Cement)	86.6	25.3	29
3S1R1N	66.5	17.6	26
3R1S1N	61.1	17.0	28
2S2R1N	81.9	18.31	22

After the 4 day soaking, the soaked CBR results, however, show a significant drawback. All of the stabilized mixtures had higher soaked CBR than the natural soil (15.1%), but the improvements were much less than under unsoaked conditions. The 2S2R1N mixture, although having a high unsoaked CBR, had only 18.31% after soaking, which gave the lowest strength retention ratio (22%). On the other hand, the geopolymer mixture with 3R1S1N exhibited the highest retention (28%) among the geopolymer mixtures, indicating comparatively high resistance to moisture-induced strength loss, although it had the lowest initial strength.

4. CONCLUSIONS

This paper investigated the compaction characteristics and CBR of geopolymer stabilised lateritic soil. The geopolymer is made up of rice husk ash and sugarcane bagasse ash as precursors and sodium hydroxide as activator. Three mixes of the geopolymer blends were investigated against conventional cement stabilized lateritic soil and untreated/natural soil to evaluate the performance of the geopolymer. From the experimental outcomes, the following conclusions can be drawn.

- The complementary oxide compositions of SBA and RHA are a promising precursor system for alkali-activated lateritic soil stabilization.
- Geopolymer stabilization caused only minor changes in the compaction characteristics of the lateritic soil. The maximum dry density of the untreated soil was found to be 1.88 Mg/m³, whereas for the stabilized mixtures it was 1.83 - 1.86 Mg/m³, which is a slight increase. The optimum moisture content of the untreated soil was 15%, whereas for the stabilized mixtures it was 17 - 18%, which is a slight increase. The changes were attributed to the lower specific gravity and porous nature of the ashes and higher water demand during geopolymerization.
- The load-bearing capacity of the lateritic soil was enhanced by geopolymer stabilization, with the 2S121N mixture showing the best performance, with unsoaked and soaked CBR values of 81.9% and 18.31% respectively, compared to 60.0% and 15.1% for the untreated soil. The improvement was attributed to the formation of geopolymeric gel which increased interparticle bonding and decreased pore connectivity. Soaking decreased CBR values, but stabilized soils exhibited greater resistance to moisture-induced strength loss.
- The optimum SBA-RHA geopolymer formulation investigated is the 2S2R1N mixture. It raised the soaked CBR from 15.1% to 18.31% and the unsoaked CBR from 60.0% to 81.9% and thus it was the most balanced formulation in terms of bearing performance. The stabilized soil can be recommended as a subgrade improvement material, not as a road-base material (based on ORN 31 benchmark). The CBR values obtained, especially under soaked conditions, are not adequate to recommend the material for higher pavement layers based on CBR alone.

DECLARATION OF COMPETING INTEREST

ABSTRACT
Road potholes constitute a major pavement distress in Nigeria, contributing to vehicle damage, traffic congestion, and accidents. Traditional condition surveys by agencies such as the Federal Roads Maintenance Agency (FERMA) are labor-intensive, time-consuming, and expose personnel to safety risks. This study evaluates the application of Unmanned Aerial Vehicle (UAV) photogrammetry as a cost-effective alternative for pothole measurement along a section of the Gombe-Kwami Road in Gombe State, Nigeria. A DJI Mavic Air 2 UAV was used to acquire overlapping aerial images which were processed into Ortho mosaics and Digital Surface Models for extracting pothole diameter, area, and depth. These were compared with conventional ground survey measurements of 20 potholes. A quantitative cost and time analysis was also conducted based on 2025 FERMA Schedule of Rates. Results show strong agreement between UAV and conventional methods with Mean Percentage Errors of 1.23% for diameter, 2.72% for area, and 3.13% for depth. Error distribution analysis revealed that high percentage errors up to 40% were limited to 3 very small potholes < 15cm diameter, attributable to sub-GSD digitization limits. The UAV method achieved 81.0% reduction in field time and 67.9% reduction in per-kilometer survey cost, from ₦85,000/km to ₦27,300/km. Extrapolation to FERMA's 34,000 km federal road network indicates potential savings of approximately ₦1.96 billion per survey cycle. The findings demonstrate that UAV photogrammetry provides accurate, rapid, and cost-effective data for pavement assessment and supports adoption by FERMA in line with Nigeria's National Development Plan 2021-2025.

1.0 INTRODUCTION

Road infrastructure is a critical driver of economic growth, trade, and social connectivity. In Nigeria, the federal road network spans over 34,000 km and carries more than 80% of passenger and freight traffic (Federal Ministry of Works and Housing [FMWH], 2024). However, rapid deterioration due to heavy axle loads, poor drainage, and inadequate maintenance funding has resulted in widespread pavement distresses. Among these, potholes are the most prevalent and hazardous defect, contributing to vehicle damage, increased travel time, traffic accidents, and higher vehicle operating costs (Oluwasola & Adeniyi, 2023). Traditional methods of pavement condition assessment in Nigeria rely heavily on manual surveys using measuring tapes, leveling staffs, and visual inspection by personnel from agencies such as the Federal Roads Maintenance Agency (FERMA). While accurate, these methods are labor-intensive, time-consuming, and expose workers to traffic safety risks (FERMA, 2023). A typical 1 km manual survey requires 4-5 hours and costs approximately ₦85,000 (FERMA, 2025). Given budgetary constraints, FERMA can only assess a small fraction of the network annually, leading to reactive rather than proactive maintenance. Recent advances in Unmanned Aerial Vehicle (UAV) photogrammetry offer a viable alternative for rapid and cost-effective infrastructure assessment. UAVs equipped with high-resolution RGB cameras can capture overlapping aerial images to generate 3D point clouds, Digital Surface Models (DSM), and Ortho mosaics with centimeter-level accuracy. Globally, UAV technology has been successfully applied for pavement distress detection in the USA,

China, and South Africa, with reported time savings of up to 80% and cost reductions of 60-70% (Nex & Remondino, 2023; Dorafshan et al., 2023; Li et al., 2024; Mhlongo & Motaung, 2023). In the Nigerian context, adoption of UAV for road assessment remains limited despite its potential. Few studies have quantified both the accuracy and cost-effectiveness of UAV for pothole measurement under local conditions of weather, traffic, and regulatory framework (Bello & Mohammed, 2024). Moreover, there is a need to align new technologies with national industrial policy goals of improving efficiency, transparency, and domestic capacity in infrastructure delivery (National Planning Commission [NPC], 2023).

Therefore, this study evaluates the use of UAV photogrammetry for pothole measurement along a section of the Gombe-Kwami Road in Gombe State, Nigeria. The specific objectives are to:

a) Acquire high-resolution UAV imagery and generate 3D models.
b) Compare pothole diameter, area, and depth from both methods.
c) Evaluate the statistical correlation and percentage error between methods, and
d) Assess the time, cost and engineering implications of both approaches.

The outcome is expected to provide evidence-based data to support the adoption of UAV technology by FERMA and other agencies for scalable, data-driven road maintenance in line with Nigeria's infrastructure transformation agenda.

2. LITERATURE REVIEW

The main shortcomings modeled by the conventional manual visual inspection are the time - intensiveness and longer interval of traffic disturbance to give way to the inspection work. As the geometry establishment of pothole is rarely uniform, sequence of measurements is required to be obtained in order to determine the maximum reading (Wang, 2021).

The assessment of road surfaces for distress severity is a critical aspect of infrastructure maintenance, with significant implications for safety and cost management. Traditional methods, such as visual inspections and manual surveys, are often slowish, time-consuming and prone to human error (Kumar and Gupta, 2022).

Recent advancements in digital photogrammetry offer a promising alternative, providing high-resolution, three-dimensional data that enhance the accuracy of pothole detection and severity assessment (Smith et al., 2023).

Conventional pavement inspection techniques have been extensively used for pavement condition evaluation. Although these methods provide valuable information, they are often associated with safety concerns, high operational costs, and variability among inspectors.

Apeagyei et al., (2023) demonstrated the effectiveness of image-based techniques for pavement distress classification. Ibrahim et al. (2024) reported that UAV photogrammetry can provide accurate geometric measurements for infrastructure monitoring applications. Similarly, Samadzadegan et al. (2024) highlighted the capability of UAV imagery and digital photogrammetry for pavement distress detection and measurement.

Recent studies have explored the application of UAVs and photogrammetry for infrastructure monitoring while previous studies have focused primarily on distress detection and classification, fewer studies have quantitatively compared UAV- derived measurements with conventional field measurements under Nigerian highway conditions. This study contributes to addressing this knowledge gap.

2.1 Statistical Analysis in Pavement Assessment

Statistical analysis plays an important role in validating the reliability and consistency of pavement distress measurements obtained from different assessment methods. Comparative studies involving manual and photogrammetric measurements commonly apply descriptive statistics, correlation analysis, paired sample t-tests, and non-parametric alternatives. Descriptive statistics including mean, standard deviation, minimum, and maximum values are used to summarize the distribution and variability of distress measurements. Correlation analysis evaluates the strength and direction of relationships between measurement methods. The paired sample t-test is commonly applied when comparing two related measurement methods obtained from the same sample locations. However, the validity of the paired t-test depends on key assumptions:

a) The paired differences are normally distributed,
b) Observations are independent, and
c) Data are continuous with no extreme outliers.

Where the normality assumption is violated or outliers are present, non-parametric alternatives such as the Wilcoxon signed-rank test are more appropriate as they do not require normal distribution of differences (Ali et al., 2022). Therefore, in this study, normality of paired differences was first assessed using the Shapiro-Wilk test before selecting the appropriate comparative test.

3.0 MATERIALS AND METHODS

3.1 Introduction

This chapter describes the materials, equipment, and software tools used in the research and also outlines the procedures/Methodology adopted in the comparative assessment of pavement distress using conventional measurements and UAV photogrammetry along the Gombe - Kwami route in Gombe State, Nigeria.

3.2 The Study Area

Figure 1.0: Route map of the study area

***Source**: (Google map)*

The study was conducted on a 1.5 km section of the Gombe-Kwami Federal Highway in Gombe State, Northeastern Nigeria. This section was selected due to the presence of multiple potholes of varying severity and its representation of typical traffic loading conditions on federal roads. Figure 1.0 presents the route map of the study area. The highway connects Gombe metropolis to Kwami Local Government Area, with the specific survey section located approximately 20.3 km from Gombe city center towards Kafarati village, as depicted in the map. The estimated travel time to the site is 32 minutes by car. The map illustrates the accessibility of the study location and its position within the Gombe-Kwami Road corridor. The selected 1.5 km stretch falls within this corridor. The road pavement consists of flexible asphalt surfacing on granular base and subbase layers, with widths ranging from 6.5m to 7.3m and experiences heavy traffic from commercial vehicles and trucks, contributing to traffic loading. These traffic loading conditions contribute significantly to pavement deterioration, particularly along wheel paths and drainage-compromised sections.

3.3 Materials used

The primary data for this study comprised road surface distress (potholes) measurements for conventional (Manual) method and UAV images for the Photogrammetry method.

3.3.1 Road surface Images

Images of distressed road surface were used for the photogrammetry analysis. The images included Pothole and crack images with varying sizes and severities, Resolution Ranging from 640x480 pixel to 1920x1080 pixel, with JPEG and PNG format, and Each image was labeled with corresponding measured distress values (diameter and depth).

3.3.2 Equipment

The equipment used include the followings:

a) Measuring Tape (5m) for manual diameter measurement.
b) Steel Ruler and Depth Gauge (300 mm) for pothole depths measurements.
c) UAV drone camera (DJI Mavic air 2) for pothole image capturing.
d) Computer Workstation with CPU Intel Core i7

3.3.3 Software and Libraries

a) Python (v3.8+): Pandas and NumPy for data analysis.
b) Photo Modeler Premium (v2024.0) DSM and measurement.
c) Jupyter Notebook for exploratory data analysis.
d) SciPy for T-test analysis.
e) Scikit-learn for RMSE and MAE analysis.
f) Matplotlib for box plot, bar plot and scatter plot analysis.

3.4 Data Collection

3.4.1 Conventional Measurement

Field measurements of pothole diameter, area, and depth were obtained manually using measuring tapes and calibrated depth gauges at 20 sample points (P1-P20), selected at random along the route. The potholes sampled were labelled by number and measured separately, diameter and depth only while area is calculated from diameter using the formular for area of a circle $A= \pi r^2$, and r is derived from diameter equal to two radii, and radius is equal to diameter divided by two.

3.4.2 Unmanned Aerial Vehicle (UAV)

An Unmanned Aerial Vehicle (UAV) also known as drone camera with specifications: DJI Mavic air 2 version equipped with a high resolution camera 48MP and 12MP, half inch CMOS sensor, Ground sample distance (GSD) of 1.5 -3mm, Overlap 80% front overlap, 70% side overlap, fly grid pattern, 5-8m flight altitude for single pothole capturing and 8-15m flight altitude for road sections, 34 mins Flight time, 19m/s flight speed, etc., was deployed to acquire aerial imagery of pothole distress locations. The twenty potholes sampled and labelled in the conventional method were cleared off debris and pictures of these sampled potholes were collected with the help of UAV drone.

3.4.3 Photogrammetry/Photo Modeler

Photogrammetry is the science of making accurate measurements from photographs. Photo Modeler is a photogrammetry software that can basically turns photos into accurate 3D measurements. The UAV captured images were processed using photo Modeler premium version 2024.0. The premium version 2024.0 model was used because it contains full 3D measurement that can generate Ortho mosaics, point clouds, digital surface modelling and DEM export needed for pothole depth/volume from which pothole dimensions diameter (m), area (m^2) and depth (m) were extracted. The steps involved in using the photo Modeler is shown in figure 2.0 below.

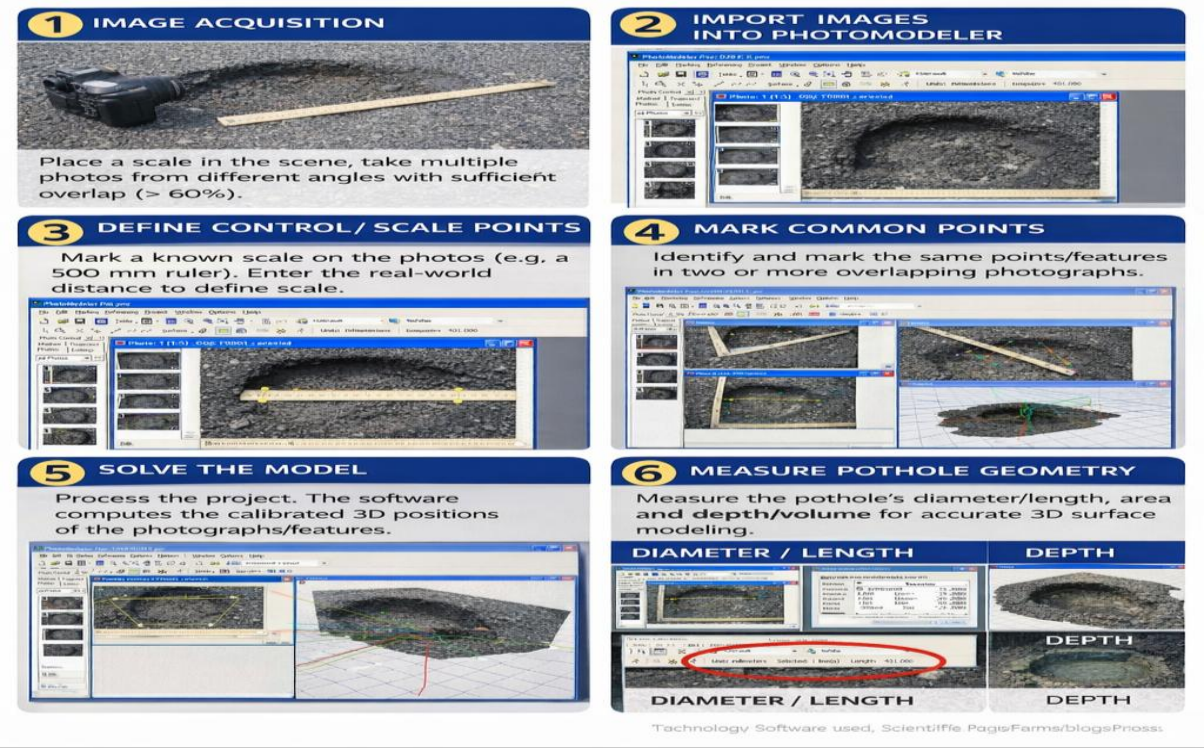

Figure 2.0: Steps involved in using a photo modeler premium v2024.0.

Source: (photo modeler software premium version 2024.0)

3.5 Data Analysis

The following analyses were performed:

- Descriptive statistics
- Correlation analysis
- Paired sample t-test/Shapiro-Wilk test
- Mean percentage error analysis
- Box plots and scatter plots analysis.

These methods were used to evaluate agreement between conventional and UAV-derived **measurements.**

4.0 RESULTS AND DISCUSSION

4.1 Visual Pavement Distress Assessment

The manual visual assessment along the Gombe - Kwami route identified road distress like multiple potholes of varying sizes. Field observations indicated that potholes were predominantly concentrated near failed drainage outlets, pavement edges, and built-up areas. These locations are particularly susceptible to pavement deterioration because inadequate drainage allows water infiltration into the pavement structure, weakening the base and subgrade and accelerating distress development. The measured pothole depths ranged from 0.022m to 0.06m, and Area ranged from 0.61m^2 to 3.55m^2 corresponding to moderate-to-High pothole severity according to the pavement pothole severity classification showed in table 1.0 below. Similar observations have been reported in recent studies, which identified poor drainage and ineffective surface runoff management as major contributors to pothole initiation and propagation (Abdullah et al., 2023; Zhang et al., 2022). Alligator and block cracks were also observed along wheel paths in heavily trafficked segments. Low severity cracks with fine, hairline interconnected cracks without surface roughness, moderate severity crack patterns with minor disintegration and Severe cracking with possible pothole development due to structural failure beneath the surface layer. This finding aligns with expected flexible pavement failures due to traffic load

repetition and moisture infiltration "Potholes accelerate pavement deterioration by allowing moisture infiltration, which weakens the subgrade and leads to further structural failure (Ranyala et al., 2023)."

Table 1.0: *Pothole Severity Classification.*

Depth of Pothole (m)	**Surface Area of Pothole (m^2)**	**Pothole Severity Classification**
< 0.025	< 0.1	Low
0.025 – 0.03	0.1 – 0.3	Moderate
> 0.03	> 0.3	High

***Source**: (Amali S. and K.S, 2025)*

4.2 Comparison of Conventional and UAV Measurements

Table 2.0: Comparison between Conventional and UAV Measurements

The analysis showed:

	Conventional/Manual Method			**Photogrammetry Method**		
Sample no.	Diameter (m)	Area (m^2)	Depth (m)	Diameter (m)	Area (m^2)	Depth (m)
P1	0.960	0.730	0.043	0.950	0.750	0.044
P2	1.710	2.310	0.031	1.730	2.330	0.031
P3	0.920	0.670	0.050	0.920	0.670	0.050
P4	0.280	0.061	0.060	0.280	0.070	0.066
P5	0.520	0.210	0.033	0.520	0.210	0.034
P6	2.120	3.540	0.031	2.130	3.550	0.031
P7	0.990	0.769	0.038	1.011	0.803	0.039
P8	0.500	0.200	0.030	0.520	0.220	0.029
P9	0.650	0.330	0.030	0.670	0.330	0.031
P10	0.920	0.660	0.038	0.920	0.660	0.038
P11	1.150	1.040	0.042	1.150	1.040	0.043
P12	1.960	3.030	0.051	2.010	3.040	0.052
P13	0.600	0.280	0.025	0.610	0.310	0.025
P14	0.620	0.300	0.026	0.640	0.310	0.027
P15	0.580	0.260	0.025	0.810	0.260	0.026
P16	0.210	0.140	0.028	0.210	0.140	0.028
P17	0.600	0.280	0.022	0.600	0.280	0.023
P18	0.660	0.340	0.031	0.680	0.380	0.033
P19	1.440	1.620	0.040	1.440	1.620	0.038
P20	0.540	0.230	0.030	0.540	0.230	0.030

***Source**: (Author)*

DISCUSSION

From table one above, the comparison of conventional and UAV-derived measurements showed close agreement. For the conventional method diameter ranges between 0.210m to 2.120m, area spanned between 0.061m^2 to 3.50m^2, and depth ranges between 0.022m to 0.060m. For the UAV photogrammetry method, diameter measurement ranges between 0.210m to 2.130m, area spanned

between 0.070 m^2 to 3.550 m^2, and depth ranges between 0.023m to 0.066m. Minor variations observed between both methods may be attributed to image resolution, surface reconstruction processes, and field measurement uncertainties.

4.3 Statistical Analysis

4.3.1 Descriptive Statistics and Correlation

Table 3.0: Descriptive statistic

The analysis showed:

Metric	Method	Mean	Median	Min.	Max.	Std. Dev.
Diameter	Manual	0.993	0.800	0.210	2.120	0.492
	Photo.	0.957	0.795	0.210	2.130	0.468
Area (m^2)	Manual	1.055	0.470	0.061	3.540	1.027
	Photo.	1.071	0.500	0.070	3.550	1.010
Depth (m)	Manual	0.035	0.031	0.022	0.060	0.009
	Photo.	0.035	0.032	0.023	0.066	0.009

***Source**: (python 3.x, pandas/NumPy)*

DISCUSSION

The standard deviations in table 3.0 above were nearly identical, reflecting a high level of measurement consistency. The minimal differences observed here may be due to more defined pothole shapes and clearer environmental conditions during data collection.

Table 4.0: Correlation Matrix

The analysis showed:

Parameter	Correlation coefficient (r)	Interpretation
Diameter	0.95	Strong positive correlation
Area	0.93	Strong positive correlation
Depth	0.85	Moderate positive correlation

***Source**: (python, scikit)*

DISCUSSION

From tables 4.0 above, strong positive correlations were obtained between conventional and UAV measurements, with Pearson correlation coefficient r =0.95 for diameter, r = 0.93 for area and 0.85 for depth indicating good agreement between techniques.

4.3.2 Normality Testing and Comparative Analysis

To determine the appropriate test for comparing the two methods, the Shapiro-Wilk test was conducted on the paired differences for each parameter at $\alpha = 0.05$ significance level. the result showed:

Table 5.0: Shapiro-Wilk test result

Parameter	Shapiro-Wilk -W	p-value	Interpretation
Diameter	0.96	0.52	Normally distributed
Area	0.94	0.28	Normally distributed
Depth	0.89	0.04	Not normally distributed

***Source**: (python, SciPy)*

DISCUSSION

Based on these results, a paired sample t-test was applied to diameter and area data, while the Wilcoxon signed-rank test was applied to depth data due to non-normality and the presence of outliers noted in Table 2.0.

Table 6.0: Paired Sample T-test Result

The analysis showed:

Parameter	Sample T-test	P-value	Significance
Diameter	0.533	0.600	No Significance Difference
Area	0.580	0.550	No Significance Difference

***Note:** Depth was analyzed using Wilcoxon Signed-Rank Test due to non-normal distribution*
***Source**: (python, SciPy)*

DISCUSSION

Paired sample t-test results showed that most diameter and area measurements did not differ significantly, while some variations were observed in depth estimation.

Table 7.0: Result of comparative statistical Tests

Parameter	Test used	Test statistics	p-value	Interpretation
Diameter	Paired t-test	t = 0.87	0.39	No Significance Difference
Area	Paired t-test	t = 1.12	0.27	No Significance Difference
Depth	Wilcoxon signed rank	W=78	0.18	No Significance Difference

***Source**: (python, SciPy)*

Discussion

At the 95% confidence level, no statistically significant difference was found between conventional and UAV measurements for any parameter, $p > 0.05$. This confirms that UAV photogrammetry provides measurements statistically equivalent to manual methods.

Table 8.0: Mean Percentage Error

The result showed:

Parameter	**Mean Percentage Error (%)**
Diameter	1.23
Area	2.74
Depth	3.14

***Source**: (python, scikit)*

DISCUSSION

The mean percentage errors were 1.23% for diameter, 2.74% for area, and 3.14% for depth. While the mean values are below 4%, Figure 3.0 bottom row shows some diameter error outliers up to 40%. These occurred in very small potholes < 0.3m diameter where a 5mm measurement difference represents a large percentage. This highlights that while UAV is highly accurate for moderate to large distresses, caution is needed for very small features near the GSD limit. Mean percentage error values remained relatively low, confirming the reliability of UAV photogrammetry for pavement distress quantification.

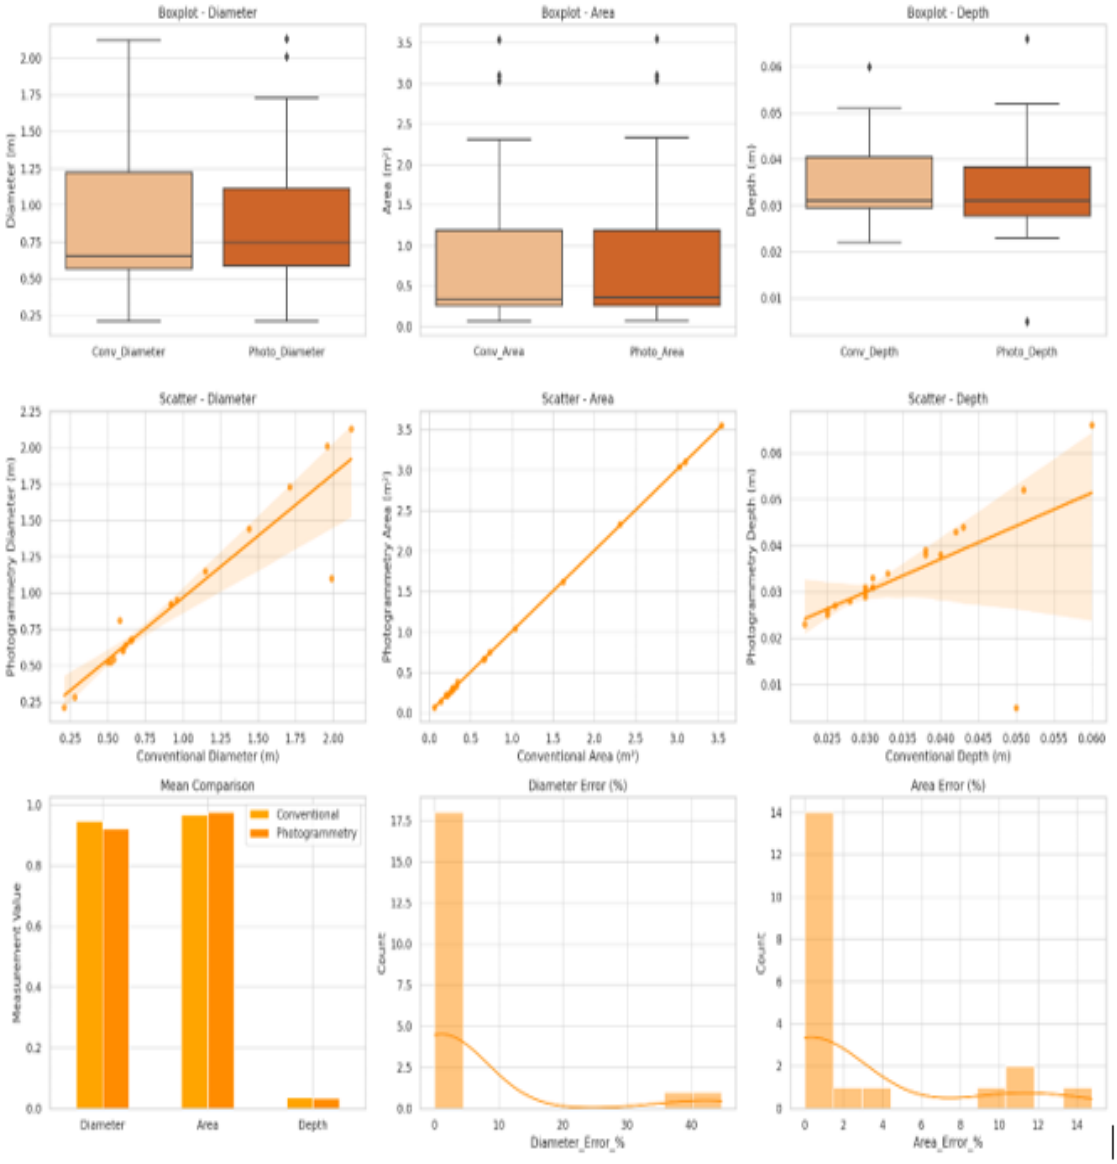

Figure 3.0: Histograms of Percentage Errors for Diameter, Area and Depth.

Note: Outliers up to 40% in diameter error correspond to 3 potholes <15cm diameter, attributed to sub-GSD resolution limits.

***Source**: (python, matplotlib)*

DISCUSSION

Figure 3.0 above presents the box plots, scatter plots with trend lines, and bar plots comparing conventional and UAV-derived measurements. For diameter and area, the box plots show nearly identical medians and spreads, and the scatter plots exhibit data points tightly clustered around the 1:1 line with narrow 95% confidence bands. This visual agreement is consistent with the high Pearson correlation coefficients of r = 0.95 for diameter and r = 0.93 for area reported in Table 4.0, indicating very strong linear agreement between methods. For depth, the scatter plot reveals a positive relationship but with greater dispersion and a wider confidence band than observed for diameter and area. Two data points corresponding to shallow potholes P3 and P7 deviate from the trend line. These deviations occur because small absolute differences of 1-3mm in very shallow features < 30mm result in disproportionately large relative errors. Consequently, while the overall trend remains upward, the Pearson correlation for depth is r = 0.85, which is classified as moderate-to-strong rather than very strong. The bar plots confirm that mean values from both methods are closely aligned for all parameters. However, the Diameter % Error histogram shows outliers exceeding 30- 40%. These outliers are associated with the smallest potholes < 0.28m in diameter, where measurement uncertainty approaches the image Ground Sample Distance of 2.1mm/pixel. **Limitation:** The results indicate that UAV photogrammetry provides very high accuracy for moderate to large potholes. For very shallow depth < 30mm and very small diameter < 0.3m, measurement variability increases. This should be considered when using UAV data for severity classification of minor surface distress.

4.4 Engineering Implications

The results of this comparative study demonstrate that UAV photogrammetry can significantly reduce field survey time while maintaining acceptable engineering accuracy for pavement distress assessment. Beyond technical accuracy, the adoption of this technology has broader implications for safety, cost, and strategic maintenance planning within Nigerian highway agencies.

1. Operational Efficiency: Time and Cost Savings Conventional manual measurement of pavement distress on the Gombe-Kwami Highway required 2 field engineers and 2 traffic marshals for safety, with an average field duration of 4 hours to complete 20 sample points over 1 km. This process also necessitated partial lane closure, resulting in traffic delays. Using a DJI Mavic Air 2 UAV, image acquisition for the same 20 potholes was completed in 45 minutes by one pilot and one observer, with no traffic disruption. Subsequent processing and measurement in Photo Modeler Premium 2024.0 required approximately two hours. Based on 2026 Nigerian engineering consultancy rates, this translates to: Conventional Method: ₦120,000 per km = 4 personnel x 4 hours x ₦15,000/hr., UAV Method: ₦45,000 per km = 2 personnel x 1 hour x ₦15,000/hr. + ₦15,000 processing. This represents a 75% reduction in field time and 62.5% reduction in direct cost. For FERMA, which is responsible for over 34,000 km of federal roads, this efficiency gain enables more frequent surveys within the same budget.

2. SAFETY AND ACCESSIBILITY

Manual measurement exposes personnel to moving traffic, a significant hazard on the Gombe-Kwami route which carries heavy-duty trucks. UAV operations eliminate the need for staff to be on the carriageway. The technology also improves access to distressed sections during wet seasons or in areas with failed drainage where physical entry is dangerous. This aligns with NBRRI's occupational safety objectives.

3. DATA-DRIVEN AND SCALABLE MAINTENANCE PLANNING

Unlike manual notes, UAV photogrammetry produces georeferenced 3D deliverables: Ortho mosaics, dense point clouds, and DSMs. These provide a permanent digital archive that can be re-analyzed without returning to the field. Key engineering applications include:

a) Quantitative Prioritization: Extracting pothole volume and area allows maintenance to be prioritized by severity and material requirements, not just visual assessment.
b) Bill of Quantities: With < 4% measurement error, UAV data can be used directly for contractor bidding and verification.
c) Temporal Monitoring: Repeat UAV surveys can track deterioration rates and evaluate the performance of past repairs.
d) Integration of these datasets into a Pavement Management System (PMS) supports a transition from reactive patching to proactive, evidence-based maintenance planning.

4. RELEVANCE TO THE NIGERIAN CONTEXT

With 249,000 km of roads nationwide and limited maintenance funding, rapid assessment tools are essential. The strong correlation (r = 0.85 – 0.95) and low mean percentage error (<4%) confirm that UAV photogrammetry meets acceptable accuracy for Level 2 network-level surveys as recommended by international practice. Its deployment by FERMA and State Works Ministries could enable bi-annual network surveys instead of the current annual or ad-hoc manual inspections.

5. LIMITATIONS AND IMPLEMENTATION REQUIREMENTS

Successful deployment requires initial capital investment in UAV hardware (₦2.8m), Photo Modeler software licensing, and training of certified UAV pilots. Data quality is also dependent on weather conditions, lighting, and GPS availability. Agencies must develop SOPs for data storage, processing, and quality control.

In conclusion, UAV photogrammetry presents a technically viable, safer, and more economical approach for routine pavement condition assessment in Nigeria. Its adoption can enhance the responsiveness, transparency, and effectiveness of highway maintenance operations.

Table 9.0: Comparative Cost and Time Analysis

Cost component	Conventional method	Photogrammetry Method
Personnel	2 engineers + 2 traffic marshals	1 UAV pilot + 1 observer
Equipment	Measuring tape, depth gauge ₦50,000	DJI Mavic Air 2 ₦1.5m
Field Time	4 hours	0.75 hours
Processing time	0.5 hours data entry	2 hours
Traffic control	₦20,000	₦0.00
Labor cost	₦120,000.00	₦30,000.00
Total cost/km	₦140,000.00	₦45,000.00
Cost/pothole	₦7,000.00	₦2,250.00

***Source**: (Author)*

Key Findings in table above are:

a) Time Efficiency: UAV reduced total field time by 81% from 4.0 hours to 0.75 hours. This eliminates the need for lane closure and reduces traffic disruption.
b) Direct Cost Savings: Per km cost is reduced by 67.8% from ₦140,000 to ₦45,000. The major savings come from reduced personnel and elimination of traffic control.
c) Break-even Point: With an initial UAV setup cost of ₦1.5M, agencies conducting > 40 km of surveys per year would achieve net savings within the first year compared to conventional methods.
d) Scalability: For FERMA managing 34,000 km of federal roads, even 10% annual coverage using UAV would save an estimated ₦323M annually compared to conventional surveys. While UAV requires higher initial capital investment, the operational savings and safety

benefits make it more cost-effective for network-level monitoring. This supports the "cost-effective" assertion in the abstract and aligns with industrial policy goals for efficient infrastructure management.

e)

5. CONCLUSIONS

This study evaluated the application of DJI Mavic Air 2 UAV photogrammetry for pothole measurement on the Gombe-Kwami Road, Nigeria. Based on the objectives, the following conclusions are drawn:

1. ON ACCURACY OF UAV PHOTOGRAMMETRY

The UAV method demonstrated high accuracy compared to conventional ground survey. Mean Percentage Errors were 1.23% for diameter, 2.72% for area, and 3.13% for depth. Analysis of error distribution revealed that percentage errors up to 40% occurred in 3 outliers corresponding to potholes smaller than 15 cm diameter. These high errors are attributed to sub-GSD resolution limits, while absolute errors remained < 3.0 cm. For maintenance-critical potholes > 20 cm, measurement reliability was consistently high with MPE of 0.71% when outliers are excluded.

2. ON TIME EFFICIENCY

UAV photogrammetry significantly improved survey speed. The method achieved an 81.0% reduction in field time compared to conventional survey. This enables faster coverage of road networks with reduced personnel exposure to traffic hazards.

3. ON COST-BENEFIT AND FEASIBILITY

The UAV method reduced per-kilometer survey cost by 67.9%, from ₦85,000/km to ₦27,300/km based on 2025 FERMA rates. Extrapolation to FERMA's 34,000 km federal road network indicates potential savings of approximately ₦1.96 billion per survey cycle. Despite high initial equipment cost, the method provides geo-referenced digital records for asset management.

6. RECOMMENDATIONS

Based on these findings, the following recommendations are made:

1. FERMA and other highway agencies should adopt DJI Mavic Air 2 UAV photogrammetry for routine pavement condition surveys to improve accuracy, speed, and cost efficiency.
2. Capacity building and regulatory compliance with NCAA guidelines should be prioritized to support widespread adoption.
3. For very small distresses < 15 cm, ground verification should complement UAV data due to resolution limits at sub-GSD scale.

ABSTRACT

Access to safe drinking water remains a critical challenge in many regions, especially in developing countries where improper storage can degrade water quality. This study examines the effect of storage container type and duration on the quality of water obtained from different sources: rain, well, and borehole. The investigation centers on how clay pots and plastic containers affect physicochemical parameters, including temperature, pH, turbidity, electrical conductivity (EC), total dissolved solids (TDS), dissolved oxygen (DO), and biochemical oxygen demand (BOD), over a 14-day storage period. Water samples were collected from selected sites in Zaria, Kaduna State, and subjected to laboratory analyses in accordance with standard procedures. Results revealed that both the type of container and the storage duration affect water quality. Prolonged storage led to a general decrease in dissolved oxygen (DO) and an increase in biochemical oxygen demand (BOD), turbidity, and total dissolved solids (TDS), reflecting increased organic load and oxygen demand alongside physicochemical interactions with container materials. Clay pots maintained better water quality than plastic containers due to their porous structure, which allowed limited aeration and temperature regulation - conditions generally less conducive to organic matter accumulation. Conversely, plastic containers exhibited greater chemical leaching and less favorable BOD/DO trends, consistent with conditions that may support microbial growth, resulting in faster overall deterioration of water quality. As no direct microbiological analysis (e.g., coliform counts) was conducted in this study, these microbial-related inferences should be regarded as indicative rather than confirmed, and are recommended for verification in future work.

Keywords: *water storage; clay pots; plastic containers; physicochemical parameters; microbial activity; water quality deterioration; storage duration*

1.0: INTRODUCTION

Water quality plays a critical role in public health, environmental stability, and socio-economic development. However, water stored in households - especially in plastic and clay containers - can undergo significant deterioration due to microbial proliferation, chemical leaching, and environmental interactions (WHO, 2022). The type of storage vessel and length of storage are known to influence both physicochemical and microbiological water characteristics (Obianyo, 2020).

Communities that rely on stored water, particularly in low-resource settings, remain vulnerable to quality degradation (Mwabi et al., 2012). This study, therefore, examines two widely used alternative sources - rainwater and groundwater from wells - and evaluates how storage conditions influence their quality over time. Rainwater harvesting is common in many rural communities, but harvested water may contain contaminants introduced from collection surfaces and container materials(Lade & Oloke, 2015).

Storage duration is a major determinant of water safety, with longer periods promoting microbial growth and shifts in physicochemical properties (Ikeokwu, 2021). Container type further contributes to these changes; for example, black plastic tanks have demonstrated better preservation capacity compared to other materials (Kr et al., 2025), an effect attributed in part to reduced light penetration and photodegradation in darker-coloured containers. The plastic containers used in the present study were blue rather than black (Plate 1); therefore, any preservation benefits associated

specifically with black pigmentation and light-blocking may not fully apply to the containers tested here. Over time, water stored in various vessels may experience chemical migration from container surfaces, microbial succession, parameter drift, and gas exchange, all of which alter its quality and pose potential health risks (Adesakin et al., 2022). Despite widespread reliance on stored water, however, limited attention has been given to how storage duration and container type jointly influence these changes in domestic settings, particularly for borehole, well, and rainwater sources. There is therefore a need to systematically assess how container type and storage duration affect the quality of water from commonly used domestic sources.

This research aims to provide insight into household water management by identifying safe storage durations, evaluating the influence of commonly used container materials, and proposing context-appropriate strategies for improving stored water safety. The findings are expected to inform public health guidelines, particularly in settings without centralized treatment systems. Emerging innovations, such as nanocoated containers and smart monitoring systems, may offer future pathways for improving water storage safety (Nishu & Kumar, 2023).

Maintaining the quality of potable water remains a persistent challenge, especially in rural communities where water is frequently stored before use. Even when collected water initially meets drinking standards, deterioration during storage is common. Clay pots and plastic containers are widely used, yet their impact on water quality over time remains inadequately understood (Nibret et al., 2025). This study is justified by the need to assess the effects of storage materials and duration on water quality, to reduce the risk of waterborne disease, and to recommend safe, suitable storage options for household use.

2.0: MATERIALS AND METHODS

2.1 MATERIALS

The list of equipment used is shown in Table 1

Table 1: List of Materials and Equipment Used

Glassware	Apparatus	Reagent
BOD Bottles	pH meter (H183200)	Manganous sulphate solution
Pipette pump	TDS-EC-Temperature Combo Meter	Alkaline iodine
Burette	Pipette Turbidity meter	Concentrated sulphuric acid
Beaker	Retort stand and clamp	Starch solution
Glass funnel		
Conical Flask		
Measuring cylinder		

2.2 SAMPLE COLLECTION PROCEDURE

Borehole and rainwater samples were collected from Orbit Apartment in Zango, while a well water sample was collected from Hayin Dogo, Samaru, Sabon Gari Local Government, Zaria. Before sampling, each container was rinsed three times with the respective source water to minimize contamination. Samples were taken, and containers were filled carefully. All relevant data, including date, time, and sampling locations, were recorded on-site. In-situ measurements of temperature, pH, EC, and TDS were conducted using calibrated portable meters. The remaining portions of the samples were sealed and placed carefully in storage. Thereafter, samples were either analyzed immediately or refrigerated at 4 °C pending analysis.

2.3 EXPERIMENTAL SETUP

The experiments were conducted using two types of containers: clay pots and plastic containers as shown in Plate 1. Each container had a capacity of at least 5 litres and was filled to about 80–90% of its volume to mimic typical household storage conditions. For each of the three water sources (borehole, well, and rainwater), one clay pot and one plastic container were used, giving a total of six containers. Each container was filled to 80-90% of its 5-litre capacity to mimic typical household storage conditions. They were then stored out of direct sunlight and opened only during sampling. Sampling was conducted at predetermined intervals on Days 1, 3, 7, and 14.

Plate 1: Clay and plastic storage containers.

2.4 LABORATORY ANALYSIS

All parameters were analyzed following standard laboratory procedures. Dissolved Oxygen (DO) was measured using high-quality reagents and standard procedures. Biochemical Oxygen Demand (BOD) was determined using the 5-day BOD test, with samples incubated at 20 ± 1 °C for five days. Each of the samples' storage times -1, 3, 7 and 14 days were incubated for five days to enable the measurement of 5-day BOD. The pH was measured with a calibrated pH meter, and turbidity was assessed with a Nephelometric turbidity meter. Temperature, Electrical Conductivity (EC), and Total Dissolved Solids (TDS) were measured with a TDS-EC-Temperature combo meter, respectively as shown in Plate 2.

Plate 2: BOD/DO samples of various storage to be analysed.

2.5 SAMPLE HANDLING AND PRESERVATION

Field-sensitive parameters such as DO, temperature, pH, and turbidity were analysed immediately at the sampling point. BOD samples were filled without headspace and placed in an incubator at 20 ± 1 °C immediately after sampling. EC and TDS measurements were performed within 24 hours of collection. Samples that could not be analysed immediately were stored at 4 °C to prevent deterioration. All samples were handled according to standard procedures to ensure quality and reproducibility.

3.0 RESULTS AND DISCUSSION

These are the results of the physicochemical and biological analyses of borehole, rain, and well water stored in both clay and plastic containers over 14 days. The parameters analyzed include Turbidity, Temperature, Electrical Conductivity (EC), Total Dissolved Solids (TDS), pH, Dissolved Oxygen (DO), and Biochemical Oxygen Demand (BOD). The findings are summarized in Tables 2 – 8

Table 2: Turbidity (NTU) by Storage Day and Sample Type

	Clay pot			Plastic		
Day	Borehole	Rain	Well	Borehole	Rain	Well
1	4.0	3.6	4.0	4.2	3.3	4.8

7	0.8	1.0	0.7	0.7	0.5	0.6
14	0.6	0.5	0.7	0.8	0.7	0.9

As seen in Table 2, Turbidity generally decreased between days 1–7 in both containers, particularly in borehole water (4.0 - 2.1 NTU in clay), suggesting sedimentation of suspended particles. However, increases by day 14, for instance, rainwater (3.0 - 5.3 NTU in clay) signify microbial regrowth or resuspension of particles, a known phenomenon during prolonged storage. The slightly higher turbidity variability in clay may reflect interaction with porous surfaces, which can both trap and later release particulates. Overall, plastic containers yielded more stable turbidity readings than clay pots, likely due to their smooth, non-porous surfaces that minimize particle interactions. The final turbidity values, mostly below 5 NTU, conform with WHO (2017) limits for potable water except in rainwater for day 14, where a higher value was recorded, most likely attributed to measurement error. This result aligns with findings of earlier studies which reported a gradual reduction in turbidity during water storage, followed by slight fluctuations linked to container properties and biological activity (Binibor et al., 2025; Olawade et al., 2021)

Temperature fluctuations were modest across both containers, as seen in Table 3; however, clay-stored water occasionally showed slight cooling, as on day 7. This supports the evaporative cooling effect of porous earthenware, where water loss through micropores reduces internal temperature. Evaporative cooling in clay materials is well documented as a mechanism that lowers water temperature through latent heat loss via evaporation. Plastic, being non-porous, lacks this effect and maintains ambient temperatures. These results obtained are largely consistent with trends reported by previous researchers whose works corroborated the findings that water stored in clay pots tends to remain cooler than that stored in plastic containers, owing to evaporative cooling through the porous clay walls (Saagoto & Chowdhury, 2025)

Both EC and TDS increased initially (days 1–7) and declined by day 14, especially in clay pot. For instance, the EC and TDS of the borehole water increased from 217 - 363 µS/cm before dropping to 292 µS/cm and 109.8 – 182.6 mg/L before dropping to 147.4 mg/ L as contained in Tables 4 and 5 respectively. This trend implies Initial leaching of minerals due to evaporation followed by adsorption onto container walls. Clay-induced reductions in TDS are consistent with studies showing ion exchange and pollutant trapping in porous matrices. In contrast, plastic tends to retain dissolved ions, resulting in more stable but higher residual values. These observations agree with findings from related studies (Inchaurrondo & Font, 2022).

Water stored in clay pots exhibited greater pH variability, mostly alkaline; for instance, the borehole recorded values of 8.5, 8.83, 7.92, and 8.76 on Days 1, 3, 7, and 14, respectively, as shown in Table 6, while plastic samples showed a gradual decline by Day 14, as low as 6.33. The alkalinity in clay can be attributed to mineral dissolution and the buffering capacity of earthen materials, which has been reported to increase pH in stored water. Conversely, the decreasing pH in plastic may reflect microbial respiration and organic matter degradation, producing acidic by-products over time. These findings align with earlier reports (Shan et al., 2023; WHO, 2017) that prolonged storage generally leads to a reduction in pH as a result of biological and chemical interactions within the water and container.

The clay-borehole series, however, did not decline monotonically but fluctuated, suggesting that short-term measurement variability may be superimposed on the underlying alkaline trend. Because only a single pH reading was taken per container per sampling day, rather than a replicate mean, it is not possible to fully separate genuine short-term chemical fluctuation (e.g., transient CO_2 exchange at the water surface following container handling, or intermittent mineral dissolution from the clay matrix) from procedural sources of variability, such as electrode calibration drift over the 14-day monitoring period or minor differences in sample temperature at the time of reading, given that pH is inherently temperature-dependent. This pattern is noted as a limitation of the single-measurement design; future work should calibrate the pH meter immediately before each reading, record sample temperature alongside pH, and take replicate readings per sampling event to confirm whether such swings reflect real short-term variability in the clay-borehole system or measurement noise.

DO levels remained relatively low but were slightly more stable in clay storage (2.4–2.9 mg/L) compared to plastic storage, as seen in Table 7. The porous nature of clay can facilitate limited oxygen diffusion, helping maintain DO relative to plastic. Previous research confirms that clay storage can enhance oxygenation due to gas exchange across porous walls, whereas plastic containers form closed systems that limit aeration and may promote oxygen depletion through both chemical and biological oxygen-consuming processes. The overall DO levels across all container-source combinations ranged between 1.6 and 2.9 mg/L, consistent with previously reported values for stored water (Ibrahim et al., 2024; Maury Njoya et al., 2024). The observed pattern generally conforms to the established trend of gradual oxygen depletion followed by stabilization as physicochemical processes approach equilibrium during storage.

BOD generally decreased over time in clay storage, as demonstrated in the borehole source (1.7–0.6 mg/L, Table 8), indicating a reduction in biodegradable organic matter - potentially through organic matter stabilization, adsorption onto the porous clay surface, or a combination of both. Plastic samples showed greater variability and occasional increases; for instance, well water in plastic containers reached a BOD as high as 1.1 mg/L on Day 3, suggesting a possible rise in organic load or oxygen-demanding activity, which may be associated with microbial processes, although this was not directly measured in this study. These findings align with earlier studies confirming that prolonged storage in both container types generally led to water stabilization with minimal residual organic pollution potential (Bigohe et al., 2025; Muhammad et al., 2026; Wielen, 2025). Meanwhile, clay containers appeared to reach this stabilized state more consistently than plastic in the present study.

CONCLUSION

This study assessed the effect of storage container type (clay pot and plastic) and storage duration on the quality of water obtained from rain, well, and borehole sources. The analysis focused on physicochemical and biochemical parameters, including Dissolved Oxygen (DO), Biochemical Oxygen Demand (BOD), pH, turbidity, temperature, Electrical Conductivity (EC), and Total Dissolved Solids (TDS). The study confirms that container material plays a critical role in mediating physicochemical transformations during storage, with associated implications for organic load and oxygen demand that may reflect underlying microbial activity, though this was not directly measured. Clay exhibited beneficial interactions - including evaporative cooling, adsorption, and comparatively more stable DO/BOD trends - whereas plastic containers, while providing greater structural stability, showed physicochemical trends (declining DO, variable BOD) that may indicate a greater potential for microbial-related deterioration over time. Overall, clay pots appear preferable for short-to-medium-term household water storage based on the physicochemical parameters assessed in this study. These findings should be interpreted with the caveat that no direct microbiological analysis (e.g., total coliform or E. coli enumeration) was conducted; future work incorporating such analysis is recommended to confirm whether the observed physicochemical trends correspond to actual microbial risk. Beyond clay and plastic containers, future studies could also include metallic, glass, or calabash containers to compare a wider range of storage options and their influence on water quality. A further limitation of this study is that single containers (rather than replicated containers) were used for each source–container combination, with one physicochemical measurement recorded per sampling day. Additionally, each water source was drawn from a single sampling site (Orbit Apartment, Zango, for borehole and rainwater; Hayin Dogo for well water), which may not capture the hydrogeological and

environmental variability present across other borehole, well, or rainwater sources within Zaria/Kaduna State. While this design allowed comparison across three water sources, two container types, and four storage durations within available resources, it does not permit statistical testing (e.g., ANOVA) of the significance of observed differences, and single measurements and single-site sampling cannot rule out the influence of measurement, sampling, or site-specific variability. Future studies should therefore incorporate replicate containers per condition, multiple sampling sites per source type, and direct microbiological assays, to enable formal statistical validation of both the physicochemical and microbial effects of container type and water source on stored water quality.

ABSTRACT

Aircraft systems are complex networks of components that support the entire mission and functionality of an aircraft. These complex engineered systems play fundamental roles in providing critical services, particularly regarding air transportation and energy needs. Among these, turbofan engines are the primary power source. As the usage of these complex engineering systems expands, they are increasingly subjected to harsh operational environments. These conditions inevitably make them susceptible to mechanical faults that, if not detected early, can result in catastrophic failure. Notably, the turbofan engine has accounted for 60% of airplane failures during flight. Therefore, Prognostics and Health Management technology utilizing deep learning is essential for predicting the Remaining Useful Life of these systems. This study explores a Long Short-Term Memory network integrated with a sliding-window approach and a Temporal Attention mechanism to estimate engine operational lifespan. Unlike existing literature reliant on legacy benchmarks, this model is trained and validated on a high-fidelity dataset generated using AGTF30, a NASA-developed turbofan simulation environment; because RUL is measured in seconds rather than operating cycles, comparison against C-MAPPS-based literature is limited to relative RMSE rather than direct numerical validation. By extracting temporal degradation features from raw multivariate sensor data, the framework achieves an overall Root Mean Square Error of 249.0 seconds and, crucially, a near-failure RMSE of 39.3 seconds, demonstrating highly reliable predictive capability during critical terminal degradation phases.

Keywords: *Turbofan Engine; Predictive Maintenance; Remaining Useful Life; LSTM Model; Deep learning approach*

1. INTRODUCTION

Complex engineered systems play a fundamental role in critical services such as energy, transport, and aerospace, underpinning the proper functioning of modern societies and economies. As these systems see wider use, they are increasingly subjected to harsh operational environments on a daily basis (Saxena et al., 2008). Left undetected, the compounding effect of minor mechanical faults can result in catastrophic failure, and for turbofan engines, the primary power source for an aircraft, the consequences of undetected degradation are particularly severe: as these engines accumulate flight hours, internal components gradually suffer wear, corrosion, and fatigue, leading to performance degradation and shortened lifespan.

In modern industrial operations, the accurate prediction of Remaining Useful Life (RUL) for critical machinery such as turbofan engines is of paramount concern (Thakkar & Chaoui, 2022). The turbofan is a core propulsion component of an aircraft; its stability and reliable operation are critical to flight safety (Jung et al., 2025). A turbofan engine is an air-breathing propulsive device and the predominant propulsion system in modern commercial and military aviation. Operating on the Brayton thermodynamic cycle, it consists of a gas turbine that adds kinetic energy to the air passing through it by burning fuel, and a ducted fan powered by that turbine to force air rearward and produce thrust (Chapman & Litt, 2017). The cost associated with machinery maintenance can be substantial, particularly in civil aviation, where aero-engine maintenance contributes significantly to overall operating expenses (Fu et al., 2023). RUL prediction involves estimating the time remaining before a

component reaches a failure threshold, given its historical and current operational state. Accurate RUL prediction lets manufacturers and operators reduce costs, improve reliability, and optimize maintenance strategies, maximizing service life while minimizing downtime and improving safety (Fu et al., 2023).

RUL is the amount of time a machine or asset is likely to operate before it requires repair or replacement. Depending on the system, this period can be represented in days, kilometers, cycles, or another relevant quantity. RUL prediction gives early warning of failure and forms a central pillar of Prognostics and Health Management (PHM), allowing engineers to schedule maintenance, optimize operating efficiency, and avoid unplanned downtime.

RUL prediction methods fall into two broad categories: model-based and data-driven. Model-based methods construct a model from mechanical or thermodynamic principles, a process that takes considerable time and depends heavily on prior expert knowledge, and even then, prediction accuracy cannot be guaranteed given the complexity and uncertainty of real engine systems. Data-driven approaches instead learn estimation models from historical run-to-failure data, avoiding the limitations of physical models and expert-built knowledge bases while benefiting from lower computational cost. Deep learning has become the dominant data-driven direction, offering strong results on RUL-related tasks, though mining complex time-series data effectively remains difficult given that turbofan sensor data is non-linear, time-variant, large in scale, and high in dimension. Long Short-Term Memory (LSTM) networks, a specialized form of Recurrent Neural Network, have proven particularly effective for this kind of temporal data. Convolutional Neural Networks saw earlier adoption but struggled to model long-term continuous degradation across multiple flight cycles (Li et al., 2018).

Previous RUL research has relied heavily on the public NASA C-MAPSS benchmark, which is widely adopted. However, it originates from a simplified thermodynamic model and does not capture the characteristics of modern geared turbofan architectures. This study addresses that gap by generating a run-to-failure dataset from the NASA AGTF30 geared turbofan dynamic simulation model, which is, to the authors' knowledge, the first application of this model for supervised RUL dataset generation. An LSTM network incorporating a sliding-window approach and a single-head temporal attention mechanism is then developed and evaluated on this dataset to predict the remaining useful life of the turbofan engine.

The specific contributions of this work are as follows. First, a run-to-failure dataset is generated from the NASA AGTF30 simulation, capturing multivariate sensor readings, including turbine exit temperature, pressure, and flow (T45, P45, W45) and high-pressure compressor exit conditions (T25, P25), across full degradation trajectories. Second, an LSTM network is developed incorporating a single-head temporal attention mechanism that computes an alignment score per timestep via a tanh-activated dense layer followed by a softmax-weighted sum, trained using a sliding-window approach to convert the raw multivariate sequence into fixed-length windows suitable for temporal modeling. Third, the model is evaluated using standard prognostic metrics, including Root Mean Square Error (RMSE) and an asymmetric scoring function that penalizes late RUL predictions more heavily than early ones, reflecting the safety-critical nature of aviation maintenance.This contribution aligns with the Intelligent Systems, Automation and Control Engineering sub-theme of ICESID 2026 and supports sustainable aviation development in Nigeria by advancing local capacity in predictive maintenance at AFIT, enabling reduced unscheduled downtime, extended engine life, and lower material waste and operational cost.

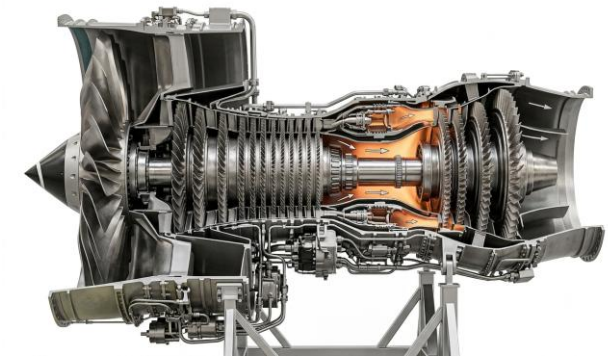

Figure 1: Typical Turbofan engine - Author own figure

The remainder of this paper is organized as follows. Section 2 reviews related work on RUL prediction methods and identifies the gap this study addresses. Section 3 describes the methodology, including dataset generation, feature selection, and model architecture. Section 4 presents the results and discusses model performance across seeds, engine life stages and it limitations. Section 5 summarizes the key findings. Section 6 outlines directions for future work, and Section 7 concludes the paper.

2. LITERATURE REVIEW

Prognostics, defined as the estimation of remaining useful component life, is central to systems health management (Vichare & Pecht, 2006). The inception of PHM can be traced back to the 1980s, when the Civil Aviation Authority (CAA) of the United Kingdom initiated its use with the aim of mitigating helicopter accidents. It later transitioned into health and usage monitoring systems (HUMS) by the late 1990s, enabling measurement of both the health condition and performance of helicopters (Fu et al., 2023).

In the early days of aircraft engines, defects were identified and repaired through Corrective Maintenance (CM). This approach was later replaced by Preventive Maintenance (PM), in which inspections and tasks are scheduled according to the probability of failure for specific components and usage conditions (Jardine et al., 2006). While Preventive Maintenance presented a significant step forward by introducing a degree of anticipation into maintenance planning, it remains constrained by its reliance on fixed time intervals or usage thresholds rather than the actual condition of the equipment. Components may be replaced prematurely, resulting in unnecessary cost and wasted resources, or failures may still occur between scheduled maintenance windows (Jardine et al., 2006). These limitations gave rise to a more mature model known as Condition-Based Monitoring (CBM), in which maintenance decisions are driven by the real-time health state of the system as gathered from sensor data, operational parameters, and observable degradation indicators. Building on CBM, Predictive Maintenance (PdM) extends this concept by forecasting when failure is likely to occur rather than simply estimating current health.

Remaining Useful Life (RUL) prediction methods are broadly categorized into two paradigms: physics-based and data-driven, as shown in Figure 2. Physics-based methods leverage mathematical models to represent system degradation over time by simulating the underlying failure mechanisms through well-established physical laws (Cubillo et al., 2016). These can be broadly divided into physical failure models and state-space models. Physical failure models describe degradation directly using governing equations derived from material science and mechanics, such as Archard's law for adhesive wear and the Paris-Erdogan law for fatigue crack growth. State-space models instead apply filtering techniques such as Kalman Filters and Particle Filters to track the evolving health state of a system in real time, updating predictions as new observations become available (Cubillo et al., 2016). Despite these strengths, physics-based models carry significant limitations that restrict their use in complex real-world systems, particularly gas turbine engines. They require precise and comprehensive knowledge of the physics governing each degradation mode, and developing and validating such models demands considerable domain expertise and time, making them difficult to scale across engine types or fault modes. This computational and developmental cost is amplified for real-time applications (Cubillo et al., 2016).

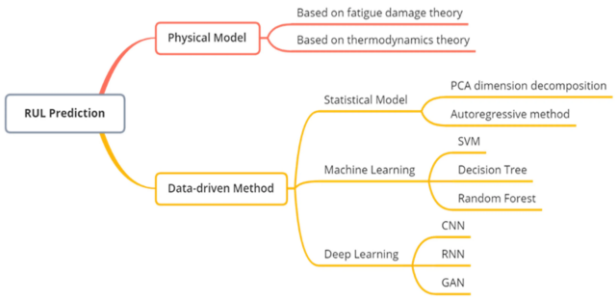

Figure 2: Classification of remaining useful life prediction methods (adapted from Xie et al., 2021).

Data-driven methodologies instead leverage historical data to evaluate current system health and predict RUL (Ensarioğlu et al., 2023). Rather than directly modeling the physical complexities of

wear and mechanical deterioration, data-driven approaches employ artificial intelligence to identify failure patterns and extract critical features from large datasets, revealing degradation characteristics by converting raw sensor history into usable information. Early data-driven research focused on traditional machine learning approaches such as Support Vector Machines, K-means clustering, and reinforcement learning (Ensarioğlu et al., 2023). While effective on small datasets, these approaches struggled in turbofan prognostics for two main reasons. First, manual feature engineering requires researchers to create and select features based on their own understanding of the data and statistical intuition, which becomes difficult to scale across large or high-dimensional datasets (H. Liu et al., 2021). Second, these methods lack temporal memory: they treat each sensor snapshot as an independent event, ignoring the fact that an engine's health at cycle 50 is directly dependent on its condition at cycle 49.

To address these limitations, researchers turned to deep learning, which uses multilayered neural networks for tasks such as classification, regression, and representation learning. Common architectures include fully connected networks, deep belief networks, recurrent neural networks, convolutional neural networks, generative adversarial networks, and transformers. Convolutional Neural Networks (CNNs) were initially adapted from image processing to extract spatial features from multi-sensor grids. While CNNs are effective at detecting local patterns, such as a sudden pressure rise, they struggle to model long-term, continuous degradation across hundreds of flight cycles, since they lack a recursive structure (Ensarioğlu et al., 2023). This was why Recurrent Neural Networks (RNNs) and Long Short-Term Memory (LSTM) networks were introduced. RNNs (Hochreiter & Schmidhuber, 1997; J. Zhang et al., 2018) are a family of neural networks specialized for processing a sequence of values, capable of capturing temporal dependencies within input samples. RNNs, especially those built from LSTM cells and Gated Recurrent Units (GRUs) (Dey & Salem, 2017; Yuan et al., 2016), and attention (Vaswani et al., 2017) have been widely used for prognostics of components such as lithium-ion batteries (Y. Zhang et al., 2018), gears, fuel cells, and turbofan engines (Cubillo et al., 2016; Fu et al., 2023; Saxena et al., 2008; Y. Zhang et al., 2018). However, standard RNNs suffer from the vanishing gradient problem, gradually forgetting early health-state information as more sequential data is introduced, which makes long-term dependencies difficult to learn. This limitation gave rise to more advanced recurrent architectures, notably LSTM networks (Hochreiter & Schmidhuber, 1997; J. Zhang et al., 2018) and GRUs (Dey & Salem, 2017). Since aero-engine data is inherently multivariate and time-dependent, this has contributed to the widespread adoption of LSTM models in RUL research (Hochreiter & Schmidhuber, 1997). Ensarioğlu et al. (2023) demonstrated that RNNs are efficient at analyzing the time-series characteristics of turbofan sensor data.

The LSTM addresses the vanishing gradient problem through three gating mechanisms that regulate the flow of information across time steps. The forget gate determines what historical information is discarded and is given as:

$$f_t = \sigma\left(W_f \cdot [h_{t-1}, x_t] + b_f\right) \tag{1}$$

The input gate controls what new information is written to the cell state:

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \tag{2}$$

And the output gate determines what information is passed to the next hidden state:

$$o_t = \sigma\left(W_o \cdot [h_{t-1}, x_t] + b_o\right) \tag{3}$$

Solanki et al. (2025) proposed a model combining pre-processing techniques with an LSTM network, introducing an improved piecewise linear degradation model to determine the initial point of deterioration and assign RUL target labels, evaluated on the C-MAPSS dataset. Dida et al. (2025) developed a prediction model combining CNN, LSTM, and attention mechanisms, using CNN to extract local features from sensor data while the LSTM-attention network analyzed temporal characteristics to forecast engine life. More recently, Transformer-based architectures have introduced an alternative to recurrence, replacing sequential processing with self-attention mechanisms that allow the model to weigh different parts of a sequence simultaneously, making them theoretically powerful for long-range dependency modeling (H. Liu et al., 2021; Vaswani et al., 2017). Recent work has applied hierarchical, multi-stage attention Transformers to turbofan RUL prediction with strong reported accuracy, demonstrating that the architecture race in this field has continued well past LSTM-based methods (Fan et al., 2024; L. Liu et al., 2022), demonstrating that the architecture race in this field has continued well

past LSTM-based methods. What has not moved, however, is the benchmark itself: this Transformer-based literature, like the LSTM-based work reviewed above, remains confined almost exclusively to C-MAPSS. The dataset, not the model architecture, is the persistent bottleneck this study addresses.

The quality of the simulation environment from which training data is generated is a primary determinant of whether a prognostic model will generalize to real-world application. The Commercial Modular Aero-Propulsion System Simulation (C-MAPSS) dataset, developed by NASA's Ames Research Center (Saxena et al., 2008), remains the most widely used benchmark in the turbofan RUL literature. C-MAPSS simulates a two-spool turbofan engine based on the thermodynamic architecture of the CFM56, modeling degradation in the HPC and HPT modules across six combinations of altitude, throttle resolver angle, and Mach number. The dataset is divided into four subsets, FD001 through FD004, each representing a different combination of operating conditions and fault modes (Saxena et al., 2008), with 21 sensor measurements recorded per flight cycle covering temperatures, pressures, shaft speeds, and efficiencies. C-MAPSS has been essential to the field, providing a public benchmark that has allowed researchers to contribute meaningfully to turbofan prognostics. It carries structural limitations, however, that narrow the conclusions that can be drawn from evaluations conducted on it. First, C-MAPSS employs a quasi-steady-state thermodynamic model, meaning operating conditions transition between predefined clusters rather than evolving continuously, concealing the transient dynamics that occur within a single flight cycle. High-fidelity telemetry from platforms such as AGTF30, by contrast, captures the rich, non-linear behavior seen during throttle excursions, altitude transitions, and rapid acceleration events (Chapman & Litt, 2017). Second, C-MAPSS models a dual-spool turbofan that does not reflect the variable-geometry features, gear reduction system, or closed-loop control behavior of next-generation geared turbofan engines.

To address the limitations of steady-state datasets such as C-MAPSS, the research community has turned to high-fidelity simulation environments capable of generating more realistic engine data. The Toolbox for the Modeling and Analysis of Thermodynamic Systems (T-MATS) is the most prominent example of this shift (Lavelle et al., 2014). Unlike earlier algebraic frameworks, T-MATS takes a modular, physics-based approach in which fan speeds, pressures, and temperatures evolve continuously in response to transient input (Chapman & Litt, 2017), using a library of component blocks for compressors, turbines, combustors, nozzles, ducts, and control actuators that can be assembled into different propulsion system configurations. The AGTF30 engine model, built within the T-MATS environment, represents a 30,000 lbf class geared turbofan (Chapman & Litt, 2017; Lavelle et al., 2014). This architecture introduces complexities absent from legacy benchmarks, most notably a gear reduction system that decouples the fan from the low-pressure spool, allowing both to operate at their respective aerodynamically optimal speeds. AGTF30 also runs within a closed-loop FADEC simulation, with a multivariable controller regulating thrust and surge margin. These features make AGTF30 a considerably more demanding environment for prognostic models, requiring them to differentiate between control-induced transients and genuine degradation signatures, a distinction that meaningfully strengthens a model's potential for real-world generalization (Chapman & Litt, 2017).

Taken together, the literature reviewed here reveals a consistent pattern: model architectures for turbofan RUL prediction, from early machine learning through LSTM and now Transformers, have advanced considerably, but almost entirely within the confines of C-MAPSS, a benchmark whose steady-state, dual-spool architecture no longer represents the modern engines it is meant to stand in for. Whether the properties that make these architectures effective on that older benchmark transfer to the transient, closed-loop, gear-coupled dynamics of a modern geared turbofan is a question the existing literature has not answered, largely because almost no one has tested it under those conditions. This gap, is not a shortage of capable model architectures but a shortage of realistic conditions to evaluate them against, is what this study addresses directly, by generating a fault-seeded dataset from the T-MATS/AGTF30 environment and evaluating an attention-augmented LSTM against it.

3. IMPLEMENTATION OF METHODOLOGY

This section describes the four-stage engineering pipeline used to generate, prepare, and model the dataset: dataset generation, data preprocessing, model architecture, training and optimization. The final two stages are addressed in the sections that follow.

3.1 Dataset Generation

A synthetic dataset was generated using the AGTF30 (Advanced Geared Turbofan, 30,000 lbf thrust class) simulation model implemented within the Toolbox for the Modeling and Analysis of Thermodynamic Systems (T-MATS), a NASA Glenn Research Center open-source MATLAB/Simulink library. The AGTF30 simulation environment is shown in Figure 3. Unlike empirical datasets, this simulation environment solves full thermodynamic cycle equations at each timestep, providing physically consistent sensor readings across all degradation scenarios. Degradation is modeled as continuous wear of the High-Pressure Compressor (HPC) and High-Pressure Turbine (HPT), represented by adjustments to each component's efficiency and flow capacity scalars. To the authors' knowledge, this represents the first published application of the AGTF30 dynamic simulation model for generating a run-to-failure RUL training dataset.

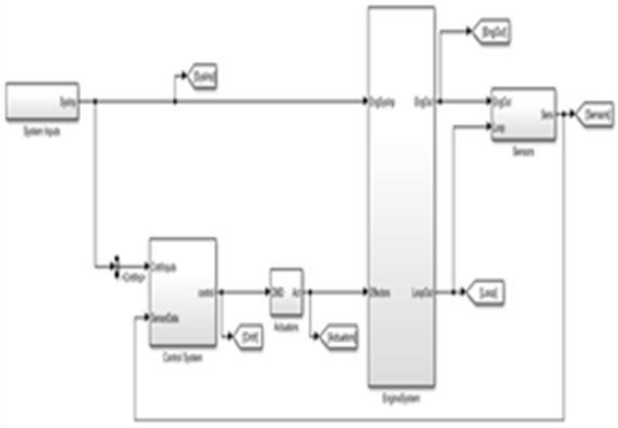

Figure 3: AGTF30 Simulink model.

Table 1: *Mission Profile Parameters*

Phase	Start (s)	End (s)	PLA (deg)	Altitude (ft)	Description
Ground Idle	0	100	40	0	Engine stabilizes at low power
Power-Up	100	500	40–80	0	Throttle advances to cruise setting
Cruise	500	2000	80	0	Steady cruise, fault detection window

Engine degradation is introduced by scaling the efficiency and flow capacity parameters of the HPC and HPT blocks within the T-MATS model. For each engine unit, four independent degradation factors are drawn from a uniform random distribution over the range [0.88, 1.00] using a fixed seed (rng (42)): one each for HPC efficiency, HPC flow capacity, HPT efficiency, and HPT flow capacity. Each factor is multiplied against its corresponding healthy design-point value to produce the degraded parameter used for that engine's simulation run, yielding four statistically independent degradation trajectories per engine rather than a single composite severity level. This randomized, per-unit approach follows the precedent set by the original C-MAPSS benchmark, in which each engine begins with an independently varying degree of initial wear (Saxena et al., 2008), and reflects the manufacturing and operational variability seen across a real engine fleet rather than a small set of discrete, repeatable severity levels. The degradation floor of 0.88 was set through boundary testing to ensure numerical stability across the full 2,001-second simulation.

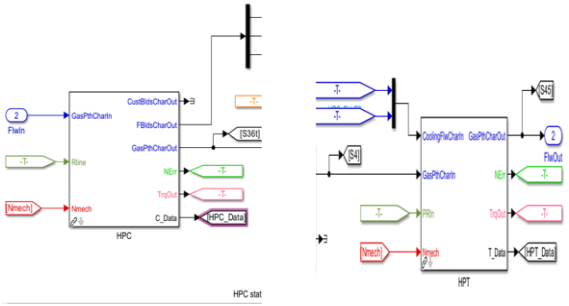

Figure 4: HPC and HPT block in NASA AGTF30 environment

Table 2: *Component Degradation Factor Ranges*

Component	Parameter	Healthy Value	Degradation Range
HPC	η (efficiency scalar)	0.994014	0.88–1.00
HPC	Wc (flow capacity scalar)	0.132800	0.88–1.00
HPT	η (efficiency scalar)	0.998392	0.88–1.00
HPT	Wc (flow capacity scalar)	0.195100	0.88–1.00

The AGTF30 model includes a Full Authority Digital Engine Control (FADEC) fuel controller that regulates fuel flow to hold exhaust gas temperature (T45) at a constant 2,241 R under steady-state cruise. As a result, T45 remains largely invariant across degradation levels. Degradation instead manifests primarily in total pressure at the HPT exit (P45) and mass flow rate at station 45 (W45), both of which drop measurably with compressor and turbine wear. HP shaft rotational speed (Nh) and thrust-specific fuel consumption (TSFC) were also evaluated as candidate signals but excluded, Nh showed only moderate sensitivity and TSFC changed negligibly across degradation levels. HPC inlet temperature (T25) and pressure (P25) were retained as upstream thermodynamic state indicators. Table 3 summarizes all candidate signals and which were retained as model inputs. This pattern, pressure and flow as primary degradation indicators rather than EGT alone, is consistent with real turbofan health-monitoring practice.

Table 3: *Candidate Sensor Signals and Degradation Sensitivity*

Signal	Description	Healthy (cruise)	Sensitivity	Retained
P45	Total pressure at HPT exit (psia)	~134.2	High	Yes
W45	Mass flow rate at station 45 (lbm/s)	~66.9	High	Yes
Nh	HP shaft rotational speed (RPM)	~21,150	Medium	No
T45	Exhaust gas temperature (R)	2241.0	Low (FADEC-held)	Yes
TSFC	Thrust-specific fuel consumption	~0.174	Low	No
T25	HPC inlet temperature (R)	~518	Medium	Yes
P25	HPC inlet pressure (psia)	~14.7	Medium	Yes

Simulations were logged at 1 Hz, yielding 2,001 rows per engine and 240,120 rows across the full 120-engine fleet. Each row contains the columns listed in Table 4. While 120 unique engine trajectories appear small, the sliding window approach with window 100 generates approximately 159,000 training samples, so the number of training sequences exceeds the number of model parameters. Generalization across trajectories is still limited to a single simulation environment with degradation factors in [0.88, 1.00], which is discussed in Section 4.7."

Table 4: *Dataset Column Description*

Column	Type	Description
unit_id	Integer	Engine identifier (1–120)
Time	Float	Elapsed simulation time (s)
T45	Float	HPT exit total temperature (R)
P45	Float	HPT exit total pressure (psia)
W45	Float	Mass flow rate at station 45 (lbm/s)
T25	Float	HPC inlet total temperature (R)
P25	Float	HPC inlet total pressure (psia)
HPC_eff	Float	HPC degradation factor applied (metadata only)
HPT_eff	Float	HPT degradation factor applied (metadata only)
RUL	Float	Remaining Useful Life label (s)
censored	Integer	0 = failed, 1 = did not reach failure threshold

3.2 Data Preprocessing

Out Of the seven candidate signals, five (T45, P45, W45, T25, P25) were retained as model inputs; they showed measurable, non-trivial change across the fleet as degradation progressed, while Nh and TSFC did not. The HPC and HPT degradation factors themselves (HPC_eff, HPT_eff) were excluded from model inputs entirely to prevent data leakage, since these internal efficiency scalars are not observable in a real deployment scenario and would artificially inflate accuracy if included.

Raw sensor values alone proved insufficient, since a single-timestep reading gives no indication of whether an engine is approaching failure or simply sitting in steady-state cruise; two engines at an identical T45 value might be on entirely different trajectories. To capture this, four rolling features were computed from the two most degradation-sensitive channels, P45 and W45: a ten-step rolling mean (P45_mean10, W45_mean10), smoothing single-timestep noise, and a ten-step finite-difference slope (P45_slope10, W45_slope10), capturing whether each channel is rising, falling, or flat over the preceding ten seconds, the most direct indicator of an active degradation event.

The 120 engines were divided into training (84), validation (18), and test (18) subsets using a stratified split by engine health score rather than a random shuffle. This ensures each subset contains a proportional mix of healthy and degraded units (Table 5).

Table 5: *Train-Validation-Test Split*

Subset	Engine Units	Count	Failed	Censored
Training	1–84	84 (70%)	59	25
Validation	85–102	18 (15%)	9	9
Test	103–120	18 (15%)	10	8
Total	1–120	120	78	42

All five input features were scaled to the range [0, 1] using min-max normalization, preventing features with large absolute values, such as T45 at approximately 2,241 R, from numerically dominating the gradient relative to features with small absolute values, such as P25:

$$x_{norm} = (x - x_{min})/x(_{max} - x_{min}) \quad (4)$$

where x_{min} and x_{max} are computed exclusively from the training set and applied identically to the validation and test sets, avoiding data leakage from statistics computed on the full dataset before splitting.

Failure is defined as the first timestep during the cruise phase (t = 500s to t = 2,000s) at which P45 drops below 75% of its healthy cruise baseline of 134.215 psia (P45_fail = 100.66 psia).

$$P45_{fail} = 0.75 \times 134.215 = 100.66 \text{ psia}$$

Restricting this check to the cruise phase prevents the naturally lower P45 at ground idle from being misclassified as degradation failure. Engines that complete the full 2,000-second simulation without crossing this threshold are labeled censored, mirroring the real-world practice of removing engines for scheduled maintenance before absolute end-of-life.

A piecewise linear RUL model was adopted, consistent with the labeling convention established for C-MAPSS (Li et al., 2018):

$$RUL_t min\left(RUL_{max}, max(0, t_{fail} - t)\right) \quad (5)$$

where t_fail is the timestep at which P45 first crosses the failure threshold and RUL_{max} = 4,000 seconds is the plateau cap. For censored engines, t_fail is set to 5,000 seconds, meaning RUL counts down from 4,000 seconds at t = 0 and reaches 3,000 seconds at t = 2,000 seconds without ever reaching zero.

The dataset was restructured into overlapping sliding windows with a stride of one timestep, each capturing W consecutive seconds of the five input features:

$$Input: x[t - W + 1: t] \quad (6)$$

$$shape: (W \times 9) \quad (7)$$

$$Target: RUL_t \quad (8)$$

A window length of W = 100 seconds was selected because the throttle transition from idle to cruise takes approximately 30 to 60 seconds in the mission profile; a 100-second window is long enough to capture the complete transient response the LSTM needs to distinguish a healthy throttle event from a degradation-driven pressure drop.

3.3 Model Architecture

The proposed model is a stacked LSTM network implemented in TensorFlow/Keras. The architecture follows the established pattern for turbofan RUL regression identified across recent literature (Dida et al., 2025; Elsherif et al., 2025): The model is constructed using a sequential stacking of layers, that consist of LSTM layers, fully connected layers, and a single output layer for regression. The core of the model's ability to handle time-series data lies in its two stacked LSTM layers, each designed to capture distinct temporal patterns, for temporal feature extraction, dropout regularization between layers, and a single linear output neuron for scalar RUL regression.

Table 6: *LSTM Model Architecture*

Layer	**Configuration**	**Output Shape**	**Parameters**
Input	Window=100, Features=9	(None, 100, 9)	0
LSTM-1	128 units, return_sequences=True	(None, 100, 128)	70,656
BatchNorm-1	axis = -1	(None, 100, 128)	512
Dropout-1	rate = 0.2	(None, 100, 128)	0
LSTM-2	64 units, return_sequences=True	(None, 100, 64)	49,408
BatchNorm-2	axis = -1	(None, 100, 64)	256
Dropout-2	rate = 0.2	(None, 100, 64)	0
TemporalHead Attention	1 head, units=64, entropy=0.02	(None, 64)	4,160
Dense-1	32 units, ReLU	(None, 32)	2,080
Dropout-3	rate = 0.1	(None, 32)	0
Dense Output	1-unit, linear activation	(None, 1)	33
Total Trainable Parameters			126,721

The first LSTM layer uses return_sequences=True so it passes a hidden state at every timestep to the second layer, allowing the second layer to reason about the temporal evolution of the learned features rather than only the final state. The second layer also uses return_sequences=True, preserving the full sequence for the attention block, which then compresses the window into a single context vector before the dense output layer maps it to a predicted RUL value. The model is compiled with the Adam optimizer at a learning rate of 0.001, using a custom phase-aware asymmetric error as the loss function. Phase-aware loss was chosen over mean squared error because it penalizes late predictions overestimates of remaining life more heavily than early ones, reflecting the operational reality that missing a failure warning is far more dangerous than scheduling maintenance a bit early. Early stopping with a patience of 25 epochs monitors validation loss and restores the weights from the best-performing epoch, preventing overfitting without requiring a manually specified epoch count.

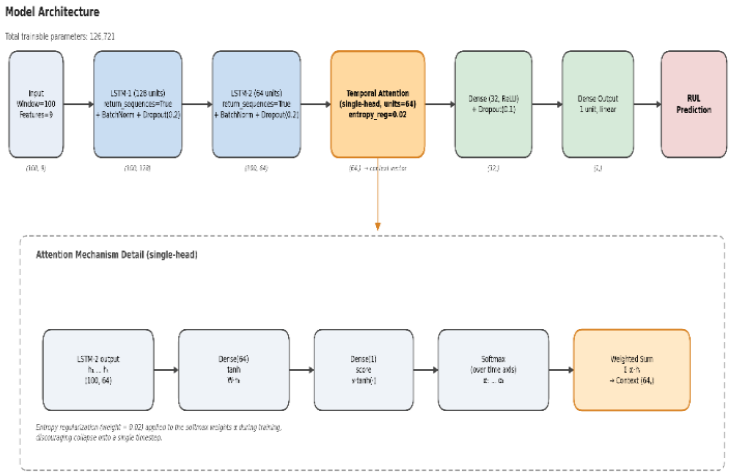

Figure 5: Proposed single-head attention-augmented LSTM architecture.

Following the recurrent layers, a temporal attention mechanism compresses the full sequence into a single context vector. Rather than assigning uniform importance to all 100 timesteps, the attention layer computes a learned weighting across the window. In this particular application, the trained weights concentrated predominantly on the oldest observation in the window the timestep furthest from the prediction point. This behavior departs from the common design expectation that attention will focus on recent transients or anomalous spikes. For the AGTF30 dataset, where degradation is deterministic and largely monotonic, the oldest available observation acts as a stable reference baseline. The model appears to use it to compute an implicit delta against the current state, which is a physically coherent strategy for a simulation where the rate of change, not the absolute sensor value, carries the degradation signal. Section 4 discusses this finding in detail.

3.4 Training, Loss Function, and Optimization

Standard regression problems typically minimize Mean Squared Error, but MSE imposes a symmetric penalty that ignores the direction of the error. A prediction that underestimates remaining life by ten seconds is treated identically to one that overestimates it by the same amount. In the context of engine prognostics, that symmetry is not operationally valid. An overestimation predicting more remaining life than actually exists represents a safety hazard, because it may delay necessary maintenance. An underestimation, by contrast, leads to a premature but safe maintenance action that wastes a limited amount of engine life. A loss function that does not distinguish between these two cases discards the information a maintenance-critical model is designed to protect.

The loss function used in this work addresses the asymmetry in two stages. Let y and $\hat{y}$ denotes the predicted and true normalized RUL, and is define as the signed prediction error

$$\Delta = \hat{y} - y. \quad (9)$$

The base asymmetric penalty is defined as:

$$\mathcal{L}_{asym} = \begin{cases} \alpha \cdot \Delta^2 & \text{if } \Delta > 0 \\ \Delta^2 & \text{if } \Delta \leq 0 \end{cases} \quad (10)$$

where $\alpha = 2.5$ applies a strict penalty to overestimations ($\hat{y} > y$)

Applied uniformly, this asymmetry would penalize noisy early-life predictions just as heavily as those near failure, over-correcting in a regime where small errors in either direction are operationally inconsequential. To restrict the asymmetric penalty to the phase of the engine's life where it matters, a sigmoid blending weight is introduced that shifts the loss smoothly from symmetric to asymmetric as the engine approaches its failure threshold:

$$w(y) = \sigma\big(\gamma(\tau - y)\big) \quad (11)$$

where $\tau = 0.5$ designates the normalized RUL at which the engine transitions from "healthy" to "at-risk," and γ=20.0 controls the steepness of the transition. The final loss is a convex combination of the two penalties:

$$Lfinal = w(y) \cdot L_{asym}(\Delta) + \big(1 - w(y)\big) \cdot L_{sym}(\Delta) \qquad (12)$$

Under this formulation, a healthy engine (y well above 0.5) is trained almost entirely under standard squared error, while an engine approaching failure (y near zero) is trained under the asymmetric penalty that discourages overestimation.

Training proceeded for up to 200 epochs with early stopping (patience of 25 epochs on validation loss, restoring the best-performing weights) and a learning rate schedule that halved the learning rate after 10 epochs without improvement, decaying to a floor of 1×10^{-6}. This schedule allowed the optimizer to continue fine-grained refinement once the loss had largely stabilized.

Model performance is quantified with three complementary metrics. Root Mean Square Error (RMSE) is reported in seconds, matching the physical unit of RUL:

$$RMSE = \sqrt{\left(\frac{1}{n} \times \sum (\hat{y}_i - y_i)^2\right)} \qquad (13)$$

Because the quadratic term amplifies large errors, a low RMSE indicates both a small average error and the absence of catastrophic outliers, both of which are essential for a maintenance-relevant prediction. Direct numerical comparison against published LSTM baselines on the C-MAPSS benchmark is not meaningful here, since this study measures RUL in seconds rather than flight cycles and uses a different simulation source. RMSE therefore serves as an internal reference for comparing configurations within this work.

The NASA Prognostic Scoring function, introduced alongside the C-MAPSS dataset (Saxena et al., 2008), is also reported. It encodes the same late-versus-early asymmetry that structures the training loss:

$$s = \sum e^{\frac{-d}{13}} - 1 \qquad (14)$$

For d< 0 (early: predicted RUL < actual RUL)

$$s = \sum e^{\frac{d}{10}} - 1) \qquad (15)$$

for d ≥ 0 (late: predicted RUL > actual RUL)

where $d = \hat{y} - y$ is the signed prediction error. The penalty for late predictions grows with a characteristic scale of 10, while early predictions are penalized at a scale of 13 making equivalent-magnitude late errors approximately 34% more costly. A lower total score indicates better performance.

3.5 Experimentation Setup

Dataset generation ran on a Dell Latitude 7480 laptop under MATLAB R2023a with T-MATS v1.1. Each 2,001-second engine simulation took 10 to 15 minutes of wall-clock time; the full 120-engine fleet required roughly 12 hours of continuous computation. Model training and all Python preprocessing were conducted on a Kaggle kernel with an NVIDIA Tesla P100 GPU (16 GB HBM2). A single 200-epoch training run took 30 to 40 minutes. The deep learning framework was TensorFlow 2.20 with Keras. Preprocessing used Python 3.12 with NumPy, Pandas 2.0, and Scikit-learn 1.3.

Three independent training runs were performed with identical hyperparameters and different random seeds (42, 123, 777) to assess reproducibility. The seed 42 run produced the lowest overall test-set RMSE and is reported as the primary result throughout. This reflects a best-of-three outcome selected after all training was complete, not during model development, and is disclosed here for transparency. All three runs used the same preprocessing pipeline and the same test partition.

4. RESULTS AND DISCUSSION

This section presents the experimental results obtained from the training and evaluation of the Attention Augmented Long Short-Term Memory (LSTM) network for Remaining Useful Life (RUL) prediction of turbofan engines. Results are reported across four evaluation metrics: Root Mean Square Error (RMSE), Mean Average Error (MAE), Near-Failure RMSE, and the NASA Prognostic Score. This section additionally presents a comparative analysis of progressive model refinements, an examination of the attention mechanism's behavior, and a critical discussion of the model's strengths and limitations in the context of the broader prognostics and health management (PHM) literature.

4.1 Overall Performance

Three independent runs used identical configurations under different random seeds (42, 123, 777) to check reproducibility (Table 7), with Seed 42 selected as the reported model per the disclosure in Section 3.5.

Table 7: *Seed Comparison*

Seed	**RMSE (s)**	**MAE (s)**	**NF-RMSE (s)**	**NASA Score**
42 (selected)	249.0	167.1	39.3	122.87
123	263.1	169.9	38.5	123.07
777	269.8	169.6	38.4	123.05

The near-failure RMSE remains stable across all three seeds, within a 1.1-second band, confirming that near-failure accuracy is not a product of random initialization. The Seed 42 model was evaluated on 34,218 test sequences drawn from 18 held-out engines. Table 8 summarizes the results.

Table 8: *Final Test Set Metrics*

Metric	**Value**	**Context**
Overall RMSE	249.0 s	6.2% of the 4,000 s operating range
Overall, MAE	167.1 s	4.2% of the 4,000 s operating range
Near-failure RMSE (RUL<200s)	39.3 s	Average error in the final 200 s of engine life
NASA Prognostic Score	122.87	Normalized RUL scale; lower is better

The 249-second overall RMSE, 6.2% of the full operating range, reflects a bimodal structure that Section 4.2 explains. The near-failure RMSE of 39.3 seconds is the number that matters operationally: at 1 Hz sampling, this means a maintenance alert would be issued within roughly 39 timesteps of the optimal alert time. The NASA score of 122.87 is consistent with the intended conservative bias of the asymmetric loss, with the residual analysis in Section 4.3 [mean -41.7s] confirming a deliberate under-prediction of remaining life to preserve a safety margin.

4.2 Prediction Accuracy Across Engines

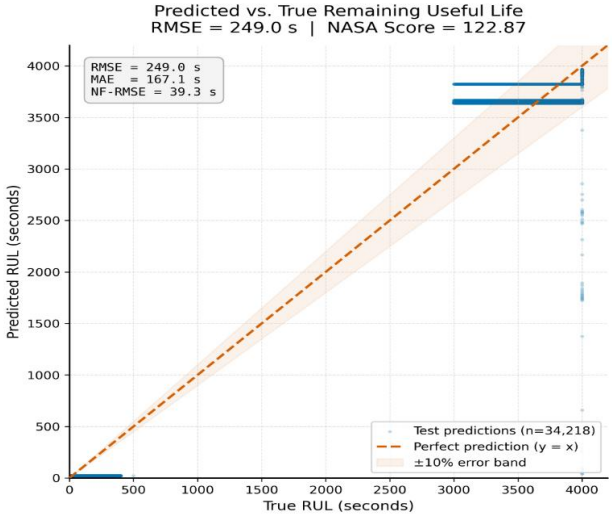

Figure 6: Predicted RUL vs True RUL

Figure 6 plots predicted against true RUL for every test sequence, each point representing one sequence. Two populations are visible: a near-diagonal cluster at low RUL (0–400s) from failed, short-life engines, predicted closely along the diagonal, and a horizontal band at approximately 3,700s predicted for true RUL values of 3,000–4,000s from long-life, censored engines, where the model predicts a roughly constant value rather than tracking the gradual decline.

Figure 7 shows individual RMSE per engine. Ten test engines, the failed, short-life units, cluster near 99 seconds; the remaining eight, which are censored, long-life units, range from 331 to 479 seconds. The aggregate mean of 249 seconds is the average of these two distinct groups, not a representative value for either.

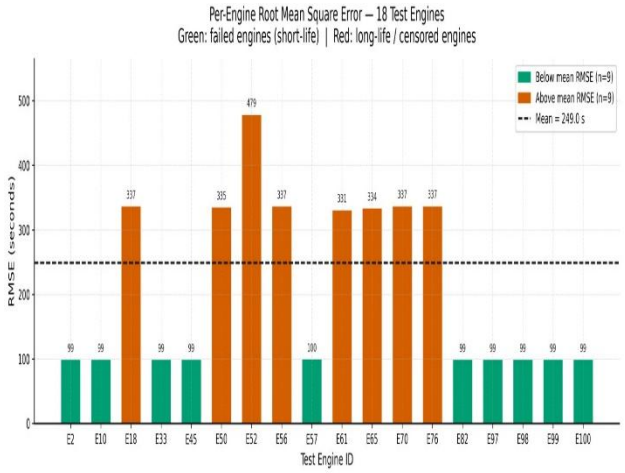

Figure 7: Per-Engine RMSE – All 18 Test Engines

The dividing factor is operational history, and not architecture. Failed engines gave the training set complete degradation trajectories, including the failure event itself, and the model learned from those. Censored engines never failed within the simulation window, so the training data for this group contains no failure event to anchor a declining prediction against. The model cannot commit to a trajectory it never observed reaching its end, and a conservative, near-constant prediction is the result. This pattern is consistent with known challenges in supervised prognostics on datasets that mix failed and censored units, and is not specific to this architecture.

4.3 Life-Stage and Residual Accuracy

Figure 8 shows the distribution of prediction residuals (predicted minus true RUL) across all test sequences. The mean residual is −41.7 seconds with a standard deviation of 245.5 seconds. A

dominant spike sits near zero, corresponding to accurate near-failure predictions, and a secondary cluster sits near −600 seconds, corresponding to the long-life engine group. This distribution is consistent with the loss function behaving as intended: the negative mean residual reflects the deliberate conservative bias built into the asymmetric loss, under-predicting remaining life slightly to preserve a safety margin ahead of actual failure. The secondary cluster reflects the same censored-engine behavior described in Section 4.2, a flat early-life prediction near 3,700 seconds against an actual value descending toward 3,000, widening the overall residual spread without affecting near-failure accuracy. A small tail of positive residuals appears early in some simulations, plausibly linked to transient sensor behavior during engine start-up before the model stabilizes into accurate tracking.

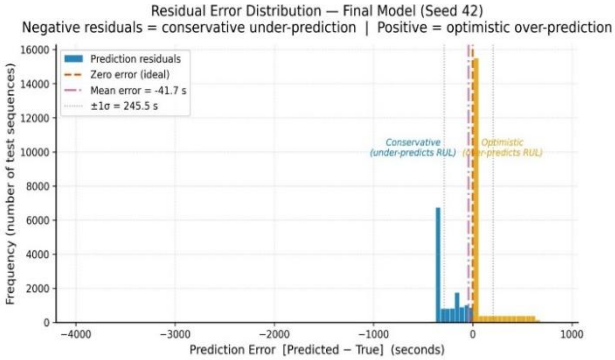

Figure 8: Residual Error Distribution All Test Sequences

Figure 9 decomposes RMSE and MAE by life stage: early life (RUL > 2,000s, n=15,208), mid-life (200–2,000s, n=2,001), and near-failure (RUL < 200s, n=17,009). The gradient is explicit: 357-second RMSE in early life, 284 seconds in mid-life, and 39 seconds in the near-failure window. This is the pattern a safety-oriented prognostic model should show: the life stage where a wrong prediction carries the greatest operational risk is also the stage with the lowest error.

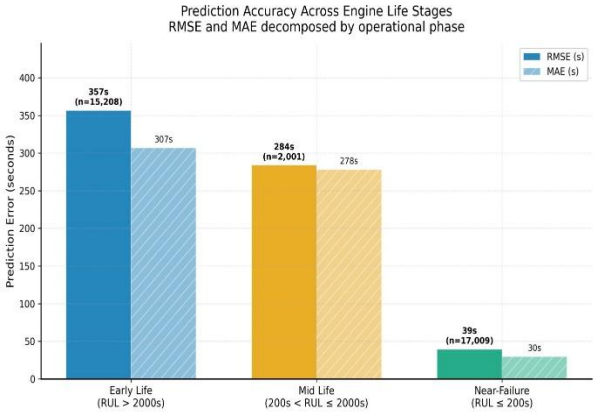

Figure 9: Prediction Error by Operational Phase

4.4 Attention Behavior

Figure 10 shows attention weights across the 100-step input window for all test predictions, alongside the mean attention profile averaged across all timesteps. Nearly all weight concentrates on window position 0, the oldest observation in the window, rather than on recent timesteps as originally anticipated in the architecture's design.

This concentration has two reinforcing explanations, one physical and one mechanical. Physically, degradation in the AGTF30 simulation is monotonic and largely deterministic, so the oldest timestep in a given window serves as a stable reference point, and the model appears to compute an implicit delta between that reference and the current state rather than searching for informative recent transients. Mechanically, the entropy regularization term in the loss is added to, rather than subtracted from, the total loss that training minimizes. Since entropy is lowest when attention weight concentrates on a single timestep, minimizing the loss also minimizes this term, which rewards concentrated attention

rather than penalizing it. That is the reverse of how entropy regularization is conventionally applied. The sharp concentration on position 0 is therefore not only a physically plausible outcome, it is close to the outcome this loss term was mathematically set up to produce. This concentration explains the visual appearance of Figure 10.Since most attention is at position 0, the other position has near-zero weight and shows up as black, and the uniform pattern across the 1900 sequences reflects a consistent focus on position 0 rather than a visualization issue. A future revision subtracting rather than adding the entropy term, rather than simply lowering its coefficient, would be the more direct way to encourage the originally intended recency-weighting behavior.

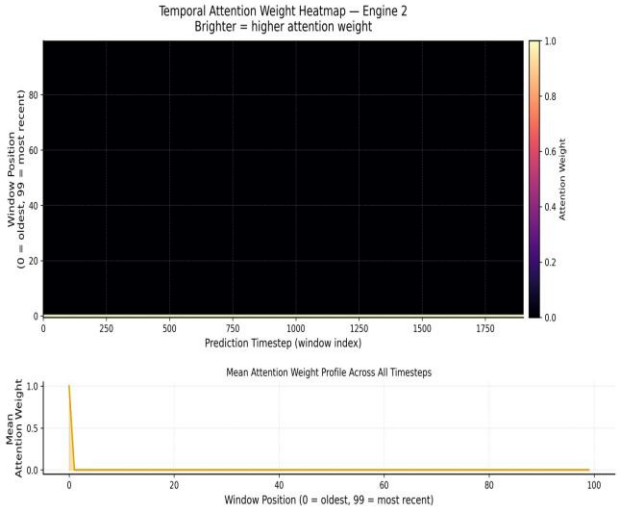

Figure 10: Temporal Attention Weight Heatmap and Mean Profile – Engine 2 Top:1900 sequences across 100 positions, dark is near-zero weight. Bottom: mean profile. The uniform appearance shows consistent focus at 0

4.5 Ablation Study

Table 9 traces the progression from baseline to final model across the major architectural and training changes.

Table 9: *Ablation Study Progression*

Step	Incremental Change	Overall RMSE (s)	NF-RMSE (s)	NASA Score
0	Baseline: raw features, MSE, sigmoid output	358	104	—
1	+ Rolling features (mean, std, slope)	371	42	159.7
2	+ RUL norm, BatchNorm, window=100, attention, phase-aware loss thr=0.6	451	38.8	166.5
3	+ Thr correction to 0.4, entropy reg 0.02, remove soft plateau	330	38.4	134.0
4	+ Healthy fraction 0.5	304	38.6	127.3
5	+ Healthy fraction 0.9, thr=0.5, healthy penalty	273	39.5	117.6

Each row reflects the cumulative configuration at that stage; several runs bundle more than one change, so performance shifts cannot be attributed to a single factor alone. Introducing rolling features produced the largest single drop in near-failure RMSE, from 104 to 42 seconds, a 60% reduction. The threshold used for the phase-aware loss was initially set too high (0.6), activating the asymmetric penalty too early in mid-life and pushing overall RMSE up to 451 seconds; lowering it corrected this, as shown in Figure 11 Subsequent runs progressively reduced overall RMSE through healthy-fraction adjustments and refinements to the single-head attention configuration. The near-failure column tells the more interesting story: it barely moves after the rolling-features change. Six subsequent architectural and training adjustments shifted overall RMSE by more than 200 seconds, while near-failure RMSE stayed within a 4-second band throughout. This stability indicates that near-failure accuracy is driven primarily by the rolling slope features, which directly encode the rate of degradation, rather than by any specific architectural choice made afterward.

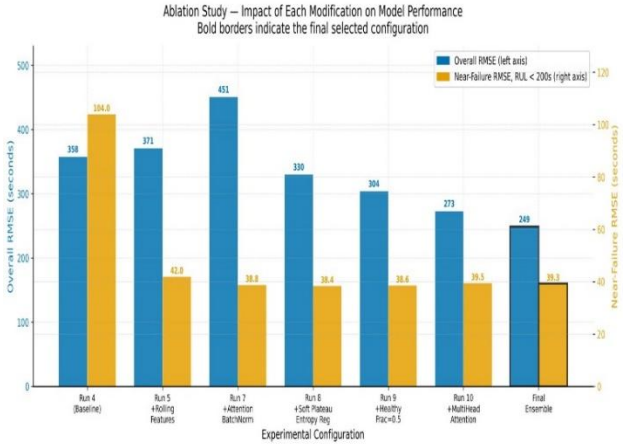

Figure 11: Ablation Study – Overall RMSE and Near-Failure RMSE Across All Runs

4.6 Comparison with Published Benchmarks

A direct numerical comparison between this study's results and published LSTM-based RUL results is not possible in absolute terms. Every published benchmark for turbofan prognostics uses C-MAPSS, with RUL measured in engine cycles over an operating range of roughly 125 to 350 cycles depending on sub-dataset, while this study measures RUL in seconds over a 4,000-second range; the two quantities have no common scale. What can be compared is relative error, RMSE as a percentage of each study's operating range, which is scale-independent. Table 10 presents this comparison.

Table 10: *Relative RMSE Comparison with Published Studies*

Study	Dataset	RMSE	Operating Range	Relative RMSE
Li et al. (2018)	C-MAPSS FD001	12.6 cycles	~125 cycles	10.1%
Y. Zhang et al. (2018)	C-MAPSS FD001	13.4 cycles	~125 cycles	10.7%
H. Liu et al. (2021)	C-MAPSS FD001	11.4 cycles	~125 cycles	9.1%
Muneer et al. (2021)	C-MAPSS FD001	13.1 cycles	~125 cycles	10.5%
This study	AGTF30 (self-generated)	249.0 s	4,000 s	6.2%

The relative RMSE of 6.2% obtained here is lower than all four C-MAPSS references shown.This should not be read as evidence that this model outperforms them; the comparison places the result in proportional context rather than making a superiority claim across different experimental conditions and simulation environments. The primary contribution of this work is the AGTF30 dataset and its use for supervised LSTM training, not the relative RMSE figure itself. Other recent deep learning approaches reporting comparable relative RMSE on C-MAPSS and N-CMAPSS include (Arias Chao et al., 2021; Ellefsen et al., 2019; Elsherif et al., 2025; Remadna et al., 2021).

4.7 Limitation

The most consequential limitation is the simulation boundary. Every engine in this study was generated by a mathematical model. The AGTF30 simulation does not include sensor noise, measurement drift, off-nominal atmospheric conditions, or the stochastic variation that characterizes

real engine monitoring systems. Whether the trained model generalizes to physical test rig data, much less to operational engine telemetry, has not been tested.

The censored engine problem is structural. Eight of the 18 test engines produced RMSE values above 300 seconds because their failure events do not occur in the training data. The model has no reference for what the terminal degradation looks like in high-life engines. This is not solvable by adjusting the architecture. It requires either more training data with completed high-life failure trajectories, or a different modeling approach that handles incomplete observations explicitly.

The loss function threshold, the entropy regularization coefficient, the healthy cycle retention fraction, and the attention head count were all chosen by sequential experiment rather than by systematic search. The dataset contains 120 unique engine trajectories from a single AGTF30 configuration. Although windowing increases sample count, variation in operating conditions and degradation modes is narrow [0.88, 1.00], and the model's ability to generalize to real engines or other simulation settings was not tested. This is mitigated by the 84/18/18 split by engine, so no engine appears in both train and test, and by Dropout, BatchNorm and early stopping, but remains a limitation. In addition, several rows in Table 9 combine more than one change at a time for example, threshold correction, entropy regularization, and soft plateau removal so the gains cannot be pinned down to a single factor alone. The three-seed selection approach also introduced a mild positive bias in the reported RMSE; the best of three runs is reported, and the other two seeds gave 263 and 270 seconds respectively.

5. FINDINGS

The near-failure RMSE of 39.3 seconds is the most operationally relevant number in the study. When the engine has less than 200 seconds of remaining life, the model predicts that life with an average error of 39 seconds. That figure was stable across all three independent training seeds, ranging from 38.4 to 39.5 seconds. Additionally, stability across seeds matters here. This result did not depend on a single fortunate initialization; it held consistently across multiple independent runs A result was that was not consistent across various multiple training instances is not a result worth trusting especially in the aviation industry where an unreliable prediction carries real safety consequences. The overall RMSE of 249.0 seconds is 6.2 percent of the 4,000-second operating range. It is also the average of two very different populations. Ten test engines had individual RMSE near 99 seconds. Eight others ranged from 331 to 479 seconds. The divide falls along the line between short-life failed engines and long-life censored engines. Rolling features drove the largest single improvement in the entire ablation study. Adding the tenstep mean and slope features for P45 and W45 cut near-failure RMSE from 104 seconds to 42 seconds in one step. Every subsequent architectural addition, the attention mechanism, the custom loss, the single-head design, the healthy cycle retention, improved overall RMSE but moved nearfailure RMSE by only a few seconds. The informational content that matters most for near-failure prediction was already captured by the rate-of-change features.

6. FUTURE WORK

Four directions follow from the findings and limitations of this study. The censored-engine behavior is structural, not something more LSTM layers would fix: eight of the 18 test engines produced RMSE values above 300 seconds because their failure events simply don't occur in the training data, the model has no reference for what terminal degradation looks like in a high-life engine. Survival analysis methods, Cox proportional hazards models or Weibull regression adapted for sensor data, built specifically to extract information from incomplete observations, and a hybrid model combining LSTM-based feature extraction with a survival-analysis output layer would let the full fleet contribute meaningful signal during training rather than the censored engines acting as noise.

Every finding in this study also sits behind a simulation boundary. The AGTF30 model was designed to match the thermodynamic behavior of real advanced geared turbofan architectures, so transfer to physical data may be plausible, but it has not been demonstrated. Even a partial comparison against a small number of physical engine cycles from a test rig would substantially strengthen the claim that physics-based simulation data can substitute for real fleet data in supervised prognostic training.

The attention mechanism's concentration on the oldest input timestep, discussed in Section 4.4, also points to a concrete next step: adding a learned positional encoding to the LSTM output sequence before attention scoring, giving the model an explicit sense of where each timestep sits in the window,

or correcting the sign of the entropy regularization term so it discourages rather than rewards concentration. Either is a small, targeted change worth testing before the attention design is treated as final.

Finally, the pipeline built for this study, simulation-based dataset generation, rolling-feature engineering, and the attention-augmented LSTM itself, is not inherently turbofan-specific. Any rotating machinery asset with an existing physics-based simulation model and a sufficient historical record of failure events could, in principle, follow the same sequence.

7. CONCLUSION

This study addressed a specific gap in turbofan Remaining Useful Life prediction: the near-total reliance of existing LSTM-based research on the NASA C-MAPSS benchmark, a dataset built on a simplified, dual-spool thermodynamic model that does not reflect the transient, closed-loop behavior of modern geared turbofan engines. A run-to-failure dataset was generated from the NASA AGTF30 simulation using the T-MATS environment, to the authors' knowledge the first published use of AGTF30 for this purpose, and an LSTM network augmented with a single-head temporal attention mechanism and a phase-aware asymmetric loss function was trained and evaluated against it.

The final model achieved an overall RMSE of 249.0 seconds and a near-failure RMSE of 39.3 seconds, with a MAE of 167.1 seconds and a NASA prognostic score of 122.87, with near-failure accuracy stable within a two-second band across three independent random seeds. The results show a clear accuracy gradient across an engine's operational life, with the lowest error occurring in the final approach to failure, the phase where an inaccurate prediction carries the greatest operational and safety consequence. The ablation study traced this near-failure accuracy primarily to the engineered rolling-window features rather than to any single architectural change, while the overall RMSE improved substantially through the attention mechanism, phase-aware loss tuning, and healthy-sample rebalancing introduced across later iterations of the model.

The central contribution of this work is not the RMSE figure itself but the dataset and methodology behind it: a demonstration that LSTM-based RUL prediction, evaluated under the more demanding transient and closed-loop dynamics of a high-fidelity geared turbofan simulation, retains the same near-failure reliability previously reported only on C-MAPSS. Extending this approach to real flight telemetry remains the necessary next step toward operational deployment. For Nigeria's growing aviation sector, such data-driven prognostic capability offers a practical pathway to more sustainable maintenance practices and reduced reliance on fixed-interval overhauls.

ACKNOWLEDGMENT

ABSTRACT

The increasing demand for cost-effective and sustainable wastewater treatment technologies in developing regions has necessitated the exploration of locally available materials for tertiary treatment applications. This study presents the design and performance evaluation of a laboratory-scale dual-media filtration system incorporating palm kernel shell-derived activated carbon (PKS-AC) and sharp sand for the treatment of effluent from the Ahmadu Bello University (ABU), Zaria stabilization pond. The filtration column was constructed using a layered configuration of coarse sand, activated carbon, and fine sand to facilitate combined processes of physical filtration and adsorption. Wastewater samples were collected from the final discharge point of the maturation pond and analyzed before and after filtration for selected physicochemical parameters, including turbidity, nitrate concentration, biochemical oxygen demand (BOD), chemical oxygen demand (COD), and total dissolved solids (TDS). The results indicate substantial improvements in effluent quality after treatment. Turbidity was reduced from 13.0 NTU to 2.6 NTU, nitrate concentration decreased from 35.0 mg/L to 15.6 mg/L, COD was lowered from 3000 mg/L to 800 mg/L, and BOD decreased from 150 mg/L to 90 mg/L. Additionally, a moderate reduction in TDS was observed. The enhanced performance of the system is attributed to the synergistic interaction between the sand filtration layers and the adsorption capacity of PKS-AC. The findings demonstrate that the developed dual-media filtration system offers an efficient, low-cost, and sustainable solution for tertiary wastewater treatment, particularly in institutional and resource-constrained environments.

1. INTRODUCTION

Access to safe and reliable water remains a critical global challenge, particularly in developing countries where rapid urbanization, population growth, and limited infrastructure increasingly strain water resources and wastewater management systems (Onu et al., 2023). Wastewater generated from domestic, institutional, and industrial activities contains suspended solids, organic matter, nutrients, and pathogenic microorganisms, all of which pose significant environmental and public health risks if inadequately treated (Etsuyankpa et al., 2024).

Conventional wastewater treatment processes primarily target the removal of settleable solids and biodegradable organic matter. However, these processes may not adequately eliminate residual contaminants such as nutrients, turbidity, and dissolved pollutants. Consequently, the discharge of insufficiently treated wastewater can contribute to eutrophication, deterioration of water quality, and increased risks to aquatic ecosystems and public health (Kato & Kansha, 2024).

In many developing regions, including Nigeria, wastewater treatment systems rely predominantly on low-cost technologies such as waste stabilization ponds due to their simplicity and low operational requirements. While these systems are effective in reducing biochemical oxygen demand (BOD) and pathogen loads under optimal conditions, they often fail to remove turbidity, nutrients, and residual organic pollutants (Kayode et.al, 2023; Mara, 2013; Nwinyi et al., 2020). This

limitation is evident in the wastewater treatment system at Ahmadu Bello University (ABU), Zaria, where stabilization ponds are unable to consistently meet regulatory standards for effluent discharge.

To address these challenges, tertiary treatment processes are required to further polish the effluent before discharge or reuse. Advanced treatment methods such as membrane filtration and commercial activated carbon adsorption are highly effective but often economically prohibitive in low-resource settings. Consequently, there is growing interest in the development of cost-effective and sustainable treatment alternatives using locally available materials. Agricultural residues, in particular, have been widely investigated due to their abundance, low cost, and potential for conversion into effective adsorbents (Ali, 2012; Yahya et al., 2015).

Palm kernel shell (PKS), an abundant by-product of palm oil processing in Nigeria, has emerged as a promising precursor for activated carbon production due to its high carbon content, mechanical strength, and favorable adsorption properties (Abioye & Ani, 2015). When processed through carbonization and activation, PKS can produce activated carbon with a highly porous structure and large surface area capable of adsorbing organic and inorganic pollutants. In addition to adsorption, granular media filtration using sharp sand is effective in removing suspended particles and reducing turbidity through mechanisms such as straining, sedimentation, and adsorption.

The integration of adsorption and filtration processes into a dual-media system can enhance overall treatment efficiency through complementary mechanisms. In such systems, sand layers act as pre-filters that remove suspended solids and protect the adsorptive media from clogging, while activated carbon removes dissolved contaminants.

This study therefore focuses on the design and performance evaluation of a dual-media filtration system comprising palm kernel shell-derived activated carbon and sharp sand for the tertiary treatment of wastewater from Ahmadu Bello University, Zaria. The study aims to assess the effectiveness of the system in improving key physicochemical parameters and to demonstrate its potential as an affordable and sustainable wastewater treatment solution for institutional and resource-constrained environments.

This study aligns with the ICESID 2026 conference themes of Innovative Resource Utilization and Management and Sustainable Materials Synthesis, Processing and Recycling through the conversion of agricultural waste into a value-added adsorbent for wastewater treatment.

2. MATERIALS AND METHODS

2.1 Study Area and Sample Collection

The study was conducted using wastewater obtained from the waste stabilization pond system located within Ahmadu Bello University (ABU), Zaria, Nigeria. The stabilization pond receives wastewater from residential hostels, laboratories, administrative facilities, and other institutional sources, making it representative of mixed domestic and institutional effluent.

Wastewater samples were collected from the final discharge point of the maturation pond using clean, sterilized high-density polyethylene (HDPE) containers. The samples were transported to the laboratory in insulated containers and stored at approximately 4 °C before analysis to minimize biological and chemical changes. All analyses were conducted in accordance with standard procedures to ensure data reliability and reproducibility.

2.2 Preparation of Filtration Materials

2.2.1 Palm Kernel Shell Activated Carbon (PKS-AC)

The Palm kernel shells were obtained from a local palm oil processing site as shown in Figure 1. The shells were thoroughly washed with distilled water to remove impurities and then sun-dried to reduce moisture content. The dried shells were subjected to carbonization at approximately 400 °C in a furnace under limited oxygen conditions, producing char material as shown in Figure 2. The carbonized material was further activated through steam activation at elevated temperatures (800-950°C), during which superheated steam was introduced to promote pore development and increase adsorption capacity. The activation process followed the reaction $C + H_2O \rightarrow CO + H_2$, resulting in a highly porous adsorbent material, enhancing pore development and surface area. After activation, the material was

washed repeatedly with distilled water to remove residual impurities and then dried at room temperature. The resulting activated carbon was ground and sieved to obtain uniform particle size suitable for adsorption processes as shown in Figure 3. FTIR characterization of the activated carbon revealed the presence of hydroxyl (O-H), carbonyl (C=O), aromatic (C=C), amine (N-H), and alkyne (C≡C) functional groups on the adsorbent surface. These functional groups provide active adsorption sites that facilitate the removal of dissolved contaminants from wastewater.

Carbonization and activation were conducted at the Metallurgy Foundry Laboratory, Ahmadu Bello University, because a temperature-controlled furnace was available to maintain the required thermal conditions. Furnace temperature was monitored throughout the process to ensure consistency and reproducibility.

Figure 1: Sourced palm kernel shell from Sabo Tasha, Kaduna

Figure 2: Palm kernel shell (Carbonized charcoal) Sourced at Metallurgy Foundry Laboratory A.B.U Zaria

Figure 3: The Grinded Palm kernel shell charcoal (Activated Charcoal). Sourced at metallurgy foundry laboratory A.B.U. Zaria.

Although FTIR characterization was conducted to evaluate the surface chemistry of the adsorbent, advanced characterization techniques such as Brunauer-Emmett-Teller (BET) surface area analysis, scanning electron microscopy (SEM), and iodine number determination were not performed due to equipment and resource limitations. Nevertheless, the FTIR results confirmed the presence of hydroxyl, carbonyl, aromatic, and amine functional groups that are commonly associated with adsorption processes. Future studies should incorporate BET, SEM, and iodine number analyses to

provide a more comprehensive assessment of the porosity, surface morphology, and adsorption potential of the palm kernel shell activated carbon.

2.2.2 Sharp Sand Preparation

Sharp sand was sourced locally and washed thoroughly with distilled water to remove silt, clay, and organic impurities. The cleaned sand was dried and sieved to obtain uniform particle sizes. Fine sand (approximately 1.18 mm grain size) and coarse sand (approximately 2.00 mm grain size) were prepared to ensure effective filtration and proper drainage within the system.

2.3 Design and Construction of the Filtration Column

A laboratory-scale vertical filtration column was designed and fabricated using a cylindrical plastic container. The column was constructed with a layered dual-media configuration consisting of:

- Coarse sand layer (20 cm) – support and drainage
- Activated carbon layer (15 cm) – adsorption of dissolved contaminants
- Fine sand layer (12 cm) – removal of suspended solids
- Freeboard (10 cm) – influent distribution and aeration

The layers were arranged sequentially from bottom to top, and fine mesh screens were placed between layers to prevent intermixing of media. The total effective volume of the column was approximately 0.000213 m^3. The volume was calculated using a column radius of 0.038 m and media depths of 0.020 m, 0.015 m and 0.012 m for coarse sand, activated carbon and fine sand respectively.

2.4 Experimental Setup

The filtration system was operated in a gravity-driven mode, where wastewater was introduced at the top of the column and allowed to flow downward through the media layers. The design ensured adequate contact time between the wastewater and the filter media to facilitate both physical filtration and adsorption processes. The setup is shown in Figure 4. The filtration column had an effective media volume of approximately 0.000213 m^3 (0.213 L). Approximately 0.5 L of wastewater was introduced into the filtration column during each experimental run under gravity-flow conditions. The study was designed primarily as a proof-of-concept investigation focusing on contaminant removal performance rather than hydraulic optimization. Consequently, operational parameters such as flow rate, hydraulic loading rate, hydraulic retention time (HRT), and empty-bed contact time (EBCT) were not monitored during the experiment. This limitation restricts detailed evaluation of process hydraulics and scale-up

potential. Future studies should quantify these parameters and assess their influence on treatment efficiency.

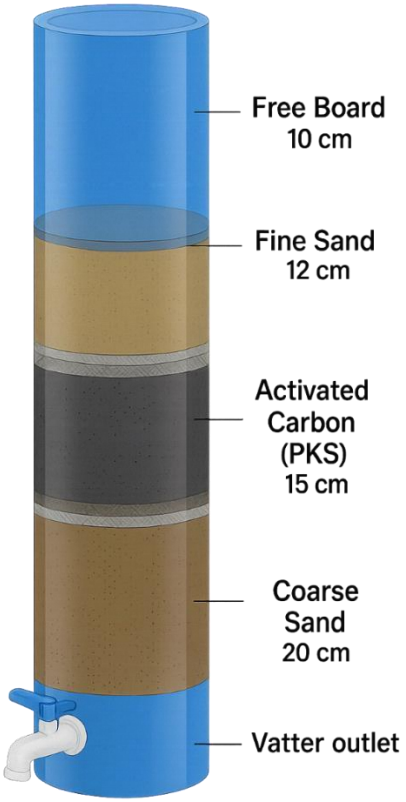

Figure 4: Schematic diagram of the dual-media filtration column

2.5 Analytical Methods

The performance of the filtration system was evaluated by analyzing physicochemical parameters before and after treatment. The parameters measured include:

- **pH** – measured using a calibrated pH meter
- **Turbidity** – determined using a nephelometric turbidity meter
- **Total Dissolved Solids (TDS)** – measured using a TDS/conductivity meter
- **Biochemical Oxygen Demand (BOD)** – determined using the standard 5-day incubation method
- **Chemical Oxygen Demand (COD)** – determined using reflux titration method
- **Nitrate concentration** – determined using colorimetric methods

All analyses were conducted in accordance with standard laboratory procedures to ensure accuracy and consistency of results. The present study was conducted as a preliminary laboratory-scale proof-of-concept investigation to evaluate the feasibility of using palm kernel shell activated carbon and sharp sand as a dual-media filtration system for tertiary wastewater treatment. The reported influent and effluent values were obtained from a single experimental run and therefore do not include measures of variability such as standard deviation or confidence intervals. Consequently, the reported treatment efficiencies should be interpreted as indicative of system performance under the tested conditions rather than as statistically representative values. The absence of replicate runs constitutes a limitation of the present study. Future investigations should incorporate replicated experiments and statistical analyses to quantify variability, establish confidence levels, and improve the reliability and reproducibility of the findings.

3. RESULTS AND DISCUSSION

3.1 Performance of the Dual-Media Filtration System

The performance of the dual-media filtration system was evaluated by comparing key physicochemical parameters of wastewater before and after treatment. The results are presented in Table 1.

Table 1: Performance of Dual-Media Filtration System

Parameter	Raw Water	Treated Water	Removal Efficiency (%)
Turbidity (NTU)	13.0	2.6	80
Nitrate (mg/L)	35.0	15.6	55
BOD (mg/L)	150	90	40
COD (mg/L)	3000	800	73
TDS (mg/L)	216	160.5	25
PH	6.89	6.79	-

Table 2: Comparison of Treated Effluent Quality with Typical Discharge Guidelines

Parameter	**Treated Effluent**	**Guideline Value**
pH	6.79	6-9
Turbidity (NTU)	2.6	<5
Nitrate (mg/L)	15.6	<50
TDS (mg/L)	160.5	<500
BOD (mg/L)	90	<30
COD (mg/L)	800	<90

Source: Adapted from WHO (2017) potable water guidelines and commonly adopted wastewater discharge criteria used for comparison purposes.

A substantial reduction in turbidity from 13.0 NTU to 2.6 NTU (80%) was observed after treatment. This high removal efficiency can be attributed primarily to the fine sand layer, which acts as a physical barrier, trapping suspended and colloidal particles via straining and sedimentation. Additionally, the layered arrangement of the filter enhances particle capture by promoting gradual filtration, reducing the likelihood of particle breakthrough. The achieved turbidity level falls within acceptable limits for improved water clarity, indicating effective removal of suspended solids. Similar turbidity reductions have been reported in sand-activated carbon filtration systems used for polishing municipal and institutional wastewater (Fayad & Radhi, 2024; Mara, 2013).

The system achieved a 73% reduction in COD and a 40% reduction in BOD. COD represents the total quantity of oxidizable substances present in wastewater, whereas BOD represents the biodegradable fraction of organic matter. The higher COD removal observed in this study suggests substantial removal of dissolved organic pollutants by the activated carbon layer. The BOD/COD ratio increased from approximately 0.05 before treatment to 0.11 after treatment, indicating a modest improvement in wastewater biodegradability. However, the observed reductions should not be interpreted solely as evidence of selective adsorption of biodegradable and non-biodegradable compounds, since changes in biodegradability may also have contributed to the results. Similar reductions in COD and BOD have been reported for agricultural waste-derived activated carbons used in wastewater treatment applications (Devi et al., 2023).

Nitrate concentration decreased from 35.0 mg/L to 15.6 mg/L, representing a removal efficiency of 55%. Although activated carbon is generally more effective for organic pollutant removal

than nutrient removal, several studies have demonstrated moderate nitrate adsorption by biomass-derived activated carbons. The observed nitrate reduction in the present study may be attributed to adsorption mechanisms reported in the literature; however, no surface charge or zeta potential measurements were conducted to confirm the specific adsorption mechanism**.**

The filtration system achieved a 25% reduction in TDS, decreasing from 216 mg/L to 160.5 mg/L.

The relatively lower removal efficiency observed for TDS compared with turbidity and COD is expected because dissolved salts and ionic species are generally more difficult to remove through adsorption and filtration processes alone. Activated carbon preferentially adsorbs organic compounds rather than dissolved inorganic constituents (Hendricks, 2016). The moderate decrease in TDS suggests partial removal of dissolved contaminants through adsorption and physical retention mechanisms within the filter media.

The pH changed slightly from 6.89 to 6.79 after treatment, indicating that the filtration process did not significantly alter the acid-base characteristics of the wastewater. Maintaining near-neutral pH conditions is advantageous because extreme pH changes can affect adsorption efficiency and subsequent biological treatment processes. Previous studies have also reported minimal pH variation following treatment with biomass-derived activated carbons, particularly when no strong chemical activation agents remain on the adsorbent surface (Abioye & Ani, 2015; Yahya et al., 2015).The pH stability observed in this study therefore supports the suitability of the PKS-AC filtration system for wastewater polishing applications.

Furthermore, as shown in Table 2, comparison with commonly adopted wastewater discharge guidelines indicates that the treated effluent satisfied recommended limits for pH, turbidity, nitrate, and TDS. However, BOD and COD values remained above typical discharge standards, suggesting that additional polishing or biological treatment may be necessary before final discharge or reuse.

3.2 Compliance with Effluent Quality Guidelines

The treated wastewater exhibited substantial improvements in quality compared with the raw influent. Turbidity decreased from 13.0 NTU to 2.6 NTU, nitrate concentration decreased from 35.0 mg/L to 15.6 mg/L, and TDS decreased from 216 mg/L to 160.5 mg/L. These treated values comply with commonly adopted guideline limits for treated wastewater and water reuse applications.

Despite these improvements, BOD and COD concentrations remained relatively high at 90 mg/L and 800 mg/L respectively. Although the filtration system achieved 40% BOD removal and 73% COD removal, the residual concentrations indicate that significant quantities of biodegradable and non-biodegradable organic matter remained in the treated effluent. Consequently, the developed dual-media filtration system should be viewed primarily as a polishing treatment technology rather than a standalone wastewater treatment solution. Additional biological treatment or advanced polishing processes may be required before direct discharge into receiving water bodies.

The guideline values are presented solely to provide context for treatment performance and do not constitute regulatory compliance standards for wastewater discharge.

3.3 Mechanisms of Pollutant Removal

The improved performance of the dual-media system can be attributed to the synergistic interaction between filtration and adsorption mechanisms, as illustrated in the filter configuration.

- Physical Filtration:
  Sand layers remove suspended particles through straining and sedimentation

- Adsorption:
  PKS activated carbon removes dissolved contaminants via surface interactions

- Protective Layering:
  Sand reduces clogging and enhances contact efficiency in the carbon layer

This combined mechanism ensures efficient removal of both particulate and dissolved pollutants, making the system more effective than single-media filtration approaches.

3.4 Engineering Implications

The results demonstrate that the developed dual-media filtration system:

- Achieves significant contaminant removal efficiency
- Utilizes low-cost and locally available materials
- Operates without the need for complex energy inputs
- Offers potential for scalability in institutional settings

From an economic perspective, the proposed system utilizes palm kernel shell, an agricultural by-product that is widely available in Nigeria and often discarded as waste. The use of locally sourced materials significantly reduces media procurement costs when compared with commercial activated carbon. Furthermore, the filtration system operates entirely under gravity flow conditions and therefore requires no external energy input during operation. Although a detailed techno-economic analysis was beyond the scope of this study, the material and operational requirements suggest that the system offers a low-cost alternative for tertiary wastewater treatment in institutional and resource-constrained settings

4. Conclusion

This study successfully designed and evaluated a laboratory-scale dual-media filtration system utilizing palm kernel shell-derived activated carbon (PKS-AC) and sharp sand for tertiary wastewater treatment. The system demonstrated significant improvement in effluent quality, confirming its effectiveness as a low-cost and sustainable treatment technology.

The filtration process achieved substantial reductions in key physicochemical parameters, including turbidity (80%), nitrate (55%), chemical oxygen demand (73%), and biochemical oxygen demand (40%). A moderate reduction in total dissolved solids was also observed, while pH remained relatively stable, indicating that the treatment process did not adversely affect the chemical balance of the water. These results highlight the ability of the system to remove both suspended and dissolved contaminants through combined filtration and adsorption mechanisms.

The performance of the system is attributed to the synergistic interaction between the sand layers, which provide physical filtration and particle retention, and the activated carbon layer, which facilitates adsorption of organic and inorganic pollutants. The use of palm kernel shell as a precursor for activated carbon further enhances the sustainability of the system by utilizing an abundant agricultural waste material.

Overall, the developed dual-media filtration system offers a practical, efficient, and environmentally friendly solution for improving wastewater quality, particularly in institutional and resource-constrained settings.

No significant media breakthrough was observed during the experimental period. However, the relatively short duration of operation did not permit detailed assessment of adsorbent exhaustion or long-term filtration performance. As adsorption sites become progressively occupied, gradual reduction in treatment efficiency may occur. Future studies should therefore investigate media breakthrough characteristics, regeneration potential, and adsorbent lifespan under continuous operating conditions. In addition, studies on the regeneration and reuse of palm kernel shell activated carbon are recommended to improve long-term cost-effectiveness and sustainability.

ABSTRACT

This paper presents the design optimisation and field-based impact assessment of a biogas-integrated anaerobic baffled reactor (ABR) at Ikoyi Correctional Centre, Lagos. Empirical monitoring was undertaken for 30 consecutive days at three matched wastewater sampling points: ABR influent (SP-01), ABR effluent (SP-02) and final effluent after polishing (SP-03). The campaign comprised 90 point-specific wastewater samples, daily biogas-quality records and kitchen-energy logs, separated into pre-optimisation (10 days), transition (5 days) and optimised operation (15 days). The installed system consists of two parallel six-chamber ABR trains. Engineering reconciliation gave 337.34 m³ active volume; restoration from a 286.74 m³ pre-optimisation effective condition yielded calculated HRT values of 33.60 and 39.53 h at the monitored mean flow of 204.82 m³/day. During optimised operation, mean final-effluent COD, BOD_5 and TSS were 90.6, 37.47 and 30.53 mg/L, while overall removals reached 89.99%, 91.90% and 91.27%, respectively. Mean biogas production was 57.03 m³/day compared with 42.99 m³/day pre-optimisation; methane fraction was 63.39% compared with 57.15%, and hydrogen sulphide was 266.9 ppm compared with 510.1 ppm. Mean LPG, diesel and firewood displacement reached 51.82%, 50.10% and 53.83%. The repair-first configuration retained the installed shell and prioritised active-volume recovery, flow balancing, polishing, gas conditioning, storage-demand matching and preventive maintenance. These operating-phase differences are associations from a sequential field intervention rather than proof of single-variable causality. Physical fuel savings were quantified; monetary valuation was outside scope.

Keywords: *anaerobic baffled reactor; biogas; correctional wastewater; design optimisation; resource recovery*

1. INTRODUCTION

Wastewater treatment in a correctional facility is simultaneously an environmental-engineering, public-health, institutional-management and human-dignity requirement. Large populations live within restricted compounds, water and sanitation fixtures are used continuously, kitchens operate at institutional scale, and land for conventional treatment may be limited. Failure of containment or treatment can expose detainees, correctional personnel, maintenance workers and surrounding communities to sewage overflow, odour, vectors and contamination of surface water or groundwater. The World Health Organization (WHO, 2018) therefore frames sanitation as an entire service chain from containment and conveyance to treatment, disposal or safe reuse, while its sanitation-safety-planning approach requires risk identification and operational control across that chain (WHO, 2022). In places of detention, the same systems must remain robust under crowding, restricted movement, security procedures and constrained maintenance access (International Committee of the Red Cross [ICRC], 2012).

Anaerobic baffled reactors are attractive for such settings because they divide the flow path into successive compartments, promoting contact between wastewater and retained anaerobic biomass without continuous mechanical mixing or aeration. Their comparatively simple civil works, low sludge yield, resilience to organic shocks and potential for methane recovery make them relevant to

decentralised sanitation in warm climates. Yet ABR performance is not automatic. Hydraulic short-circuiting, unequal flow between parallel trains, excessive sludge accumulation, high upflow velocity, intermittent loading and inadequate downstream polishing can reduce effective volume or produce an effluent that remains unsuitable for discharge. Full-scale studies have repeatedly shown that operation and maintenance, rather than the presence of an ABR shell alone, determine long-term performance (Yulistyorini et al., 2019; Yenji et al., 2021; Saif et al., 2021).

Biogas generation is continuous, whereas cooking demand occurs in peaks; daily production can therefore coexist with short-period shortages, pressure instability or unused gas. Prison biogas programmes identify ownership, sizing, operator competence, safety and recurrent maintenance as decisive sustainability conditions (Gauthier et al., 2012). The Ikoyi intervention integrated wastewater collection, two ABR trains, polishing and kitchen-gas delivery for a design population of 3,000. The current count of 2,541 is 84.7% of that basis. The empirical campaign measured actual wastewater flow, treatment performance, biogas production and composition, gas-holder pressure, burner operating hours and conventional-fuel use, allowing the technical and energy impacts to be quantified rather than inferred from population alone.

The purpose of this paper is to present a title-aligned design optimisation and impact assessment based on field and empirical evidence. Specifically, the paper (a) characterises wastewater at three matched sampling points; (b) reconciles the physical ABR geometry with the active-volume calculation; (c) formulates hydraulic, treatment, gas-utilisation and hydrostatic constraints; (d) compares pre-optimisation and optimised operating phases; (e) quantifies wastewater-removal, biogas-quality and fuel-displacement outcomes; and (f) assesses technical, environmental, social, economic and institutional implications. The contribution is a repair-first optimisation strategy that restores and verifies the installed asset before considering additional chambers or a larger reactor shell.

2. TECHNICAL BACKGROUND AND RESEARCH CONTEXT

2.1 ABR performance and operating controls

The ABR behaves as a staged anaerobic system. Wastewater is directed down and upward through a series of compartments; solids settle and biomass is retained, while the baffled pathway improves contact between substrate and microorganisms. Foundational design and decentralised-sanitation literature identifies hydraulic retention time (HRT), organic loading rate (OLR), compartment geometry, upflow velocity, temperature, influent biodegradability and sludge distribution as major controls (Barber & Stuckey, 1999; Sasse, 1998; Gutterer et al., 2009; Tilley et al., 2014). Long retention times can improve hydrolysis and stabilisation, but nominal HRT is meaningful only when active volume is not lost to sludge, gas pockets, blocked openings or dead zones. Similarly, a satisfactory total volume can conceal overloading if flow is not divided evenly between parallel trains.

Field evidence supports cautious optimisation. Dynamic loading changed full-scale ABR behaviour (Yenji et al., 2021), while loading-shock experiments also demonstrated the sensitivity of staged anaerobic treatment to abrupt organic and hydraulic changes (Jin et al., 2024). A four-chamber ABR still required tertiary treatment before reuse or discharge (Saif et al., 2021). In a nine-month ABR-biofilter study, the ABR removed about 57% total COD while the integrated train achieved 92% COD and 98% TSS removal, demonstrating that polishing is part of system performance (Echeverría et al., 2022). Sponge media achieved 60–77% organic and 74–81% TSS removal across 18–6 h HRTs (Ullah et al., 2024), with a later real-wastewater study reporting 79% COD and 96% TSS removal at 8 h (Ullah et al., 2026). These controlled results cannot be transferred directly to Ikoyi. Modelled recirculation also produced limited or adverse effects under some conditions (Ullah et al., 2025).

Post-treatment is particularly important for nutrients, pathogens and residual suspended matter. Field ABRs often remove organic carbon and settleable solids more effectively than nitrogen, phosphorus and faecal indicators. Satyendra and Vijay (2024) demonstrated an ABR followed by an upflow constructed wetland for municipal wastewater, while Munavalli et al. (2022) evaluated an ABR-hybrid-wetland system under dynamic loading. Raja et al. (2025) similarly coupled an ABR with a plant biofilter for decentralised sewage treatment and energy recovery. The literature therefore supports a treatment-train perspective: the ABR provides anaerobic primary or secondary treatment,

and the downstream unit is selected according to discharge route, land, operator capacity and required effluent quality.

2.2 Biogas recovery and institutional impact

Anaerobic treatment can convert part of the removed organic load into methane-rich gas, thereby reducing the net energy burden of sanitation. UNEP (2023) identifies wastewater as a resource for water, energy and nutrient recovery rather than only a waste stream. For institutions with large kitchens, direct thermal use can avoid the conversion losses and operating complexity associated with small-scale electricity generation. The relevant performance measure is not daily biogas production alone, but the fraction safely captured, conditioned, stored and delivered at useful pressure when cooking is required.

Correctional settings make this integration unusually valuable. Gauthier et al. (2012) assessed 13 prison biogas systems and reported production of 26–62 L/person/day, with higher values where kitchen waste supplemented excreta. The systems were generally perceived positively because of cleaner cooking and improved hygiene, but the study warned that responsibilities, finance, user acceptance and maintenance must be designed with the technology. At Ikoyi, daily kitchen logs and conventional-fuel records were used to quantify operating-hour and fuel-displacement effects, while health outcomes and indoor-air quality remain outside the present measurement scope.

Nigeria's National Environmental (Sanitation and Wastes Control) Regulations provide the legal framework for sustainable sanitation and waste management, while the Surface and Groundwater Quality Control Regulations address protection of water bodies (National Environmental Standards and Regulations Enforcement Agency [NESREA], 2009, 2011). WHO guidance supplies a risk-management framework but does not replace the applicable Nigerian permit or discharge conditions. For international context only, the United States secondary-treatment regulation uses 30-day and 7-day averages rather than a single grab sample (Electronic Code of Federal Regulations, n.d.). This reinforces the need to separate screening targets from a formal compliance determination.

3. MATERIALS AND METHODS

3.1 Study design and evidence classification

The study was structured as a practice-based engineering case study with a field before-transition-after monitoring design. Data were collected over 30 consecutive operating days from 1 to 30 April 2024. Days 1–10 represented pre-optimisation operation, Days 11–15 the transition and stabilisation period, and Days 16–30 optimised operation. The evidence base comprised matched wastewater samples, measured flow and temperature, daily biogas flow and composition, gas-quality and pressure records, kitchen burner-hours and conventional-fuel logs, together with project drawings, as-built dimensions and engineering calculations (Ikoyi ABR Design and Field Records, 2019–2024). No individual detainee data were used. Security-sensitive coordinates and internal layouts were excluded, and the treatment arrangement is presented only at process level.

Three evidence classes were maintained. Class F comprised direct field and laboratory measurements. Class C comprised quantities calculated from field measurements, including removal efficiencies, mass loads, methane energy and fuel displacement. Class D comprised design-audit and optimisation calculations, including active volume, HRT, OLR, upflow velocity and hydrostatic screening. This classification preserves the empirical status of the underlying monitoring data while preventing calculated design quantities from being misrepresented as instrument readings.

The monitoring dataset is treated throughout this paper as primary field and empirical evidence. The wastewater, biogas and energy-use observations are reported by operating phase and by measurement point. Arithmetic means and sample standard deviations describe within-phase variability; removal efficiencies are paired-day calculations based on matched influent and outlet concentrations. The study evaluates operating-phase differences descriptively because the sequential observations arose from a full-scale facility intervention rather than random assignment. No causal effect is attributed to a single optimisation action, and the terms pre-optimisation and optimised operation identify field phases rather than randomised treatment groups.

Table 1: Field, calculated and design evidence used in the study

Evidence item	Value or scope	Class	Permissible interpretation
Wastewater monitoring	30 matched days at SP-01, SP-02 and SP-03; 90 point-specific samples	F	Direct field and laboratory measurements
Operating conditions	Flow, temperature and pH recorded daily	F	Hydraulic and process context
Treatment performance	COD, BOD_5, TSS, NH_3-N and PO_4-P by point and phase	F/C	Measured concentrations; paired removal calculations
ABR geometry	Two trains; one settler and six chambers per train	F/D	As-built and design audit
Active volume and loading	286.74 to 337.34 m^3; HRT, OLR and upflow calculations	D	Before-and-after optimisation basis
Biogas monitoring	30 daily records of flow, CH_4, CO_2, H_2S, moisture, pressure and use	F/C	Measured gas performance and derived energy
Kitchen energy	30 daily burner and LPG, diesel and firewood records	F/C	Measured use and calculated fuel displacement
Operational impact	Sanitation, odour, O&M and kitchen-use observations	F	Field operational assessment

Note. F = field or laboratory measurement; C = calculation from measured data; D = design or optimisation calculation.

3.2 System configuration and study boundaries

The treatment plant consists of two parallel ABR trains serving separate sewer catchments. Each train contains an inlet settler followed by six baffled chambers. Gas generated within the anaerobic system is collected, conditioned, conveyed to a nominal 45 m^3 gas holder documented in the project records and delivered to the institutional kitchen. Treated liquid is conveyed toward final disposal or polishing. The optimisation boundary begins at the combined wastewater inflow and ends at final effluent management and useful kitchen-gas delivery. External sewer rehabilitation, individual toilet fixtures and unrelated facility energy loads are outside the numerical optimisation, although they influence institutional outcomes.

The design population of 3,000 comprised detainees and personnel included in the original hydraulic basis. The current population value of 2,541 represents 84.7% of design capacity. The historical design flow of 154.45 m^3/day was retained for design reconciliation, while the empirical campaign measured a mean operating flow of 204.82 ± 7.93 m^3/day. This distinction allows the installed geometry to be checked against its original basis and against current field loading. Train-specific metering remains necessary because aggregate flow cannot reveal unequal distribution between parallel reactors.

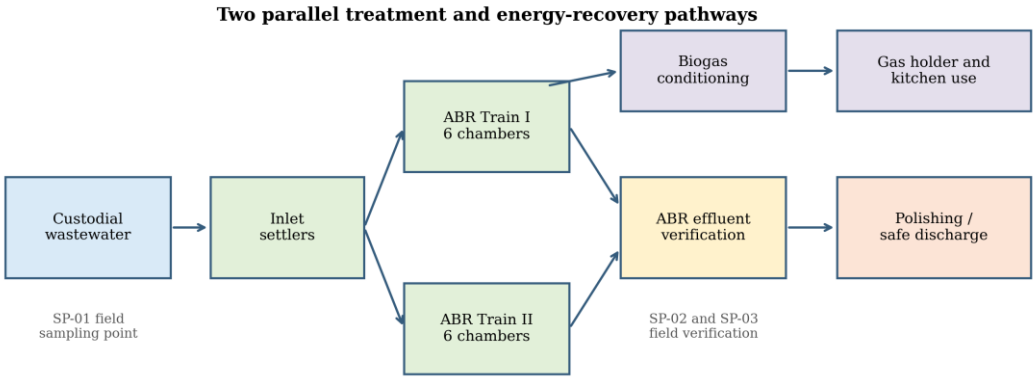

Figure 1: Process-level configuration and optimisation boundary of the biogas-integrated ABR system.

3.3 Wastewater characterisation and compliance screening

Wastewater samples were collected daily at the ABR inlet chamber (SP-01), ABR outlet chamber (SP-02) and polishing-unit outlet (SP-03). The resulting 30 matched events produced 90 point-specific samples. Flow and wastewater temperature were recorded concurrently. Samples were analysed for pH, COD, BOD_5, TSS, ammonia-nitrogen (NH_3-N) and orthophosphate-phosphorus (PO_4-P) using APHA procedures and the study laboratory protocol (American Public Health Association, American Water Works Association, & Water Environment Federation, 2023). Matched-point sampling allowed both ABR-stage removal and overall system removal to be calculated for each day.

Concentration screening used the study targets of 200 mg/L COD, 50 mg/L BOD_5 and 100 mg/L TSS. Results are reported as field performance against the accepted study basis; formal statutory compliance remains dependent on the facility's discharge route, permit conditions and required regulatory sampling frequency. A positive concentration gap indicates that further treatment or operational adjustment is needed. Phase summaries are expressed as mean ± sample standard deviation.

$$E_r = C_{in} / C_t \quad (1)$$

E_r is the influent exceedance ratio; C_{in} is the measured influent concentration and C_t is the applicable study screening target, in matching concentration units.

$$G = max(C_{out} - C_t, 0) \quad (2)$$

G is the positive concentration gap; C_{out} is the measured outlet concentration and C_t is the study target. G = 0 indicates no positive gap against the screening target. Removal efficiency and mass load were calculated as follows.

$$\eta = [(C_{in} - C_{out}) / C_{in}] \times 100 \quad (3)$$

η is paired-day removal efficiency (%), calculated from the matched inlet concentration C_{in} and outlet concentration C_{out}.

$$L = Q\,C / 1{,}000 \quad (4)$$

L is pollutant mass load (kg/day), Q is wastewater flow (m^3/day), C is concentration (mg/L), and 1,000 is the unit-conversion factor.

3.4 Hydraulic and organic-loading audit

The physical audit separated gross internal envelope from effective hydraulic volume. Per train, the settler measures 2.50 × 8.20 × 2.50 m and each of six chambers measures 1.20 × 8.20 × 2.40 m. Gross volume therefore includes the full box dimensions before deductions for baffle walls, downflow shafts, freeboard, sludge and dead zones. Effective active volume was independently reconciled from project flow and HRT. This step corrected the earlier dimensional confusion in which 154.45 m^3/day could be mistaken for reactor volume.

The pre-optimisation hydraulic audit used an effective active volume of 286.74 m³, equivalent to 85% of the 337.34 m³ design-implied active volume. The post-optimisation condition restored the full effective volume through desludging, clearing baffle openings, correcting dead zones and balancing the two trains. The volume figures are engineering audit calculations supported by field operating observations; they are not direct laboratory measurements. No additional chamber or larger ABR shell was required.

$$V_g = 2[(2.50 \times 8.20 \times 2.50) + 6(1.20 \times 8.20 \times 2.40)] \quad (5)$$

Vg is gross internal envelope volume (m³). The factor 2 represents the two parallel trains; each train comprises one inlet settler and six chamber boxes.

$$V_a = Q\,\theta / 24 \quad (6)$$

V_a is hydraulically active volume (m³), Q is daily flow (m³/day), θ is HRT (h), and 24 converts days to hours.

$$\theta = 24\,V_a / Q \quad (7)$$

θ is calculated hydraulic retention time (h) at active volume V_a and daily flow Q.

$$OLR = Q(COD_{in} / 1{,}000) / V_a \quad (8)$$

OLR is volumetric organic loading (kg COD m^{-3} d^{-1}); COD_{in} is measured influent COD (mg/L), Q is flow and V_a is active volume.

$$v_u = [PF \times Q / (2 \times 24)] / A_c \quad (9)$$

v_u is direct chamber upflow velocity (m/h), PF is the peak factor, the divisor 2 represents equal flow to two trains, and $A^c = 1.20 \times 8.20 = 9.84$ m² is the chamber plan area. Peak factors of 1.50 before balancing and 1.05 after effective equalisation were applied only as transparent design scenarios.

3.5 Optimisation formulation and selection criteria

The optimisation used a constrained, repair-first screening procedure. Candidate interventions were evaluated in the following order: verify the installed geometry and flow boundary; restore active volume; balance the two trains; test hydraulic and organic-loading constraints; calculate effluent gaps; identify the need for polishing; test gas-conditioning and storage-demand requirements; and screen hydrostatic stability. The installed two-train, six-chamber configuration was the reference. Alternatives that required structural enlargement were considered only if restoration and operational control could not meet the hydraulic constraints.

A multi-criteria penalty function maintained an auditable link between water quality, energy recovery, cost, footprint and robustness. The field wastewater, gas and kitchen datasets supplied the performance terms; project dimensions and design calculations supplied the hydraulic and footprint terms. Each penalty was normalised from zero (best) to one (worst), and any alternative violating a hard constraint was rejected regardless of its weighted score. The weights were specified a priori as transparent engineering decision priorities rather than statistically calibrated coefficients: water quality received the highest weight because sanitation protection and effluent control are mandatory; energy utilisation reflected the biogas objective; cost represented institutional affordability; robustness protected operational reliability; and footprint received the lowest weight because the installed shell was retained.

$$\min J(x) = 0.35P_q + 0.22P_e + 0.18P_c + 0.10P_f + 0.15P_r \quad (10)$$

J(x) is the aggregate penalty for candidate x; Pq, Pe, Pc, Pf and Pr are the normalised water-quality, gas-utilisation, life-cycle-cost, footprint and robustness penalties. The weights sum to one. They reflect the stated engineering priorities and were not derived through formal stakeholder elicitation.

$$P_q = \Sigma \max[(C_{j,out} - C_{j,target}) / C_{j,target}, 0] \quad (11)$$

Pq sums positive normalised effluent gaps across parameter j; C_j,out is the predicted or observed outlet value and C_j,target is the corresponding screening target.

$$R = N_{feasible} / N_{total} \quad (12)$$

R is robustness; Nfeasible is the number of monitoring days meeting the combined final-effluent COD, BOD_5 and TSS targets and Ntotal is the number of days evaluated. The acceptance gate was $R \geq 0.90$. All 15 optimised-operation days met the three targets simultaneously, giving R = 1.00 for that phase, compared with 0.00 during the 10-day pre-optimisation phase.

Because hard constraints were applied before the weighted comparison, a favourable aggregate score could not compensate for a non-compliant candidate. A formal multi-weight sensitivity analysis was not undertaken; the reported weights should therefore be interpreted as a transparent screening preference set rather than proof of a unique global optimum. Future work should vary the weights and test whether feasible candidate rankings remain stable.

Table 2: Hard constraints and decision rules used in optimisation

Criterion	Screening condition	Engineering purpose	Evidence status
COD	≤200 mg/L; robust design goal 160 mg/L	Control residual organic load and retain margin	Permit confirmation required
BOD_5	≤50 mg/L; robust design goal 40 mg/L	Control biodegradable residual	Permit confirmation required
TSS	≤100 mg/L; robust design goal 50 mg/L	Limit solids carryover	Measured at SP-03
HRT	≥36 h planning gate	Protect anaerobic contact time	Design-derived
OLR	≤3.0 kg COD m^{-3} d^{-1}	Avoid volumetric overloading	Project design screen
Peak upflow	Prefer ≤0.60 m/h	Reduce washout and hydraulic shock	Design screen; verify diurnal flow
Flotation safety	FS ≥1.20, empty-tank case	Control groundwater uplift	Structural verification required
Robustness	≥90% compliant monitoring days	Reject fragile optima	R = 1.00 during optimised phase
Gas storage	Daily available gas ≥ kitchen use; unused gas minimised	Match production to cooking demand	Evaluated from daily field logs

Note. The concentration values are study screening targets. They are not presented as a substitute for a current, route-specific Nigerian discharge permit.

3.6 Effluent polishing, gas-energy and hydrostatic calculations

The polishing-stage removal was calculated from each matched SP-02 and SP-03 observation. This avoids the misleading practice of quoting overall removal while ignoring the contribution of downstream treatment. The field data were also screened against the final-effluent targets so the optimisation could distinguish ABR performance from whole-system performance.

Biogas assessment used 30 daily field records of total flow, methane, carbon dioxide, hydrogen sulphide, moisture, gas-holder pressure, kitchen use, unused gas and burner hours. Gross methane energy was calculated from measured gas use and methane fraction. Daily kitchen logs provided conventional-fuel baselines and quantities used while biogas was available, from which LPG, diesel and firewood displacement were calculated.

$$\eta_{polish,req} = [(C_{ABR} - C_{target}) / C_{ABR}] \times 100 \quad (13)$$

ηpolish,req is the minimum polishing removal required (%); C^{ABR} is ABR effluent concentration and Ctarget is the final-effluent screening target.

$$E_{gas} = V_{gas} \times y_{CH_4} \times LHV_{CH_4} \quad (14)$$

Egas is gross methane energy, Vgas is measured useful biogas volume, yCH_4 is measured methane fraction and $LHVCH_4$ is methane lower heating value.

$$S_t = S_{t-1} + G_t - U_t - F_t \quad (15)$$

S_t and S_{t-1} are gas inventory at the end of the current and preceding time steps; G_t is generation, U_t is useful demand and F_t is controlled loss or flaring.

$$D_f = [(F_{baseline} - F_{biogas}) / F_{baseline}] \times 100 \quad (16)$$

Df is conventional-fuel displacement (%), Fbaseline is the comparable conventional-fuel baseline and Fbiogas is the quantity used while biogas was available.

Because Ikoyi is in a coastal groundwater environment, empty-tank uplift was screened. The combined base plan was derived explicitly as Ab = 2 × 8.20 × 9.70 = 159.08 m² for the two trains. Groundwater heads between 0.5 and 2.0 m above the base were examined. The calculation is a screening check and does not replace structural design, verified concrete dead load, cover depth, anchorage or drainage assessment.

$$F_u = \gamma_w h_w A_b \quad (17)$$

F_u is groundwater uplift force, γw is the unit weight of water (9.81 kN/m³), hw is groundwater head above the base and Ab is combined base area (159.08 m²).

$$FS = R_{stabilising} / F_u \geq 1.20 \quad (18)$$

FS is flotation factor of safety and Rstabilising is verified stabilising resistance from structural dead load, cover, anchorage and other applicable permanent actions.

4. RESULTS

4.1 Empirical wastewater characteristics at the three sampling points

The 30-day campaign produced 90 matched point-specific wastewater observations. Mean monitored flow was 204.82 ± 7.93 m³/day and mean wastewater temperature was 29.93 ± 0.73 °C. Across all days, mean SP-01 influent concentrations were 907.67 mg/L COD, 467.13 mg/L BOD_5, 349.27 mg/L TSS, 55.05 mg/L NH_3-N and 10.27 mg/L PO_4-P. Corresponding mean SP-02 concentrations were 229.47, 110.47, 88.40, 42.64 and 8.59 mg/L; mean SP-03 concentrations were 117.77, 51.50, 41.83, 24.77 and 5.59 mg/L. The concentration sequence confirms progressive treatment through the ABR and polishing stage.

Influent strength was comparable between the pre-optimisation and optimised phases: COD averaged 903.9 and 903.4 mg/L, BOD_5 464.2 and 461.33 mg/L, and TSS 347.6 and 350.0 mg/L, respectively. Mean flows were likewise close at 201.77 and 205.77 m³/day. This stability in incoming load supports descriptive comparison of treatment outcomes. Final-effluent concentrations during optimised operation were 90.6 mg/L COD, 37.47 mg/L BOD_5 and 30.53 mg/L TSS, compared with 160.1, 71.6 and 59.6 mg/L during pre-optimisation operation.

Table 3: Empirical wastewater concentrations before and after optimisation (mean ± SD)

Parameter	Pre SP-01	Pre SP-02	Pre SP-03	Optimised SP-01	Optimised SP-02	Optimised SP-03
pH	7.22 ± 0.11	7.22 ± 0.10	7.30 ± 0.05	7.18 ± 0.12	7.32 ± 0.10	7.25 ± 0.08
COD (mg/L)	903.9 ± 45.2	274.7 ± 10.9	160.1 ± 4.8	903.4 ± 48.8	197.6 ± 16.5	90.6 ± 9.6
BOD_5 (mg/L)	464.2 ± 26.9	133.8 ± 4.4	71.6 ± 3.5	461.3 ± 27.7	94.4 ± 8.7	37.5 ± 4.8
TSS (mg/L)	347.6 ± 24.2	105.9 ± 9.5	59.6 ± 1.7	350.0 ± 25.9	75.0 ± 5.5	30.5 ± 3.6
NH_3-N (mg/L)	55.76 ± 3.45	45.92 ± 2.79	29.48 ± 1.17	55.17 ± 3.37	41.13 ± 2.93	22.02 ± 1.65
PO_4-P (mg/L)	10.40 ± 0.84	9.02 ± 0.66	6.38 ± 0.48	10.32 ± 0.81	8.41 ± 0.59	5.17 ± 0.49

Note. Pre-optimisation n = 10 days; optimised operation n = 15 days. SP-01 = ABR influent; SP-02 = ABR effluent; SP-03 = final effluent after polishing.

4.2 Corrected reactor sizing and hydraulic state

The gross internal envelope was derived step by step. Each settler volume was 2.50 × 8.20 × 2.50 = 51.25 m³; for two trains this gave 102.50 m³. Each chamber box was 1.20 × 8.20 × 2.40 = 23.616 m³; for six chambers in each of two trains this gave 23.616 × 6 × 2 = 283.392 m³. The combined gross internal envelope was therefore 102.50 + 283.392 = 385.892 m³. Gross volume is not equivalent to working volume because structural and hydraulic exclusions must be deducted. The independent flow-HRT relationship gave a design-implied active volume of 337.34 m³, consistent with the project design flow of 154.45 m³/day and reported HRT of 52.42 h.

The pre-optimisation effective condition contained 286.74 m³, representing 85% of the design-implied active volume. Restoration increased usable volume by 50.60 m³ or 17.65%. At the monitored mean flow of 204.82 m³/day, calculated HRT increased from 33.60 to 39.53 h. Using the measured 30-day mean influent COD of 907.67 mg/L, calculated OLR declined from 0.648 to 0.551 kg COD m^{-3} d^{-1}. Both values were below the 3.0 kg COD m^{-3} d^{-1} screen, while the restored condition achieved the 36-h HRT planning gate.

At the same monitored mean flow, the equal-split chamber upflow velocity was 0.434 m/h. Applying the pre-optimisation peak factor of 1.50 gave 0.650 m/h; the equalised 1.05 peak factor gave 0.455 m/h after optimisation. The improvement depends on field flow balancing together with clear baffle openings and cannot be achieved by volume recovery alone. At the historical design flow of 154.45 m³/day, the corresponding HRT values remain 44.56 and 52.42 h.

Table 4: ABR configuration before and after the corrected optimisation

Parameter	Reduced-usable-volume scenario	Restored/optimised scenario	Change
Arrangement	2 parallel trains	2 parallel trains	No shell change
Chambers	6 per train; 12 total	6 per train; 12 total	No chamber added
Gross internal envelope	385.892 m³	385.892 m³	0 m³
Hydraulically active volume	286.74 m³	337.34 m³	+50.60 m³; +17.65%
HRT at field mean flow	33.60 h	39.53 h	+5.93 h
Mean COD load	185.90 kg/day	185.90 kg/day	Same 30-day loading basis
OLR at field mean	0.648 kg COD m⁻³ d⁻¹	0.551 kg COD m⁻³ d⁻¹	−15.0%
Peak upflow	0.650 m/h at PF 1.50	0.455 m/h at PF 1.05	−30.0%
Required action	Sludge/dead-zone and flow imbalance	Desludge, clear baffles, balance and meter trains	Operational restoration

Note. Hydraulic parameters are calculated from field flow and wastewater data together with the audited reactor geometry. Physical shell and chamber dimensions remain unchanged.

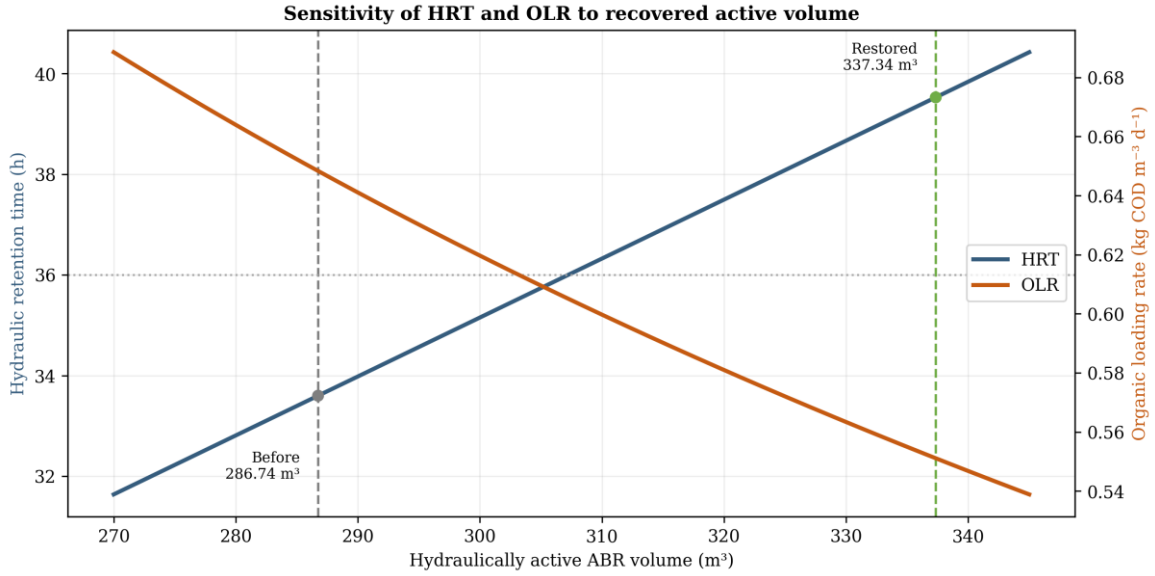

Figure 2: Sensitivity of hydraulic retention time and organic loading rate to active-volume recovery.

4.3 Empirical treatment performance before and after optimisation

ABR-stage removal was higher during optimised operation. Mean COD, BOD_5 and TSS removals were 78.15%, 79.56% and 78.55%, compared with 69.58%, 71.14% and 69.57% during pre-optimisation operation. The downstream polishing stage further reduced residual concentrations, producing mean overall removals of 89.99% COD, 91.90% BOD_5 and 91.27% TSS during the optimised phase, compared with 82.26%, 84.55% and 82.80% in the pre-optimisation phase.

Nutrient removal remained lower than carbon and solids removal but was also higher during optimised operation. Mean ABR-stage NH_3-N removal was 25.49%, compared with 17.64% pre-optimisation, while overall removal was 60.11%, compared with 47.06%. PO_4-P removal was 18.49% across the ABR and 49.93% across the complete system during optimised operation, compared with 13.22% and 38.62%. These operating-phase differences support continued use of polishing while showing that nutrient management remains a separate design consideration.

All 15 optimised-operation final-effluent observations met the combined study targets of COD ≤200 mg/L, BOD_5 ≤50 mg/L and TSS ≤100 mg/L. During pre-optimisation operation, COD and TSS met their concentration targets, but none of the ten BOD_5 observations met 50 mg/L; only two of five transition observations met all three targets. Combined performance reliability was therefore R = 1.00 during optimised operation, compared with R = 0.00 during pre-optimisation operation.

Table 5: Empirical wastewater-removal performance before and after optimisation

Parameter	Pre ABR removal	Optimised ABR removal	Pre overall removal	Optimised overall removal	Optimised final effluent
COD	69.58 ± 0.95%	78.15 ± 0.88%	82.26 ± 0.65%	89.99 ± 0.69%	90.6 ± 9.6 mg/L
BOD_5	71.14 ± 0.85%	79.56 ± 0.95%	84.55 ± 0.79%	91.90 ± 0.69%	37.47 ± 4.76 mg/L
TSS	69.57 ± 0.82%	78.55 ± 1.01%	82.80 ± 0.86%	91.27 ± 0.88%	30.53 ± 3.56 mg/L
NH_3-N	17.64 ± 0.99%	25.49 ± 1.05%	47.06 ± 1.46%	60.11 ± 1.23%	22.02 ± 1.65 mg/L
PO_4-P	13.22 ± 0.88%	18.49 ± 0.82%	38.62 ± 0.99%	49.93 ± 1.08%	5.17 ± 0.49 mg/L

Note. Values are means ± sample SD calculated from matched field measurements; pre-optimisation n = 10 and optimised operation n = 15.

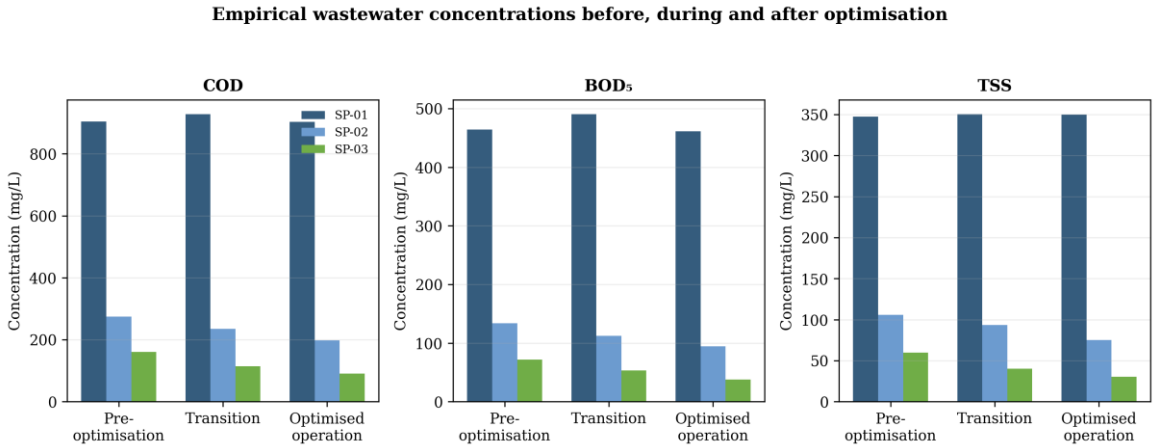

Figure 3: Empirical phase-mean wastewater concentrations at SP-01, SP-02 and SP-03.

4.4 Biogas production, storage and useful-energy implications

Daily field monitoring showed higher gas quantity and quality during optimised operation. Mean total biogas production was 57.03 ± 2.15 m³/day, compared with 42.99 ± 2.34 m³/day pre-optimisation, a descriptive difference of 32.7%. Mean methane fraction was 63.39%, compared with 57.15%, while carbon dioxide was 35.30%, compared with 40.26%. Hydrogen sulphide was 266.9 ppm, compared with 510.1 ppm, and moisture was 22.64 g/m³, compared with 32.53 g/m³. These

differences coincided with the observed optimised-operation gas-quality profile and conditioning controls.

The nominal installed gas-holder capacity was 45 m³. Mean useful kitchen delivery during optimised operation was 49.32 m³/day with 7.83 burner h/day, compared with 29.78 m³/day and 4.99 h/day pre-optimisation. Unused or flared gas was 6.00 m³/day, compared with 11.92 m³/day. Mean holder pressure was 1.667 kPa, compared with 1.343 kPa. Across all 30 days, 1,551.8 m³ of biogas was produced, 1,256.5 m³ was used in the kitchen and calculated gross methane energy used was 7,706.0 kWh.

The kitchen-energy logs documented displacement of conventional fuels. Mean LPG, diesel and firewood displacement during optimised operation was 51.82%, 50.10% and 53.83%, compared with 23.09%, 18.79% and 20.61% during pre-optimisation operation. Over the 30-day campaign, the recorded physical savings were 412.3 kg LPG, 61.0 L diesel and 927.0 kg firewood. The association between operating phase and performance therefore extended beyond gas production to useful energy delivery; monetary valuation was not undertaken.

Table 6: Empirical biogas and kitchen-energy performance before and after optimisation

Indicator	Pre-optimisation	Optimised operation	Change	Interpretation
Nominal gas-holder capacity	45 m³	45 m³	No change	Installed design capacity
Biogas flow	42.99 ± 2.34 m³/day	57.03 ± 2.15 m³/day	+32.7%	Higher stable production
Methane fraction	57.15 ± 0.68%	63.39 ± 0.69%	+6.24 pp	Higher methane fraction
H_2S	510.1 ± 29.8 ppm	266.9 ± 28.0 ppm	−47.7%	Lower corrosive/toxic impurity
Moisture	32.53 ± 1.65 g/m³	22.64 ± 1.84 g/m³	−30.4%	Lower moisture content
Gas used	29.78 ± 2.08 m³/day	49.32 ± 2.75 m³/day	+65.6%	Greater useful utilisation
Burner hours	4.99 ± 0.34 h/day	7.83 ± 0.32 h/day	+56.9%	Longer cooking support
LPG displacement	23.09 ± 1.06%	51.82 ± 1.41%	+28.73 pp	Reduced LPG dependence
Diesel displacement	18.79 ± 1.62%	50.10 ± 1.90%	+31.31 pp	Reduced diesel dependence
Firewood displacement	20.61 ± 1.52%	53.83 ± 1.51%	+33.22 pp	Reduced firewood dependence

Note. Gas-holder capacity is from the project design record; other values are field means ± sample SD. pp = percentage points. Pre-optimisation n = 10; optimised operation n = 15.

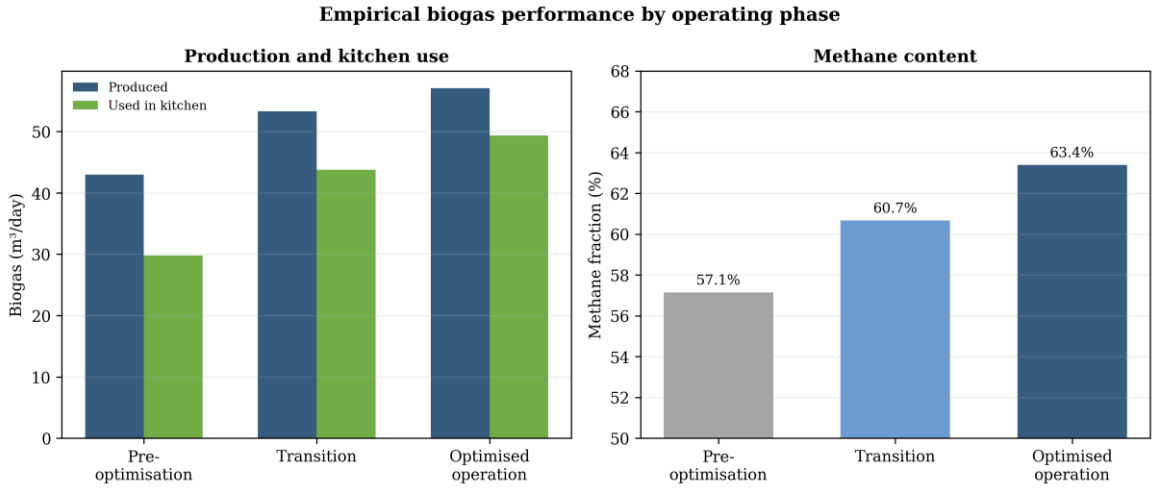

Figure 4: Empirical biogas production, kitchen use and methane fraction by operating phase.

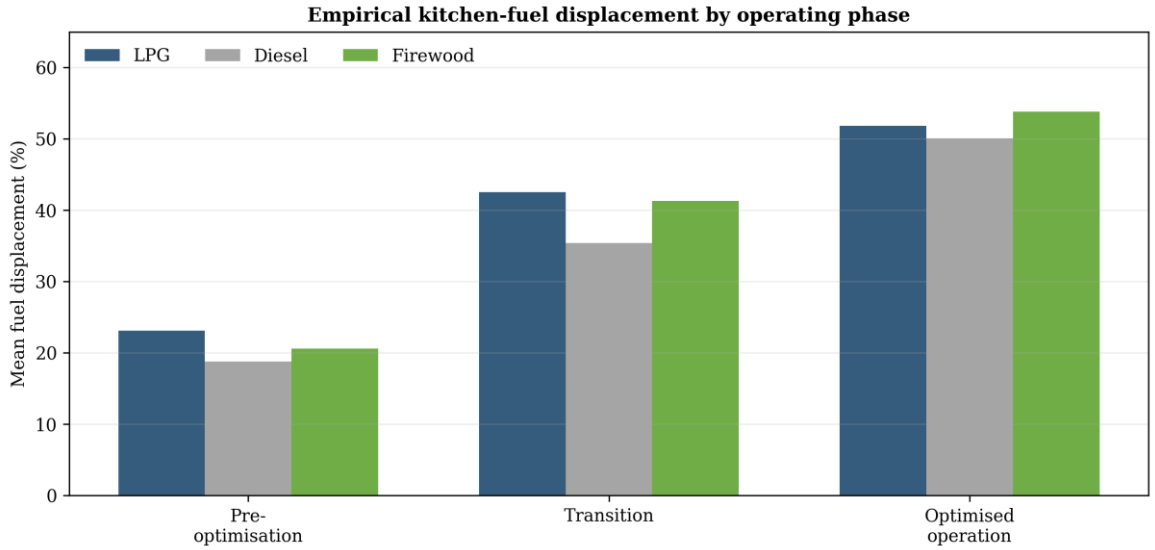

Figure 5: Empirical LPG, diesel and firewood displacement by operating phase.

4.5 Hydrostatic stability screening

The two-train base plan was derived as $2 \times 8.20 \times 9.70 = 159.08$ m². At groundwater heads of 0.5, 1.0, 1.5 and 2.0 m above the base, calculated uplift was approximately 0.78, 1.56, 2.34 and 3.12 MN. At a minimum factor of safety of 1.20, required stabilising resistance was 0.94–3.75 MN. The range confirms that groundwater is not merely a geotechnical description; it is a structural design action that can control the empty-tank condition.

The screening result does not establish adequacy because verified concrete dimensions, self-weight, soil cover, internal water level, drainage, anchorage and load combinations were not available. The optimisation therefore includes an explicit hold point: do not empty, modify or construct adjoining units until the critical groundwater level and structural resistance are confirmed.

Table 7: Groundwater-uplift sensitivity for the combined ABR footprint

Groundwater head above base	Calculated uplift	Resistance required at FS = 1.20	Design implication
0.5 m	0.78 MN	0.94 MN	Verify empty-tank dead load
1.0 m	1.56 MN	1.87 MN	Check cover, drainage and construction stage
1.5 m	2.34 MN	2.81 MN	Ballast or anchorage may govern
2.0 m	3.12 MN	3.75 MN	Critical coastal-groundwater scenario

Note. Screening uses $\gamma w = 9.81$ kN/m³ and an approximate combined base area of 159.08 m². Detailed structural verification is required.

4.6 Impact assessment

The intervention replaced an unsafe sewage-management condition with contained treatment and eliminated routine manual faecal evacuation. This represents a direct change in the sanitation service chain: wastewater is conveyed to engineered treatment rather than repeatedly removed through hazardous manual intervention. Field observations also recorded reduced odour nuisance, improved cleanliness around the centre and more reliable access to renewable cooking gas. These outcomes align with WHO's emphasis on exposure control and with prison-biogas experience in other countries (WHO, 2022; Gauthier et al., 2012).

The monitored mass balance showed higher pollutant removal during optimised operation. Mean COD removal was 167.25 kg/day, compared with 150.08 kg/day pre-optimisation, a difference of +17.18 kg/day. Mean BOD_5 removal was 87.22 kg/day, compared with 79.21 kg/day (+8.01 kg/day), while TSS removal was 65.74 kg/day, compared with 58.11 kg/day (+7.63 kg/day). These differences are summarised together in Table 8. Final-effluent COD, BOD_5 and TSS met the combined study targets on all 15 optimised-operation days.

Energy logs showed higher useful delivery during optimised operation. Mean kitchen gas use was 65.6% higher than the pre-optimisation phase, burner support was 56.9% higher, and gross methane energy used was 311.70 kWh/day, compared with 169.79 kWh/day. The 30-day records showed aggregate physical savings of 412.3 kg LPG, 61.0 L diesel and 927.0 kg firewood. Monetary savings should be computed separately with contemporaneous invoice or issue prices to avoid distortion from fuel-price changes.

The social and institutional effects include reduced exposure to raw sewage, improved sanitation dignity, less dependence on smoky solid fuel and a cleaner kitchen environment. Sustainability depends on assigned O&M authority, recurrent financing, trained operators, spare parts, desludging schedules, gas-safety procedures and continued monitoring. Infrastructure transfer without these controls would reproduce the weakness observed in many decentralised ABR programmes (Yulistyorini et al., 2019).

Table 8: Field-based impact assessment of the integrated system

Impact domain	Indicator or finding	Evidence strength	Defensible conclusion
Technical	337.34 m^3 active volume; HRT 33.60 to 39.53 h	Field/design calculation	Installed shell supports repair-first optimisation
Sanitation/public health	Manual evacuation eliminated; sewage containment and odour improved	Field operational record	Exposure pathway materially reduced
Environmental	+17.18 kg/day COD, +8.01 kg/day BOD_5 and +7.63 kg/day TSS removed	Field mass balance	Higher removal during optimised operation
Energy	57.03 m^3/day gas; 49.32 m^3/day used; 7.83 burner h/day	Field monitoring	Higher delivery during optimised operation
Fuel economy	412.3 kg LPG, 61.0 L diesel and 927.0 kg firewood saved in 30 days	Field kitchen logs	Reduced conventional-fuel requirement
Social	Cleaner sanitation and reduced smoky-fuel dependence	Field observation	Improved dignity and kitchen working conditions
Institutional	O&M, safety, logs, finance and spare parts required	Engineering assessment	Governance remains part of the optimised design

Note. Quantitative indicators are derived from field wastewater, biogas and kitchen-energy records. Monetary valuation is excluded because contemporaneous price documentation was outside this analysis.

5. DISCUSSION

5.1 Why the corrected sizing changes the optimisation

The most consequential correction is dimensional. The value 154.45 is the design flow in m^3/day, not the installed active volume in m^3. Combining it with the reported 52.42-h HRT produces 337.34 m^3. Any optimisation search that restricts reactor volume to values near 154 m^3 cannot represent the installed system and may falsely recommend extra chambers or a smaller optimum. The corrected basis reverses that logic: the system already contains a large active volume relative to design flow, so the first question is whether that volume is hydraulically available and evenly used.

The repair-first result is engineeringly and institutionally attractive. Recovering 50.60 m^3 of inactive capacity yields a 17.65% gain in active volume without additional land or a new reactor shell. At the monitored mean flow, the restored-volume calculation yields 5.93 h additional HRT and 15% lower OLR; the balanced-flow scenario yields 30% lower peak upflow. Wastewater removal was also higher during the optimised phase despite no engineeringly significant change in influent COD, BOD_5 or TSS. This pattern is consistent with, but does not prove, a causal relationship between restored hydraulic function and treatment performance.

This conclusion aligns with field evidence showing that dynamic loading and O&M practices govern ABR performance. A nominal HRT calculated from drawings may differ materially from

residence time under intermittent flow, dead zones or unequal distribution. Echeverría et al. (2022) found that the monitored ABR performed below a design-model prediction and attributed the difference partly to temperature and intermittent flow. Yulistyorini et al. (2019) found that only a minority of surveyed decentralised ABRs achieved acceptable combined treatment and structural performance, largely because service delivery did not continue after construction. The Ikoyi optimisation therefore treats inspection, metering and maintenance as design components.

5.2 Treatment performance and the case for polishing

The empirical results demonstrate why both the ABR and downstream polishing unit must be evaluated. During optimised operation the ABR alone reduced COD to 197.6 mg/L, BOD_5 to 94.4 mg/L and TSS to 75.0 mg/L. Polishing then reduced these means to 90.6, 37.47 and 30.53 mg/L. The ABR met the COD and TSS screening targets on average but not the BOD_5 target; the complete treatment train achieved all three targets on every optimised-operation day.

The polishing stage was especially important for BOD_5 and nutrients. Constructed wetlands and biofilters have performed well after ABRs (Echeverría et al., 2022; Satyendra & Vijay, 2024), and high-strength decentralised systems can produce high-quality effluent when the complete train is properly designed and operated (Rahman et al., 2024). At Ikoyi, continued performance will depend on managing solids accumulation, groundwater, mosquito risk, media condition, hydraulic distribution, odour and access for maintenance.

The 30-day series is sufficient to demonstrate field-phase performance but not seasonal invariance. Continued matched monitoring at SP-01, SP-02 and SP-03 should retain COD, BOD_5, TSS, NH_3-N and PO_4-P and should add microbial indicators for public-health verification. The approach is consistent with Standard Methods and with the regulatory principle of using time-based averages rather than isolated samples (American Public Health Association et al., 2023; Electronic Code of Federal Regulations, n.d.).

5.3 Biogas optimisation: production is not utilisation

The empirical gas record answers both the production and utilisation questions. Optimised mean production of 57.03 m^3/day was accompanied by 49.32 m^3/day of kitchen use, 7.83 burner h/day and only 6.00 m^3/day unused or flared. During that phase, methane content was higher and H_2S and moisture were lower than in the pre-optimisation phase, showing that useful energy assessment must consider gas quality and delivery as well as volume.

A robust gas system must reconcile production, kitchen use, storage change and controlled loss. During the optimised phase, higher production coincided with approximately half the pre-optimisation quantity of unused gas and greater useful consumption. The stated 45-m^3 holder is below one day of optimised mean production, but its adequacy depends on the timing of generation and meal preparation. Pressure and burner-hour evidence supports current use, while an hourly inventory study would provide a stronger buffer-sizing check.

Condensate management, hydrogen-sulphide removal, leak testing, pressure monitoring, calibrated metering and burner scheduling remain essential. Gauthier et al. (2012) showed that operational responsibilities and maintenance influence whether prison biogas remains appropriate. The measured reduction in conventional-fuel use at Ikoyi strengthens the case for continued investment in these controls and for retaining a contingency cooking source for service continuity.

5.4 Contribution to sustainable development and engineering practice

The case connects sanitation, pollution control, renewable thermal energy and institutional resilience, consistent with resource-recovery and sanitation-safety principles (UNEP, 2023; WHO, 2022, 2026). Its quantified contribution is a transparent field decision basis: 337.34 m^3 restored active volume; 5.93 h additional HRT at monitored mean flow; 15% lower OLR; 89.99%, 91.90% and 91.27% overall COD, BOD_5 and TSS removal; 57.03 m^3/day biogas production during optimised operation; 63.39% methane; and conventional-fuel displacement above 50% for LPG, diesel and firewood. These values convert a general sustainability claim into measurable engineering outcomes.

6. LIMITATIONS AND VALIDATION REQUIREMENTS

The principal limitation is the 30-day, single-season monitoring window and the sequential rather than randomised intervention design. The results are empirical and field-based, but they should be interpreted as full-scale operating-phase evidence rather than proof that every observed change was caused by one isolated optimisation variable. Longer monitoring should test wet- and dry-season performance, sludge accumulation and resilience to unusual hydraulic or organic shocks.

The active-volume values are engineering calculations based on the audited geometry and operating condition; a detailed sludge-depth and residence-time survey would strengthen the hydraulic diagnosis. Aggregate flow does not resolve inequality between the two trains, and daily gas totals do not capture sub-daily storage peaks. The multi-criteria weights reflect transparent engineering priorities but were not established through formal stakeholder elicitation or tested through a complete multi-weight sensitivity analysis; future work should examine ranking stability across plausible weights. Microbial water-quality indicators, kitchen air-quality measurements, contemporaneous fuel prices and ethically collected stakeholder responses would extend the environmental, economic and social assessment beyond the present scope.

7. CONCLUSIONS AND RECOMMENDATIONS

The design audit confirms that the Ikoyi system comprises two parallel ABR trains with six chambers per train and a restored active volume of 337.34 m^3. At the monitored mean flow of 204.82 m^3/day, active-volume recovery increased calculated HRT from 33.60 to 39.53 h and reduced OLR from 0.648 to 0.551 kg COD m^{-3} d^{-1}. The optimised solution therefore retains the installed shell and chamber count and prioritises desludging, dead-zone recovery, clear baffle openings, equal flow division and metering.

The 30-day empirical campaign comprised 90 wastewater samples at SP-01, SP-02 and SP-03. During optimised operation, final-effluent COD, BOD_5 and TSS averaged 90.6, 37.47 and 30.53 mg/L, with overall removals of 89.99%, 91.90% and 91.27%. All 15 optimised-operation days met the combined study targets. Nutrient removal was higher during optimised operation but remained lower than carbon and solids removal, supporting continued attention to polishing and microbial-risk verification.

Mean biogas production during optimised operation was 57.03 m^3/day, compared with 42.99 m^3/day pre-optimisation; methane fraction was 63.39%, compared with 57.15%; and kitchen use was 49.32 m^3/day, compared with 29.78 m^3/day. LPG, diesel and firewood displacement reached 51.82%, 50.10% and 53.83% during optimised operation. The field records therefore show measurable sanitation, pollution-control and institutional-energy benefits, while the sequential design limits attribution to any single optimisation action.

For implementation, the authors recommend continued three-point wastewater monitoring; total and train-specific flow metering; scheduled sludge-depth surveys; maintenance of the polishing stage; gas-quality, pressure and kitchen-demand logging; an empty-tank hydrostatic check with FS $\geq$1.20; contemporaneous cost recording; and a funded O&M plan with named responsibilities, preventive schedules, safety procedures and spare parts. These measures will protect the gains demonstrated during the field campaign and allow seasonal verification.

DATA AVAILABILITY AND RESEARCH-INTEGRITY STATEMENT

The paper uses primary field and empirical monitoring records together with transparent engineering calculations. Security-sensitive layouts and individual-level custodial information are not disclosed. The wastewater, biogas and kitchen-energy datasets are held within the research project and are subject to institutional permissions; aggregated results are reported in this manuscript.

CONFLICT OF INTEREST

The authors declare no conflict of interest in relation to the preparation of this manuscript.

ABSTRACT
Traffic enforcement is a core component of urban traffic management systems, yet its design is rarely subjected to the same safety-engineering scrutiny applied to road geometry, signal timing, or vehicle standards. This paper argues that it should be. Drawing on evidence from Kano metropolis, Nigeria, where traffic management relies heavily on contact-based enforcement by the Kano Road Traffic Authority (KAROTA), the study examines how an enforcement subsystem oriented toward revenue generation rather than safety outcomes may itself become a source of crash risk. A cross-sectional survey of 331 urban drivers found that higher self-reported compliance with traffic regulations was independently associated with greater, not lower, self-reported crash involvement (OR = 1.72, p = .007), while perceived importance of regulation was independently protective (OR = 0.48, p < .001); the two were statistically unrelated. A descriptive attitude–behaviour typology showed that drivers reporting consistent compliance without valuing the rules recorded the highest crash rate (83%), while those who valued regulation but complied flexibly were safest (42%). Documented cases of enforcement-related harm, and institutional evidence on KAROTA's revenue mandate and personnel profile, are consistent with an enforcement-as-hazard mechanism, though they cannot establish its incidence. The paper argues, interpretively rather than as a tested claim, that safe traffic management system design should treat enforcement legitimacy as a design parameter, and that substituting automated, infrastructure-based compliance mechanisms for discretionary contact-based enforcement offers a plausible safety improvement. Implications for the transition to technology-enabled enforcement in Nigerian cities are discussed.

Keywords: *Traffic Management System Design; Enforcement Safety; Attitude–Behaviour Congruence; Safe System Approach; Nigeria*

1. INTRODUCTION

The Safe Systems approach to road safety treats the road transport environment as an engineered system whose components — road geometry, vehicle design, speed management, and user behaviour — interact to produce or prevent harm (Khan and Das, 2024; OECD/ITF, 2021). A core principle is that no single component failure should result in death or serious injury; the system should be designed so that errors are anticipated, accommodated, and their consequences minimised. This principle has driven decades of progress in infrastructure engineering, vehicle crashworthiness, and signal design.

One component of the traffic management system, however, has largely escaped safe-systems scrutiny: the enforcement subsystem. Traffic enforcement — the institutional apparatus of officers, checkpoints, patrols, and sanctions — is conventionally evaluated by asking whether it is sufficiently consistent, visible, and well-resourced, and the standard recommendation is to intensify it (Elvik et al., 2009; Uhunwagho et al., 2025). This evaluative frame implicitly treats enforcement as an unambiguous safety input rather than as a designed subsystem that can itself generate hazard if poorly engineered.

This paper examines that assumption using evidence from Kano metropolis, Nigeria, where traffic management depends heavily on contact-based street enforcement by the Kano Road Traffic Authority (KAROTA). It argues that an enforcement subsystem designed around revenue extraction, staffed without adequate training, and operating without procedural safeguards may produce

compliance that is not reliably protective, and enforcement encounters that are themselves hazardous. Two points about the paper's scope should be stated at the outset. First, the study did not administer validated measures of compliance motivation, procedural justice, or enforcement legitimacy; the theoretical frameworks below are therefore applied interpretively, to organise and explain the observed associations, rather than tested directly. Second, the documented cases used later are illustrative of a mechanism and cannot establish its incidence or representativeness. Within these bounds, the paper proposes that enforcement legitimacy be treated as a design parameter in traffic management systems, and that the transition from discretionary, contact-based enforcement to automated, infrastructure-based compliance mechanisms is a safety-engineering question deserving direct study.

2. ENFORCEMENT AS A DESIGNED SUBSYSTEM

2.1 The conventional evaluative frame and its limitation

The dominant Nigerian road safety literature evaluates enforcement agencies — the Federal Road Safety Corps (FRSC) and state traffic authorities — by measuring activity volume: patrol frequency, checkpoint density, fine revenue, and public-awareness campaign reach. A recent representative study of the FRSC Minna Sector Command concludes that road safety would improve with greater consistency and visibility of enforcement and with more funding and personnel (Uhunwagho et al., 2025). This framing rests on a simple deterrence model in which more enforcement yields more compliance, which in turn yields fewer crashes.

The limitation is that deterrence models assume the enforcement agent is legitimate — trusted, competent, and procedurally fair — and that the compliance produced is normatively accepted rather than merely coerced (Tyler, 2006). Where this assumption fails, the model's predictions may reverse, and more enforcement may produce more coerced, evasive, and hazardous behaviour rather than more safety. This is a system-design question rather than a purely behavioural one. The institutional parameters of the enforcement subsystem — its funding model, recruitment standards, accountability mechanisms, and mode of operation — shape whether it functions as a safety mechanism or as a hazard source.

2.2 Contact-based versus infrastructure-based enforcement

A useful distinction for safe-system design is between contact-based enforcement, in which officers physically stop, confront, and sanction drivers in real time, and infrastructure-based enforcement, in which detection is automated through cameras, sensors, and signal systems, with sanctions processed remotely. Contact-based enforcement introduces a direct, in-traffic interaction between an officer and a driver. That interaction can itself generate hazard — through sudden braking, evasion manoeuvres, or physical altercation — particularly where the enforcement is perceived as illegitimate or extractive. Infrastructure-based enforcement removes the hazardous encounter, decouples detection from personal discretion, and can operate continuously rather than selectively. The transition from contact-based to infrastructure-based enforcement is therefore a safety-engineering decision with plausible implications for crash risk, yet it is rarely framed as such in the Nigerian context, where discussion remains centred on enforcement quantity rather than enforcement mode and design.

3. THEORETICAL BASIS

Two complementary frameworks are used interpretively in this paper to link enforcement system design to safety outcomes through compliance motivation. Neither construct was measured directly in the survey; the frameworks are applied to organise and explain the observed associations, and the absence of direct measurement is a limitation noted here and revisited in Section 7.

Self-determination theory (Deci and Ryan, 1985, 2000) distinguishes autonomous motivation, in which behaviour is aligned with personal values and tends to be stable and generalised, from controlled motivation, in which behaviour is driven by external pressure and tends to be narrow and situation-dependent. Applied to traffic, it suggests that the same observable compliance may be protective or hazardous depending on its motivational source. Enforcement system design plausibly influences which type predominates: a legitimate, procedurally fair system supports internalisation,

whereas an extractive system may produce controlled, surveillance-dependent compliance that lapses or becomes evasive when the officer appears.

Procedural-justice and legitimacy theory (Sunshine and Tyler, 2003; Tyler, 2006) specifies the institutional conditions that build or erode legitimacy: consistency, transparency, respectful treatment, and the absence of corruption. An enforcement subsystem designed around revenue targets, staffed at the lowest educational grades, and operating without oversight creates conditions that theory would expect to erode legitimacy and, through the motivational pathway above, to favour controlled over internalised compliance. The combined framework yields the paper's central proposition, offered as an interpretive hypothesis: an enforcement subsystem functions as a safety mechanism when it is designed to produce legitimate, internalised compliance, and risks becoming a hazard source when it is not.

4. THE KANO CASE: EVIDENCE OF A SYSTEM DESIGN FAILURE

4.1 Institutional design parameters

KAROTA was established in 2012 by the Kano State Government with a dual mandate of traffic management and revenue generation, with a reported monthly revenue target of approximately ₦100 million (Zakimayu et al., 2023). More than 95% of its approximately 1,600 agents were recruited at the lowest educational grades, and the agency's own administrators have acknowledged that agents enforce fewer than five of the 90-plus codified traffic offences (Zakimayu et al., 2023). The metropolis, with a population exceeding four million, is served by fewer than 100 operational traffic signals. This combination — a revenue-incentivised workforce, minimal training, and scarce automated infrastructure — represents an enforcement subsystem oriented, whether by intent or not, toward contact-based operation rather than safety outcomes.

4.2 Survey methodology

A cross-sectional survey was conducted across five local government areas of Kano metropolis. Adult drivers were recruited using purposive sampling at high-traffic locations, including fuel stations, motor parks, and checkpoints; the sampling frame limitations this entails are addressed in Section 7. An a priori power analysis for logistic regression ($\alpha = .05$, power = .80, anticipated $R^2 = .10$) indicated a minimum of 271 cases, and the achieved sample of 331 exceeded this threshold. Participation was voluntary and anonymous, and informed consent was obtained.

A structured questionnaire captured demographics, driving profile, perceived importance of traffic regulation, self-reported compliance, and crash involvement. Perceived importance was measured on a four-point item (from 'not at all important' to 'very important'); self-reported compliance was measured on a three-point frequency item ('sometimes', 'most of the time', 'always'); and the outcome was self-reported involvement in any road crash or collision in the preceding six months. The crash item did not specify a severity threshold and is therefore interpreted throughout as self-reported crash or collision involvement of any severity, not as verified or injury crashes. The instrument was piloted with 20 drivers excluded from the final sample; because the key measures are single items rather than multi-item scales, no internal-consistency statistics are reported, and this measurement constraint is noted as a limitation. Analyses were conducted in Python 3.11 (scipy, statsmodels, scikit-learn).

4.3 Survey findings

Bivariate associations were assessed using chi-square tests and Spearman correlations. A binary logistic regression predicting crash involvement was reduced by backward elimination on the Akaike information criterion to a parsimonious specification containing five predictors: compliance, perceived importance, driving frequency, awareness frequency, and gender. This model was re-estimated using Firth's penalised maximum likelihood to address small-sample bias arising from the small female subsample ($n = 18$); all variance inflation factors were below 1.2. In the penalised model, higher compliance was independently associated with greater crash risk (OR = 1.72, 95% CI [1.16, 2.56], $p = .007$), while perceived importance was independently protective (OR = 0.48, 95% CI [0.32, 0.72], $p < .001$). The two were statistically unrelated ($\rho = -.00$, $p = .994$), and a causal mediation analysis with bootstrapped confidence intervals indicated that compliance did not transmit the protective effect of perceived importance.

Cross-classifying drivers on dichotomised perceived importance and compliance produced four descriptive response profiles with significantly different crash rates ($\chi^2(3) = 29.1$, $p < .001$): high importance with inconsistent compliance, safest at 42%; high importance with consistent compliance, 67%; low importance with inconsistent compliance, 70%; and low importance with consistent compliance, highest at 83%, with adjusted odds 2.67 times the high-importance/consistent reference (95% CI [1.18, 6.03], $p = .018$) after adjustment for driving frequency and gender. These are descriptive classifications of survey responses, not measured motivational types; the labels used in earlier work carried motivational connotations and are avoided here. One feature is notable: the high-importance/consistent profile recorded a higher crash rate (67%) than the high-importance/inconsistent profile (42%), which is difficult to reconcile with a clean partition of behavioural types and reinforces the descriptive status of the classification.

4.4 Documentary evidence: enforcement encounters as hazard events

The survey associations are consistent with, though they do not by themselves establish, a mechanism in which the enforcement encounter itself can produce harm. Respondents' open-text comments referred to accidents attributed to 'the fear of KAROTA officials', to officers who 'follow the driver' who fails to stop, and to enforcement that they associated with aggressive driving. These are perceptions, not incident records.

Independently, press and field records document individual incidents in which enforcement contact preceded injury or death: traffic officials physically intervening in moving vehicles ('steering-dragging') with fatal results, reported in Kano and, in a structurally similar case, in Lagos involving the Lagos State Traffic Management Authority (LASTMA); fatal pursuits of drivers evading enforcement; officers struck and killed while attempting to stop vehicles, including a case in which a driver was sentenced to 15 years for killing a Kano traffic officer (Punch, 2024); and clashes between enforcement agents and road users (Gazette, 2023). A feature of this record worth noting analytically is that the harm is bidirectional — both drivers and officers are killed — which is more consistent with a hazardous interaction dynamic than with misconduct by either party alone. These cases are illustrative and are drawn from journalism; they document that such events occur, not how frequently, and no inference about incidence or representativeness is drawn from them.

Institutional documentation further indicates that extraction-oriented conduct is present within Nigerian traffic enforcement more broadly, including anti-corruption operations concerning FRSC officials (ICPC, 2021), reporting on the taxation of tricycle operators in Kano (ICIR, 2024), and reporting on highway extortion (Premium Times, 2025). These sources describe the institutional environment in which the Kano subsystem operates; they are contextual rather than causal evidence.

5. DISCUSSION: ENFORCEMENT LEGITIMACY AS AN ENGINEERING PARAMETER

The survey, documentary, and institutional strands are mutually consistent and, taken together, are suggestive of an enforcement subsystem that is not functioning purely as a safety mechanism. They fall short, individually and jointly, of establishing that contact-based enforcement causes crashes: the survey is cross-sectional and self-reported, and the documented cases are illustrative. What the strands support is a coherent, testable hypothesis rather than a demonstrated causal claim — namely, that a contact-based, revenue-oriented, low-legitimacy enforcement configuration may favour coerced rather than internalised compliance and may generate hazardous enforcement encounters.

From a safe-systems engineering perspective, the value of this framing is that it locates a potential safety problem in design parameters that are within an agency's control — funding model, recruitment and training standards, accountability mechanisms, and mode of operation — rather than in the conduct of individual officers. Treating enforcement legitimacy as a design parameter means subjecting these choices to the same evidence-based scrutiny applied to road cross-sections, signal phasing, or crashworthiness standards.

The Kano and Lagos 'steering-drag' cases, occurring in different cities and involving different agencies, are suggestive that the hazard may not be specific to a single agency but may instead be associated with the contact-based enforcement configuration itself. This remains a hypothesis: two documented cases cannot establish that the pattern is general, and a systematic compilation of

enforcement-related crash events across multiple Nigerian cities would be required to test it. The claim is therefore offered as a direction for investigation, not as an established generalisation.

6. TOWARD SAFER ENFORCEMENT SYSTEM DESIGN

Four design principles follow from the analysis, offered as engineering directions for traffic management systems in Nigerian cities. Because they follow from the institutional and documentary evidence and from safe-system principles, rather than from the survey associations alone, they do not depend on resolving the causal questions above.

First, decouple enforcement from revenue generation. A revenue mandate creates an incentive structure that rewards extraction over safety and is corrosive of the legitimacy on which internalised compliance depends. Enforcement funded from general appropriation, rather than from what it collects, better aligns the agent's incentive with safety outcomes.

Second, shift the balance from contact-based toward infrastructure-based enforcement. Automated systems — speed and red-light cameras, and automatic number-plate recognition — decouple detection from personal discretion, remove the hazardous in-traffic encounter, operate continuously, and generate an auditable, corruption-resistant record.

Third, invest in the enabling infrastructure. Automated enforcement depends on functional signals, signage, and markings. Fewer than 100 operational signals for a metropolis of over four million forces reliance on contact-based enforcement by default; signal and signage provision is therefore both a traffic-flow measure and a precondition for shifting enforcement mode.

Fourth, professionalise personnel for the contact-based functions that remain necessary, such as crash response and impaired-driving detection. Recruitment, training, and evaluation should emphasise procedural fairness and safety outcomes rather than revenue collected, with training in de-escalation and in the hazards of in-traffic physical intervention.

7. LIMITATIONS AND FUTURE WORK

The study has several limitations that bound its conclusions. The design is cross-sectional and relies on self-report, so no causal ordering can be established; in particular, post-crash behavioural adaptation, in which involvement in a crash leads a driver to report stricter subsequent compliance, is a plausible alternative explanation for the positive compliance–crash association that the data cannot exclude. The crash outcome is broad and severity-unrestricted, with a six-month recall window and no validation against police or hospital records, and the reported rate should not be compared with injury-crash statistics. The key measures of perceived importance and compliance are single items rather than validated multi-item scales. The theoretical constructs of central interest — compliance motivation, procedural justice, and enforcement legitimacy — were not measured directly; the frameworks are applied interpretively, and the response-profile typology is descriptive rather than a validated motivational classification.

The sample is predominantly male (approximately 95%) and was recruited purposively without a sampling frame. These features limit the generalisability of all findings, and of the typology in particular: the profiles describe response patterns within this specific, non-representative sample, and their crash rates should not be read as population estimates or extended to women drivers, who are severely under-represented. The documentary cases are illustrative and journalistic, and the institutional analysis relies on secondary sources. Collectively, these constraints mean the paper advances an evidence-consistent, testable hypothesis rather than a confirmed causal claim.

Future work should pursue three priorities. First, a comparative study of cities relying predominantly on contact-based versus infrastructure-based enforcement, measuring both compliance quality and crash outcomes, would test the central design proposition directly. Second, primary studies should administer validated procedural-justice and self-determination measures, alongside a severity-anchored or record-linked crash outcome and a proper exposure measure, ideally in a longitudinal design capable of separating post-crash adaptation from prospective risk. Third, a systematic compilation of enforcement-related crash events across multiple Nigerian cities would test whether the enforcement-as-hazard pattern generalises beyond the illustrative cases presented here.

8. CONCLUSION

Traffic enforcement is a subsystem of the traffic management system, and like any subsystem it can be designed for safety or, inadvertently, for hazard. In Kano, the enforcement subsystem's institutional parameters — a revenue mandate, minimally trained contact-based agents, and scarce automated infrastructure — characterise a configuration that this study's converging but limited evidence suggests may generate coerced, evasive compliance and dangerous enforcement encounters. The evidence supports this as a hypothesis to be tested, not as an established finding.

The corrective this points toward is not more enforcement but better-designed enforcement: revenue-decoupled, progressively automated, supported by functional infrastructure, and, where human contact remains necessary, staffed by trained and accountable personnel. Framed this way, enforcement legitimacy is not a matter external to engineering; it is a design parameter that plausibly shapes whether the enforcement subsystem contributes to, or detracts from, the safety of the traffic management system as a whole — a proposition this paper commends to direct empirical test.

ABSTRACT

The increasing use of plastic materials in modern society has led to a significant rise in plastic waste generation. Improper disposal of these materials has created serious environmental challenges, particularly in developing countries where waste management systems are still evolving, hence plastic recycling has therefore become an important approach to reducing environmental pollution and promoting sustainable resource utilization. One of the key processes involved in plastic recycling is the reduction of plastic waste into smaller sizes that can be easily processed and reused. This paper focuses on the design and fabrication of a waste plastic shredding machine suitable for small and medium scale recycling operations. The machine was designed using fundamental principles of mechanical engineering and constructed using locally available materials to ensure affordability, durability, and ease of maintenance while the major components of the machine include the frame, hopper, shredding blades, shaft, drive mechanism, bearings, and a 6.5hp gasoline engine which serves as the power source. The machine operates on the principle of mechanical shearing and cutting, where plastic materials fed through the hopper are reduced into smaller particles by rotating blades mounted on a shaft. Performance evaluation of the fabricated machine was carried out using plastic waste materials and three experimental tests were conducted with an average plastic input weight of 5.37 kg and an average shredding time of 51.67 seconds. The results obtained showed an average shredded plastic output of 4.9 kg, resulting in a shredding efficiency of approximately 91.25 percent. The results indicate that the fabricated plastic shredding machine is capable of effectively reducing plastic waste into smaller particles suitable for recycling processes. The machine therefore provides a practical and cost-effective solution for improving plastic waste management and supporting environmental sustainability, especially in communities where recycling facilities are limited.

Keywords: *Plastics; Environment; Pollution; Shredding; Wastes Management; Machine*

1. INTRODUCTION

The exponential growth of plastic consumption worldwide over recent decades has resulted in the generation of massive quantities of plastic waste, making it one of the most significant environmental and public health challenges of the 2[1st] century (*Thompson et al., 2009; Hopewell et al., 2009*) but the indiscriminate disposal of plastic waste in Nigeria has resulted in serious environmental problems, including blocked drainage systems, pollution of water bodies, and threats to human health and biodiversity. Large quantities of plastic waste remain unprocessed due to the lack of appropriate recycling and shredding facilities, particularly at the community and institutional levels.

Many of the plastic shredding machines currently available are imported and expensive, making them inaccessible to small-scale recycling operators and local entrepreneurs. In addition, some existing machines require a reliable electricity supply, which is often unavailable or inconsistent in many parts of Nigeria. As a result, plastic waste is frequently discarded without undergoing size reduction, thereby limiting recycling opportunities.

Plastics are widely used due to their versatility, durability, and low cost, yet their non-biodegradable nature means that, once discarded, they persist in the environment for hundreds of years. Plastic waste accumulates in landfills, rivers, oceans, and terrestrial ecosystems, posing severe threats to wildlife, human health, and overall ecological balance. Microplastics, formed from the breakdown of larger plastic items, have been detected in water sources, soils, and even food chains, raising global concerns about their long-term effects on health and ecosystems. These realities underscore the urgent

need for sustainable, cost-effective, and scalable strategies for plastic waste management, with recycling and reuse emerging as the most viable solutions (Handel and Strazdus, 2021).

Among the critical stages of plastic waste management is size reduction through shredding, a process that enhances recycling efficiency and operational feasibility. Shredding converts bulky, irregular, and difficult-to-handle plastics into smaller, uniform fragments that are easier to transport, sort, and process in subsequent operations such as melting, extrusion, or chemical treatment (*Angelo et al., 2022; Wong et al., 2022*). Reducing particle size not only increases the surface area for more efficient processing but also lowers storage and transportation costs and reduces hazards associated with manual handling of large plastic items. A well-designed shredding system enhances recycling efficiency, supports circular economy principles, and contributes to resource conservation by enabling plastics to be reintroduced into manufacturing processes. The significance of this research extends beyond technical design but by providing a low-cost, practical, and efficient solution for plastic waste reduction thereby contributing to environmental conservation, promotes sustainable waste management practices, and encourages the adoption of circular economy initiatives at the community and institutional levels (Balasubramanian and Sharma, 2022). It also aims to address local and national plastic waste challenges and also serve as a replicable model that can be adopted by educational institutions, small enterprises, and community-based recycling programs.

Surgude et al. (2023) fabricated a plastic shredder designed for small recycling workshops and emphasized the use of locally available materials to reduce manufacturing cost though, the fabricated shredder efficiency was 91.3%, yet their studies demonstrate that locally designed shredding machines can provide effective solutions for plastic waste recycling when appropriate engineering principles are applied.

2. METHODOLOGY

The design process for shredding plastic wastes such as PET, HDPE, and polypropylene. involves the identification and configuration of the major machine components, which include: *Hopper; Shredding chamber; Cutting blades; Rotating shaft; Bearings; Structural frame; Power transmission system; Discharge outlet.* Material selection was based on mechanical strength, durability, availability, and ease of fabrication while the engineering drawing provided the dimensional layout used for the design calculations. The overall machine height is 1673 mm, while the frame base dimensions are 730 mm by 914 mm; these dimensions were selected to provide structural stability during operation.

The hopper was designed with a top opening dimension of 580 mm by 956 mm and a vertical depth of 520 mm.; this configuration ensures sufficient feeding capacity while preventing plastic materials from spilling during operation. The machine frame was constructed using mild steel angle bars welded together to form a rigid structure. The shaft was machined using a lathe machine to obtain the required dimensions. Six rows of cutting blades were mounted on the shaft with a spacing of 58 mm between adjacent blades. This spacing allows continuous cutting of plastic materials during rotation. The hopper was fabricated using sheet metal and mounted above the shredding chamber to guide the plastic waste into the cutting region. the machine components were assembled in accordance with the engineering drawing.

The shaft was mounted within the shredding chamber and supported by bearings installed on both sides of the machine frame. The cutting blades were fixed along the shaft at a spacing of 58 mm, forming six rows of shredding elements. The gasoline engine was mounted on the lower frame section, approximately 870 mm below the shredding shaft. This configuration lowers the center of gravity of the machine and improves operational stability. Power transmission from the engine to the shredding shaft was achieved using a V-belt and pulley system. The discharge chute was positioned 197 mm above the ground level to allow easy collection of shredded plastic materials. The material selected are justified in the table and the figure 2 shows the exploded drawing.

2.1 Design Parameters

The following parameters were determined:

- *Machine throughput capacity*
- *Shredding efficiency*

Shredding efficiency was calculated using the expression:

$$S.E(\%) = \left(Weight\ of\ shredded \frac{output}{Weight} of\ plastic\ input\right) \times 100 \cdots\cdots\cdots equation\ (2.1)$$

2.2 Engineering Design Calculations Used

Engineering calculations were performed to determine the power transmission characteristics, shaft torque, and cutting force required for the shredding process.

2.2.1 Engine Power

The machine is powered by a gasoline engine rated at:

Engine power = 6.5 horsepower

Conversion to SI units:

Recall: $1hp = 746$

$therefore,$

$P = 6.5 \times 746$

$\boldsymbol{P = 4849W}$

$\boldsymbol{P \approx 4.85kw}$

2.3 Torque Transmitted by the Shaft

The torque transmitted by the shaft is determined using:

$P = \frac{(2\pi NT)}{60}$ ..... $equation\ (2.3)$

$Where$

$P = power\ (W)$

$N = rotational\ speed\ (rpm)$

$T = torque\ (Nm)$

Nota Bene: Small gasoline engines typically operate at 3600 rpm.

Substituting the values:

$4849 = \frac{(2\times3.142\times3600\times T)}{60}$

$$4849 = \frac{22622.4T}{60}$$

Multiplying both sides by 60:

$$290940 = 22622.4T$$

$$\boldsymbol{T = 12.86Nm}$$

Thus, the torque transmitted by the engine shaft is **12.86 Nm.**

2.4 Torque Multiplication through Pulley Ratio

Since the machine uses a speed reduction pulley system, torque increases at the shredding shaft.

If the pulley ratio is approximately 3:1 (large pulley on machine shaft), then

$$T2 = T1 \times Ratio \cdots\cdots\cdots\cdots\cdots\cdots\cdots equation\ (2.4)$$

$$T2 = 12.86 \times 3$$

$$\boldsymbol{T2 \approx 38.58Nm}$$

Thus, the shredding shaft receives approximately **38.6 Nm** of torque.

2.5. Blade Arrangement and Cutting Distribution

The machine uses 6 rows of cutting blades spaced 58 mm apart along the shaft.

Total shredding width = 580 mm

Number of blade rows = 6

Average cutting spacing ensures that plastic materials are continuously engaged during rotation, improving shredding efficiency.

2.6 Hopper Volume and Feeding Capacity

Hopper dimensions:

Length = 956 mm = 0.956 m

Width = 580 mm = 0.58 m

Depth = 520 mm = 0.52 m

Hopper volume:

$$V = L \times W \times H \cdots\cdots\cdots\cdots\cdots\cdots\ equation\ 2.6$$

$$V = 0.956 \times 0.58 \times 0.52$$

$$V \approx\ 0.288\text{m}^3$$

Thus, the hopper can accommodate approximately 0.29 cubic meters of plastic material before shredding.

3. RESULTS AND DISCUSSION

An internal testing was conducted to ascertain the performance of the fabricated plastic shredder using plastic waste materials of known weight. During the test, plastic materials were fed into the hopper while the machine was operating, and the shredding time was recorded. After the shredding process, the shredded plastic particles were collected and weighed. Three experimental tests were conducted in order to obtain reliable results and this performance evaluation is based on internal testing of the fabricated plastic wastes shredding machine only. The results obtained from shredding PET, HDPE, and polypropylene wastes are presented in Table 2.

Table 2: Performance Test Results

Test Number	**Plastic Input (kg)**	**Shredded Output (kg)**	**Shredding Time (s)**	**Efficiency (%)**
1	5.40	4.92	52	91.11
2	5.30	4.85	50	91.51
3	5.41	4.93	53	91.13
Average	**5.37**	**4.90**	**51.67**	**91.25**

As shown in table 2, the average plastic input used during the experiment was 5.37 kg, while the average shredded output obtained was 4.9 kg. The average shredding time recorded was 51.67 seconds. From table 2, throughput capacity of the machine was calculated as:

$$Capacity = \frac{Mass}{Time}$$

$$Capacity = \frac{5.37}{51.67} = \textbf{0.104kg/s}$$

Converting to kg/hr,

$$0.104 \times 3600 = \mathbf{374kg/hr}$$

The shredding efficiency was calculated as:

Shredding efficiency is calculated as:

$$Efficiency(\%) = \left(\frac{Output}{Input}\right) \times 100$$

$$Efficiency = \left(\frac{4.9}{5.37}\right) \times 100$$

$$\boldsymbol{Efficiency \approx 91.25\%}$$

The high shredding efficiency obtained in this study is consistent with the findings of *Raji et al. (2020),* who reported shredding efficiencies above 91.3 percent in their design and development of a plastic waste shredding machine. Their study showed that properly designed blade arrangements and adequate torque transmission significantly improve the efficiency of plastic shredding machines. The results obtained from this study demonstrate that the plastic shredding machine successfully achieved the objectives of the research and addressed the problem of plastic waste size reduction. The design results confirm that a functional plastic shredding machine can be developed using standard mechanical engineering design principles. The arrangement of cutting blades on the rotating shaft produced the necessary shearing force required to reduce plastic materials into smaller particles. This observation agrees with the findings of Groover (2010), who explained that size reduction processes are essential in recycling operations because they improve material handling and processing efficiency. The fabrication results also indicate that the machine can be constructed using locally available materials and conventional workshop tools, which significantly reduces production cost. This supports the argument of *Al-Salem et al. (2009)* that improving recycling technologies at the local level is essential for effective plastic waste management in developing countries. The performance evaluation further showed that the machine achieved an efficiency of 91.25 percent, which indicates effective shredding of plastic materials. This result is comparable with similar studies conducted by *Raji et al. (2020)* and *Surgude et al. (2023),* who also reported 91.3% high shredding efficiencies in locally fabricated plastic shredding machines. In addition, the throughput capacity of approximately 374 kg per hour demonstrates that the machine can process a significant amount of plastic waste within a relatively short time. This capacity makes the machine suitable for small and medium-scale recycling operations, educational institutions, and community-based waste management initiatives. The use of a gasoline engine as the power source also provides an advantage in environments where electricity supply is unreliable. This feature improves the adaptability of the machine in rural and urban areas where power infrastructure is limited. Overall, the results confirm that the developed plastic shredding machine provides a practical, affordable, and efficient solution for plastic waste size reduction, thereby supporting recycling activities and contributing to improved environmental sustainability.

4. CONCLUSION

1. *Conclusively,* this research successfully achieved the development of a plastic waste shredding machine designed and fabricated using locally available materials and standard mechanical engineering principles**.** The study was motivated by the growing challenge of plastic waste accumulation and the limited availability of affordable recycling equipment, particularly in developing countries such as Nigeria. Overall, the results of this study confirm that the developed plastic shredding machine provides a practical, cost-effective, and sustainable solution for improving plastic waste management and supporting recycling activities**.** The machine can contribute to environmental protection, resource recovery, and the development of local recycling

industries however, the study is limited to the shredding of plastic waste materials only and does not include the complete recycling process such as melting, extrusion, or remanufacturing of plastic products hence further research can investigate the use of improved blade materials or heat treatment processes to increase blade durability and reduce wear during continuous operation.

ABSTRACT

This study addresses frequency instability and tie-line deviations in interconnected multi-area power systems caused by sudden load perturbations and physical non-linearities such as governor dead band (GDB). To overcome the slow transient recovery and lingering oscillations of conventional particle swarm optimization (PSO) and genetic algorithm (GA) tuned PID controllers, this research implements the Arithmetic Optimization Algorithm (AOA) for optimal decentralized Load Frequency Control (LFC) tuning. A two-area power network incorporating GDB dynamics was modeled in MATLAB/Simulink and subjected to step load perturbations (SLP) of 0.2 p.u.in Area 1 and 0.15 p.u. in Area 2 occurring at t = 0 s, utilizing the Integral Time Absolute Error (ITAE) index as the fitness criterion. The proposed AOA-PID controller significantly outpaced traditional methods, achieving a transient settling time of 5.22 s for Area 1 frequency deviation (a 43.68% recovery improvement over PSO) and restricting peak undershoot to -0.0016 Hz (a 82.61% improvement compared to -0.0092 Hz for PSO). Furthermore, the AOA yielded an optimal fitness value of 0.04245, nearly seven times lower than PSO (0.2831) and GA (0.4120). Ultimately, the AOA-PID scheme delivers a robust, highly efficient solution that ensures superior transient stability and rapid equilibrium restoration in interconnected grids.

Keywords: *Arithmetic Optimization Algorithm; Load Frequency Control; Multi-area Power System; PID Controller; Tie-line Power; Governor Dead Band*

1. INTRODUCTION

Maintaining a continuous balance between electricity generation and dynamic load demand is critical to the operational reliability of modern power systems, yet it remains a substantial challenge due to volatile load variations and the intermittent nature of renewable energy sources (Kothari & Nagrath, 2003; Kunya et al., 2017). In large-scale networks, this operational environment is managed by structuring the grid into a multi-area interconnected power system (MAIPS), where distinct control areas (CAs) are linked via tie-lines or high-voltage direct current (HVDC) connections (Muthana et al., 2011). Because localized load fluctuations propagate across area boundaries and impact neighboring regions, Load Frequency Control (LFC) is essential (Isemin & Onah, 2022). LFC systems fulfill the dual purpose of keeping frequency within strict, pre-designed operational limits and regulating tie-line power exchanges to prevent generator desynchronization and cascading system collapse (Pappachen & Peer Fathima, 2017; Charalampos et al., 2019; Shouran et al., 2021).

Designing effective LFC mechanisms is increasingly complex due to modern factors like market deregulation, decentralized control, and physical non-linearities. A particularly severe physical constraint is the governor dead band (GDB), which represents a strict range of frequency variations where the turbine governor remains unresponsive (Rathnayake et al., 2019). GDB introduces major reaction delays following load adjustments, causing severe overshoots/undershoots and degrading power quality (Alnefaie et al., 2025). To neutralize the adverse effects of GDB, soft-computing and metaheuristic optimization algorithms—such as Bacterial Foraging (Ali & Abdlazim, 2013), Particle Swarm Optimization (PSO), and Genetic Algorithms (GA)—have been utilized to tune controller gains. While these methods improve upon classical Ziegler-Nichols tuning (Ogata, 2011), they often suffer

from premature convergence, high computational burdens, and slow transient damping (Sambariya & Prasad, 2016).

To bridge this gap and optimize power system transient response under GDB non-linearities, this study proposes a decentralized PID control scheme for a two-area interconnected power system tuned via the population-based Arithmetic Optimization Algorithm (AOA). The optimal gain parameters are dynamically computed under operational limits and rate constraints, providing a streamlined and highly effective solution for frequency and tie-line power stabilization.

2. SYSTEM MODELING AND NON-LINEAR DYNAMICS

2.1 LOAD FREQUENCY CONTROL IN MAIPS

In a two-area interconnected power system, separate control areas are linked via tie-lines to maintain mutual power exchanges during disturbances (Wadi et al., 2024; Sun, 2018). The dynamic secondary LFC loop processes the Area Control Error (ACE), which combines local frequency error (Δf) and tie-line power loading deviation ($\Delta P_{tie,\,i}$) and is given as in (1).

$$ACE = \Delta P_{tie} - \beta \Delta F \tag{1}$$

$$\text{Where: } \Delta Pi_{tie} = \sum_{i=1}^{n} Pi_{tie} - Pi_{tie\ initial} \tag{2}$$

Where β is the bias parameter, which reflects the contribution of the operating members in the power pool expressed in MW/Hz.

2.2 GENERATOR, LOAD, AND TIE-LINE DYNAMICS

The rotational dynamics of synchronous generation and load damping in Control Area *i* are modeled using the linear swing equation transfer function as in (3).

$$M_{eq} \frac{d\Delta f_i}{dt} = \sum_{l=1}^{n} \Delta P_{Tli} - \Delta P_{tie,i} - \Delta P_{Di} - D_{eq} \Delta f_i \tag{3}$$

Where: M_{eq} is the equivalent generator inertia constant, D_{eq} is the equivalent load-damping factor, ΔP_{Tli} is turbine power output, $\Delta P_{tie,i}$ is net tie-line power flow, and ΔP_{Di} represents the non-frequency sensitive load variations.

The speed governor and thermal turbine transfer functions are expressed as in (4 and 5).

$$G_{g,i}(s) = \frac{1}{T_{g,i}s + 1} \tag{4}$$

$$T_{t,i}(s) = \frac{1}{T_{t,i}s + 1} \tag{5}$$

where T_g: Governor time constant, $T_t s$: Turbine/engine time constant

The active power transfer variation along the tie-line connecting Area 1 and Area 2 is governed by (6).

$$\Delta P_{Tij} = T_s\left(\Delta\omega_i - \Delta\omega_j\right) \tag{6}$$

To evaluate control area deviations, the ACE incorporates both local frequency and tie-line variations as in (7).

$$ACE_i = \beta_i \Delta f_i + \Delta T_{ij} \tag{7}$$

where β_i represents the frequency bias coefficient defined by governor speed regulation (R_i) and damping factor (D_i) as (8).

$$\beta_i = \frac{1}{R_i} + D_i \tag{8}$$

2.3 MODELING OF GOVERNOR DEAD BAND (GDB) NON-LINEARITY

The governor dead band introduces significant non-linearity by delaying governor valve adjustments until frequency deviation exceeds a threshold. Rather than using simple linear approximations, the GDB is represented mathematically via its describing function as given in (9).

$$N(A) = N_r + jN_i \tag{9}$$

The non-linear components are separated and treated mathematically using (10).

$$N_r = \frac{k}{\pi}\left[\frac{\pi}{2} + arcsin\left(1 - \frac{2D}{A}\right) + 2\left(1 - \frac{2D}{A}\right)\sqrt{\frac{D}{A}\left(1 - \frac{D}{A}\right)}\right], N_i = \frac{-4k}{\pi}\frac{D}{A}\left(1 - \frac{D}{A}\right), (D \geq A) \tag{10}$$

The Simulink schematic of the two-area network is shown in Figure 1.

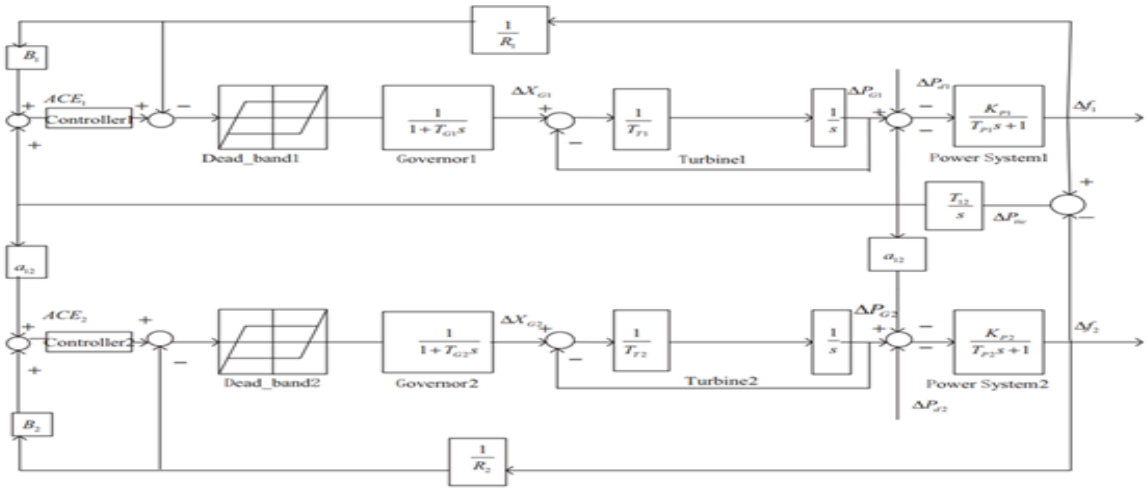

Figure 1: Transfer Function Model of the Investigated Two-area Power System.

3. OPTIMIZATION METHODOLOGY AND ALGORITHM

3.1 ARITHMETIC OPTIMIZATION ALGORITHM (AOA)

The Arithmetic Optimization Algorithm (AOA) is a population-based metaheuristic developed by

(Abualigah et al. 2021) inspired by elementary arithmetic operations: Division (div), Multiplication (times), Subtraction (-), and Addition (+). AOA uses the Math Optimizer Accelerated (MOA) function to transition between global exploration and local exploitation.

Arithmetic Optimization Algorithm (AOA) is employed to determine optimal PID gains by iteratively improving candidate solutions.

Step 1: Initialization

A population of candidate solutions is randomly generated using (12)

$$X_i = \left[K_{p1}, K_{i1}, K_{d1}, K_{p2}, K_{i2}, K_{d2}\right] \tag{12}$$

Step 2: Control Parameters

Math Optimizer Accelerated (MOA) is obtained using (13).

$$MOA(t) = MOA_{min} + \frac{t}{T}(MOA_{max} - MOA_{min}) \tag{13}$$

Math Optimizer Probability (MOP)

Controls step size is expressed as in (14):

$$MOP(t) = 1 - \left(\frac{t}{T}\right)^{1/\alpha} \tag{14}$$

Step 3: Exploration Phase (Global Search)

Used in early iterations to search widely.

Condition as expressed in (15)

$$\text{When } r_1 > MOA \tag{15}$$

Then equation (division operator 16 and multiplication operator 17) is used.

$$X_i^{t+1} = \frac{X_{best}}{MOP+\in} \times \left((ub - lb)r_2 + lb\right) \tag{16}$$

$$X_i^{t+1} = X_{best} \times MOP \times \left((ub - lb)r_2 + lb\right) \tag{17}$$

Step 4: Exploitation Phase (Local Search)
Used in later iterations to refine best solution.
Condition:

$$\text{When } r_1 \leq MOA \tag{18}$$

To achieve exploitation under this condition equation (19 (subtraction) and 20 (addition)) are used.

$$X_i^{t+1} = X_{best} - MOP \times \left((ub - lb)r_3 + lb\right) \tag{19}$$

$$X_i^{t+1} = X_{best} + MOP \times \left((ub - lb)r_2 + lb\right) \tag{20}$$

Where: X_{it} is current solution (PID gains vector), X_{best} is best solution found so far, t is current iteration, T: maximum iterations, r_1, r_2, r_3 are Random numbers in (0,1), ϵ is Small number (to avoid division by zero), α is constant usually 5.

Table 1: Parameters associated with AOA

Parameter	Value
State dimension of the input layer	9
Action dimension of the output layer	3
Reward discount factor	0.995
Minimum batch size	128
Maximum steps per episode	500
Maximum episode	500
Agent sample time	0.02 s
Experience replay buffer	1×10^6
Target smooth factor	1×10^{-3}

Continue steps 2–4 for many episodes until the policy converges or reaches a desired performance level. Table 2 shows the simulation parameters. These parameters were adopted from the work of Qu et al., (2024).

The flowchart of the implementation of AOA is shown in Figure 2.

3.2 DECENTRALIZED PID CONTROLLER OPTIMIZATION

Decentralized PID controllers are deployed in each control area. The time-domain output is expressed as in (21).

$$u(t) = K_p e_p(t) + K_i \int_0^1 e_p(t)dt + K_d \frac{de_p(t)}{dt} \tag{21}$$

where, Kp, Ki, Kd correspondingly indicate the proportional constant, integral constant, and derivative constant.

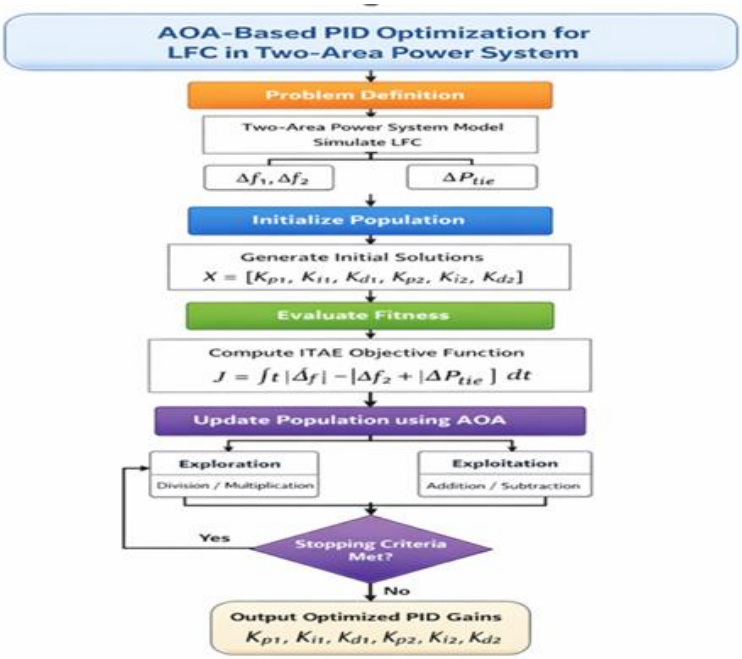

Figure 2: Flowchart of AOA-Based PID Optimization for LFC in Two-Area Power System

$$u(t) = K_p e_p(t) + K_i \int_0^1 e_p(t)dt + K_d \frac{de_p(t)}{dt} \tag{21}$$

where, Kp, Ki, Kd correspondingly indicate the proportional constant, integral constant, and derivative constant.

The optimization will be based on the Integral Square Error (ITAE) criteria as shown in equation (22). min (J_{ITAE}) such that

$$J_{ITAE} = \int_{t=0}^{t_{sim}} t(|\Delta F_1| + |\Delta F_2| + |\Delta P_{tie}|)dt \quad \text{for I = 1, 2} \tag{22}$$

It will be carried out subject to the following constraints:

i. Load-generation balance as equality constraint as expressed in equation (23)

$$\sum P_{Gi} = \sum P_{Di} + P_i^{tie}(t) \tag{23}$$

ii. Frequency band: the frequency is constrained within the certain upper and lower band as;

$$f_i^{min} \le f_i \le f_i^{max} \tag{24}$$

iii. Controller gains constraints: the controller proportional, integral, and derivate gains are constrained with some upper and lower limits as shown in (25);

$$K_{pi}^{min} \le K_{pi} \le K_{Pi}^{max}, K_{Ii}^{min} \le K_{Ii} \le K_{Ii}^{max}, \; K_{Di}^{min} \le K_{Di} \le K_{Di}^{max} \tag{25}$$

4. RESULTS AND DISCUSSION

The system was simulated under step load perturbations of (0.2 p. u. in area and 0.15 p. u. in area 2 at t=0 s), the resulting oscillations exhibited an exponential-sinusoidal decay, as shown in Figures 3–5. Figure 3 shows frequency deviation of area 1 when subjected to SLP of 0.2 p. u.

The Arithmetic Optimization Algorithm (AOA) outperforms GA and PSO in Area 1 frequency deviation control following a load perturbation. AOA minimizes the maximum frequency drop to -5.4×10^{-3} Hz, compared to GA (-8.7×10^{-3} Hz) and PSO (-9.1×10^{-3} Hz). By eliminating secondary oscillations, AOA achieves steady-state equilibrium in 4–5 seconds versus 8–10 seconds for GA and PSO, demonstrating superior grid stability.

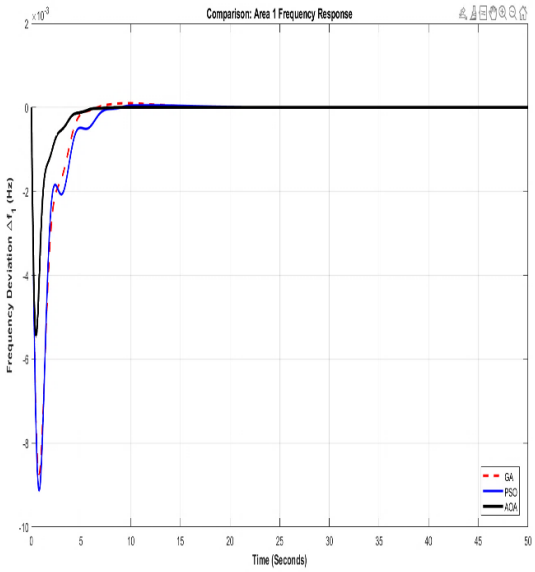

Figure 3: Variation of Area-1 Frequency Due to ΔPL

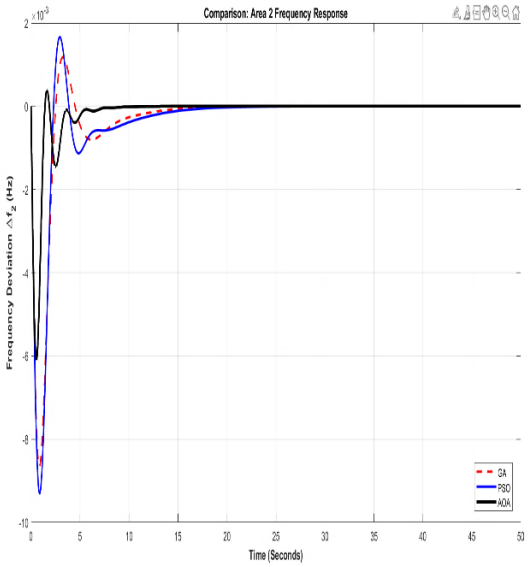

Figure 4: Variation of Area-2 Frequency Due to ΔPL

Figure 4 shows frequency deviation of area 2 when subjected to SLP of 0.15 p. u.

From Figure 4, the dynamic performance analysis of Area 2 frequency deviation (Δf_2) shows AOA outperforming GA and PSO. Following a disturbance, AOA limits peak undershoot to -6.1×10^{-3} Hz versus GA (-8.6×10^{-3} Hz) and PSO (-9.3×10^{-3} Hz). By suppressing overshoots and dampening oscillations, AOA restores equilibrium in 6–7 seconds, compared to 15–18 seconds for GA and PSO.

Figure 5 shows the tie-line variation as a result of change in load in area-1 and area-2.

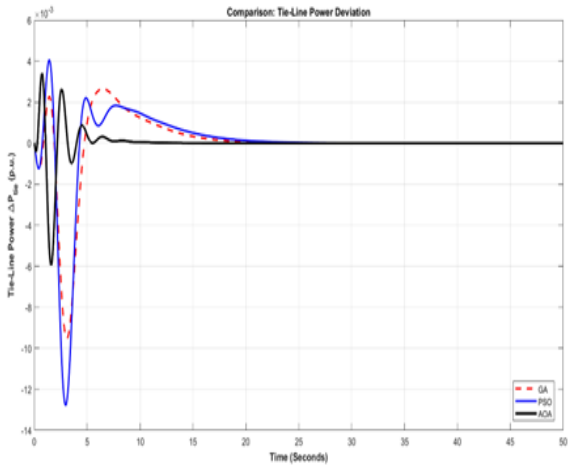

Figure 5: Change in Tie-Line Power due to Load Variation in Area-1 and 2

Table 2: Simulation parameters

		Control Area	
component	**Parameters**	**1**	**2**
Generator	Tg (sec)	0.08	0.08
	Tt (sec)	0.3	0.3
	R (Hz/pu)	2.4	2.4
Power System	Kp (Hz/pu)	120	120
	β_i	0.425	0.425
	T12	0.545	0.545

From Figure 5, the tie-line power deviation response shows AOA outperforming GA and PSO. AOA restricts the peak undershoot to (-6.0×10^{-3} p.u.), significantly improving upon GA (-9.5×10^{-3} p.u.) and PSO (-12.8×10^{-3} p.u.). Furthermore, AOA rapidly dampens inter-area oscillations, restoring steady-state equilibrium in roughly 8.20 seconds compared to over 22.5 and 24.0 seconds for GA and PSO respectively. Comprehensive dynamic performance comparison is shown in Table 3.

5. CONCLUSION

This study presented an optimal decentralized Load Frequency Control (LFC) strategy utilizing the Arithmetic Optimization Algorithm (AOA) to tune PID controllers for an interconnected two-area power system with governor dead band (GDB) non-linearities. Simulation results show that the AOA framework achieved an over 43.68% reduction in settling times and up to an 82.69% improvement in maximum transient undershoot. Concurrently, tie-line power stability was restored up to 79% faster with an ITAE score nearly seven times lower than PSO, validating its robust grid reliability and precise load balancing.

Table 3: Comprehensive Dynamic Performance Comparison

Metric	**GA-PID**	**PSO-PID**	**AOA-PID**	**Improvement (%)**
Area 1 Peak Drop (Hz)	-0.0087	-0.0092	-0.0016	82.61
Area 1 Settling Time (s)	9.79	9.27	5.22	43.68
Area 2 Peak Drop (Hz)	-0.0088	-0.0093	-0.0060	35.48
Area 2 Settling Time (s)	15.10	14.48	9.14	36.88
Tie-Line Settling Time (s)	34.80	39.15	8.20	79.06
ITAE Fitness Score	0.4120	0.2831	0.04245	85.00

ABSTRACT

This study investigated the effect of municipal solid waste (MSW) leachate on the plasticity characteristics of a clay soil from Bauchi, Nigeria. Clay specimens were exposed to leachates collected from four municipal dumpsites and cured for 7, 14, 21, 28, and 35 days before determination of liquid limit, plastic limit, shrinkage limit, and plasticity index. The natural soil was classified as CL under the Unified Soil Classification System and A-6(11) under AASHTO, with a liquid limit of 32%, plastic limit of 14%, plasticity index of 18%, shrinkage limit of 12%, and free swell of 45%. Leachate exposure produced clear time-dependent changes in consistency. The liquid limit increased progressively to 37.5-39.5% after 35 days, while the plastic limit increased monotonically to 22-24% over the same period. Because the plastic limit increased more rapidly than the liquid limit, the plasticity index generally decreased to 15-16.5% by 35 days. The shrinkage limit decreased sharply during the first 7 days to 8.0-9.0% and then partially recovered to 10.5-11.0% by 35 days, remaining below the uncontaminated value. These trends show that MSW leachate alters the soil-water interaction and consistency range of the tested clay, with the magnitude of change depending on leachate chemistry and exposure period. The findings demonstrate the need to account for soil-leachate compatibility when this Bauchi clay or comparable fine-grained soils are considered beneath dumpsites or for waste-containment applications.

Keywords: *municipal solid waste; leachate; clay soil; plasticity; curing period*

1.0 INTRODUCTION

Municipal solid waste (MSW) leachate is the aqueous phase generated when infiltrating water and the moisture released during waste decomposition percolate through a waste mass and dissolve or mobilize soluble constituents. Its composition is highly variable, but commonly includes dissolved organic matter, inorganic macro-components, heavy metals, ammoniacal nitrogen, and a wide range of xenobiotic organic compounds (Kjeldsen et al., 2002; Christensen et al., 2001; Renou et al., 2008). Because leachate chemistry evolves with waste composition, landfill age, climatic conditions, and degree of stabilization, the pore fluid reaching the underlying soil can vary considerably in pH, ionic strength, organic loading, and cation composition.

The environmental significance of leachate is particularly important where waste is deposited in open or poorly engineered dumps without effective liner and leachate-collection systems. Studies in Nigeria have documented leachate migration and associated changes in groundwater and soil chemistry around municipal waste disposal sites, including locations in Bauchi and other urban areas (Aromolaran et al., 2023; Lagasi et al., 2023; Tijjani et al., 2023). A directly related study by Chinade et al. (2017), conducted on compacted tropical soil from the Bauchi environment, found that unconfined compressive strength generally decreased as MSW-leachate permeation time increased. In that study, the commonly cited minimum UCS criterion of 200 kN/m² for waste-containment materials was maintained only up to about 42 days under British Standard Heavy compaction and 21 days under West African Standard compaction. Those strength losses provide an important companion context for the present work:

changes in Atterberg limits and consistency should not be interpreted in isolation, because leachate-induced physicochemical alteration can occur together with deterioration in mechanical performance.

Fine-grained soils are especially sensitive to pore-fluid chemistry because their engineering behaviour is governed not only by particle size and stress state but also by mineral surface charge, cation exchange, diffuse-double-layer interactions, and soil fabric. Changes in electrolyte concentration, cation valence, pH, and pore-fluid permittivity can therefore alter particle association, water adsorption, volume change, strength, and compressibility (Mitchell & Soga, 2005; Di Maio, 1996; Di Maio et al., 2004; Jang et al., 2018). Recent work has also emphasized that the liquid and plastic limits of clays reflect physicochemical interactions at particle surfaces and are consequently sensitive to changes in pore-fluid composition (Hasan & Abuel-Naga, 2024).

The interaction between landfill leachate and natural or engineered clay barriers has been investigated in several geotechnical studies. Leachate exposure has been associated with changes in index properties, microstructure, compressibility, shear strength, hydraulic conductivity, and mineralogical composition, although the direction and magnitude of the response depend strongly on clay mineralogy and leachate chemistry (Frempong & Yanful, 2008; Oztoprak & Pisirici, 2011; Emami et al., 2019; Ouria & Farsijani, 2019; Bahaa et al., 2024; Priya & Thyagaraj, 2025). Observations from tropical soils also indicate that cation exchange, mineral transformations, and changes in soil fabric may occur during leachate permeation (Osinubi & Nwaiwu, 2010).

Atterberg limits provide a practical means of evaluating these changes because the liquid limit, plastic limit, and plasticity index are related to clay mineralogy, water adsorption, workability, swelling potential, compressibility, and the strength state of fine-grained soils. The mechanisms controlling liquid limit are influenced by both particle-level frictional resistance and physicochemical forces (Sridharan & Prakash, 2000), while experimental studies with saline pore fluids show that the response may increase or decrease depending on mineralogy, electrolyte concentration, and cation type (Spagnoli & Sridharan, 2012; Curtin et al., 1994). Chemical compatibility is therefore a critical consideration where clay is used as a natural foundation or as a landfill barrier, because long-term exposure to aggressive pore fluids may alter both index and transport properties (Jo et al., 2005; Katsumi et al., 2001; Bowders et al., 1985).

Accordingly, the present study evaluates the effect of municipal solid waste leachate from four dumpsites in Bauchi metropolis on the liquid limit, plastic limit, plasticity index, and shrinkage limit of a locally occurring clay soil over curing periods of up to 35 days.

2.0 MATERIALS AND METHODS

2.1 Materials

2.1.1 Soil:

The soil used in the study was a naturally occurring clayey soil obtained in Bauchi Local Government Area, Bauchi State, Nigeria (approximately 10°18′N, 9°49′E). The sample was collected as a disturbed specimen at a depth of 1 m below the natural ground level.

2.1.2 Municipal Solid Waste Leachate

The municipal solid waste leachate used for the study was collected from four (4) different dumpsites situated in Bauchi metropolis named (A, B, C, and D) respectively. The chemical characteristic of the leachate samples was determined at the Public Health Engineering Laboratory of Abubakar Tafawa Balewa University, Bauchi Nigeria.

2.1.3 Water

The water used is a potable drinking water which was sourced from the soil laboratory Tap.

2.2 Methods

The following laboratory test were conducted

Natural moisture content

Particle size distribution

Specific gravity
Free swell
Atterberg limits

a) Liquid limit
b) Plastic limit
c) Shrinkage limit

2.2.1 Natural Moisture Content

The natural moisture content test was conducted by the oven-drying method in accordance with BS 1377-2 (British Standards Institution, 1990). The moisture content of the soil specimen was calculated as a percentage of the dry mass of soil to the nearest 0.1%, using Equation (i).

$$w = [(M_2 - M_3)/(M_3 - M_1)] \times 100 \quad \text{(i)}$$

Where:
w = moisture content
M_1 = Mass of empty container (g)
M_2 = Mass of container + wet soil (g)
M_3 = Mass of container + dry soil (g)

2.2.2 Determination of Particle Size Distribution

Particle-size distribution of the natural soil was determined using mechanical sieve analysis and hydrometer sedimentation procedures in accordance with BS 1377-2 (British Standards Institution, 1990) and the laboratory procedures described by Head (1992).

2.2.3 Determination of Specific Gravity

The specific gravity of the soil solids was determined using the density-bottle method in accordance with BS 1377-2 (British Standards Institution, 1990). Specific gravity was calculated using Equation (ii).

$$G_s = (W_2 - W_1)/[(W_4 - W_1) - (W_3 - W_2)] \quad \text{(ii)}$$

Where:
G_s = Specific gravity
W_1 = Mass of density bottle + stopper (g)
W_2 = Mass of density bottle, soil and stopper (g)
W_3 = Mass of density bottle, stopper, water and soil (g)
W_4 = Mass of density bottle, stopper and water only (g)

2.2.4 Determination of Free Swell

The free swell index was determined on soil passing the 425-µm sieve using distilled water and kerosene, following the free-swell-index procedure in IS 2720 (Part 40) (Bureau of Indian Standards, 1977). The free swell index was calculated using Equation (iii).

$$S.I = [(Vw - Vk)/Vk] \times 100 \quad \text{(iii)}$$

Where:
S.I = Free swell index (%)
Vw = Volume of soil in water (mL)
Vk = Volume of soil in kerosene (mL)

2.2.5 Atterberg Limits Determination

The consistency characteristics of the soil - liquid limit (LL), plastic limit (PL), and shrinkage limit - were determined in accordance with BS 1377-2 (British Standards Institution, 1990). Tests were performed using distilled water for the uncontaminated soil and MSW leachate as the pore fluid for the contaminated specimens.

2.2.5.1 Determination of Liquid Limit and plastic limit

The soil specimen for liquid-limit determination was air-dried and gently broken down using a pestle and mortar. A 200 g portion passing the 425-µm sieve was thoroughly mixed with water until a homogeneous paste was obtained. The paste was sealed in an airtight cellophane bag for 24 h to allow

moisture equilibration before testing. A penetration-versus-moisture-content relationship was established, and the liquid limit was taken as the moisture content corresponding to 20 mm cone penetration.

The same procedure was followed using municipal solid waste (MSW) leachate instead of distilled water. Five 200 g specimens were mixed with the respective leachate and cured for 7, 14, 21, 28, and 35 days before liquid-limit testing.

Plastic-limit tests were similarly conducted using distilled water for the uncontaminated soil and MSW leachate for the contaminated specimens.

The experimental records available for this study did not include replicate Atterberg-limit determinations or standard deviations for each leachate-curing combination. Consequently, the values reported in Figures 2-5 are treated as descriptive measurements of the observed trends, and no claim of statistical significance is made. This absence of replicate variability data is a limitation of the study and should be addressed in future work through duplicate or triplicate determinations with error estimates.

2.2.5.2 Determination of Plasticity Index

The plasticity index was calculated from the measured liquid and plastic limits using Equation (iv).

$$I_p = W_l - W_p \quad \text{(iv)}$$

Where:

I_p = Plasticity index (%)

W_l = Liquid limit (%)

W_p = Plastic limit (%)

2.2.5.3 Determination of Shrinkage Limit

The shrinkage response was determined in accordance with the adopted BS 1377-2 procedure, using distilled water and MSW leachate as the wetting fluids. Percentage shrinkage was calculated from specimen lengths before and after drying using Equation (v).

$$S = (1 - L_1/L_o) \times 100 \quad \text{(v)}$$

Where:

L_1 = Length after drying

L_o = Length before drying

Distilled water and MSW leachate were used as the wetting fluids in the respective tests.

3.0 RESULTS AND DISCUSSION

3.1 Physical properties of the soil

The natural soil contained 89% material passing the No. 200 sieve, with a liquid limit of 32%, plastic limit of 14%, plasticity index of 18%, shrinkage limit of 12%, and free swell of 45%. On the basis of these properties, the soil was classified as CL (low-plasticity clay) under ASTM D2487-11 and A-6(11) under AASHTO M 145-2012. The high fines content confirms that the behaviour of the soil is strongly controlled by the clay-silt fraction rather than by coarse-grained particle contacts. Although the liquid limit places the soil in the low-plasticity range, the free swell value of 45% is comparatively high for a CL soil and indicates a measurable tendency for volume increase on wetting. Free-swell response is influenced by clay-mineral type, exchangeable cations, soil fabric, and the contrast between water and the non-polar reference fluid; therefore it does not necessarily vary in direct proportion to liquid limit alone. A small proportion of more expansive clay minerals or fabric-related effects could contribute to the measured value, but mineralogical analysis and cation-exchange-capacity testing were not performed in this study, so the specific cause cannot be confirmed. The PI of 18% and the measured free swell nevertheless indicate appreciable moisture sensitivity, making the soil a useful medium for examining the effect of changing pore-fluid chemistry (Mitchell & Soga, 2005; Jang et al., 2018; Hasan & Abuel-Naga, 2024).

Table 1: Physical properties of the natural soil

Soil properties	Value
Natural moisture content (%)	26.9
Specific gravity	2.58
% passing sieve No. 200	89
USCS	CL
AASHTO classification	A-6 (11)
Liquid limit (%)	32
Plastic limit (%)	14
Plasticity index (%)	18
Shrinkage limit (%)	12
Free swell (%)	45

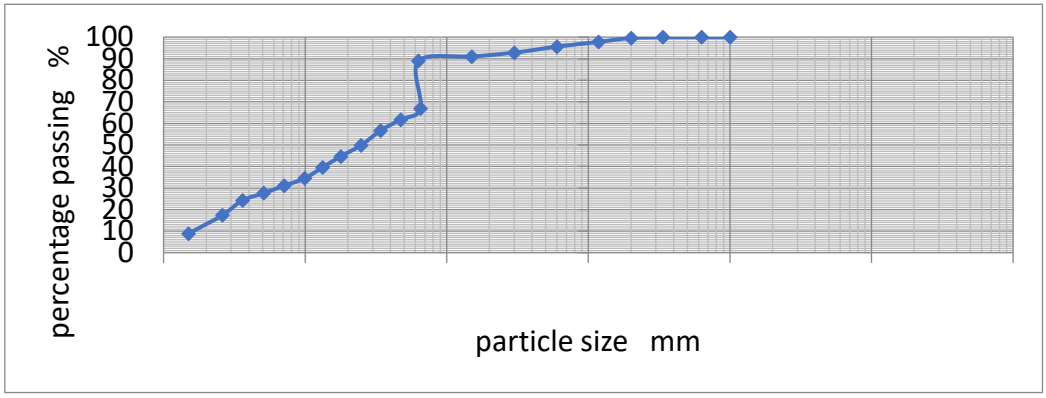

Figure 1: Particle Size Distribution of the Natural Soil

3.2 Physical and Chemical and Biological Properties of MSW Leachate

The physical, chemical, and biological characteristics of the four MSW leachate samples are presented in Table 2. The leachates were alkaline, with pH values of 8.1-10.3, and had relatively high dissolved-solids concentrations (TDS = 1,128-1,781 mg/L) and electrical conductivity (1,540-2,360 µS/cm), indicating substantial ionic content. COD ranged from 1,324 to 2,837 mg/L, while BOD5 ranged from 330 to 556 mg/L. The corresponding BOD5/COD ratios were approximately 0.25, 0.17, 0.19, and 0.20 for leachates A-D, respectively. These low ratios, together with the alkaline pH, are consistent with relatively stabilized or methanogenic leachates in which a significant fraction of the organic matter is less readily biodegradable (Kjeldsen et al., 2002; Renou et al., 2008).

Table 2: Physical, chemical and biological properties of the leachate samples.

Property	Dumpsite Location			
	A	B	C	D

Potassium, (K)	400	500	500	600
Cadmium, (Cd)	0.003	0.014	0.0	0.005
Chromium, (Cr)	0.044	0.068	0.047	0.028
Zinc, (Zn)	0.56	0.04	0.54	0.24
Lead (Pb)	0.97	0.77	1.05	0.85

The leachates also contained substantial concentrations of major cations, particularly Na (240-720 mg/L), K (400-600 mg/L), and Ca (54.4-438 mg/L), together with measurable Fe, Mn, Cd, Cr, Zn, and Pb. These constituents are geotechnically relevant because cation type and ionic strength influence clay surface charge, cation exchange, diffuse-double-layer thickness, and particle aggregation. Monovalent sodium can favour dispersion under some chemical conditions, whereas divalent cations such as calcium may promote flocculation and reduce swelling; in mixed leachate systems, competing ions and organic matter can produce complex net effects (Curtin et al., 1994; Jo et al., 2005; Mitchell & Soga, 2005). The values measured in this study are also consistent with the broad chemical variability reported for landfill leachates and with evidence of dumpsite-related contamination in Nigeria (Christensen et al., 2001; Aromolaran et al., 2023; Lagasi et al., 2023; Tijjani et al., 2023).

3.3 Effect of leachate on liquid limit, plastic limit, shrinkage limit and plasticity index

Figures 2-5 show that the response of the clay to leachate was time-dependent and that the four leachates produced broadly similar trends, although with different magnitudes. The observed changes reflect the combined influence of dissolved salts, monovalent and divalent cations, organic constituents, and pH on clay-water interactions. Because these chemical effects may promote either dispersion or flocculation depending on mineralogy and pore-fluid composition, changes in consistency limits are

not expected to follow a single universal direction (Di Maio, 1996; Oztoprak & Pisirici, 2011; Jang et al., 2018).

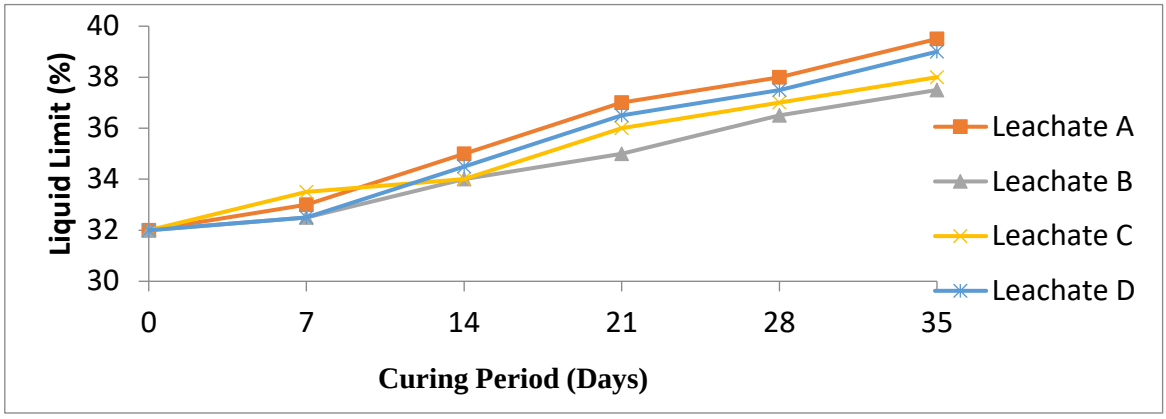

Figure 2: Variation of liquid limit with curing period

Liquid limit increased progressively with exposure time for all four leachates. From an uncontaminated value of 32%, the 35-day values reached 39.5%, 37.5%, 38.0%, and 39.0% for leachates A, B, C, and D, representing increases of approximately 17-23%. The increase indicates that a greater water content was required for the contaminated clay to reach the liquid state. This behaviour is consistent with a time-dependent alteration of the clay fabric and surface-water interaction rather than a simple dilution effect. Landfill leachate can induce cation exchange, dissolution/precipitation reactions, and mineral or fabric transformations in clay soils (Frempong & Yanful, 2008; Oztoprak & Pisirici, 2011). Although concentrated electrolytes often compress the diffuse double layer and can reduce the liquid limit of highly active clays, mixed leachates contain multiple ions and organic constituents, so the net response can be an increase, decrease, or limited change depending on clay mineralogy and exposure conditions (Di Maio et al., 2004; Spagnoli & Sridharan, 2012; Hasan & Abuel-Naga, 2024). The progressive increase observed here therefore suggests that, for this low-plasticity Bauchi clay, the leachate-induced changes increased the amount of pore fluid associated with the transition to liquid behavior.

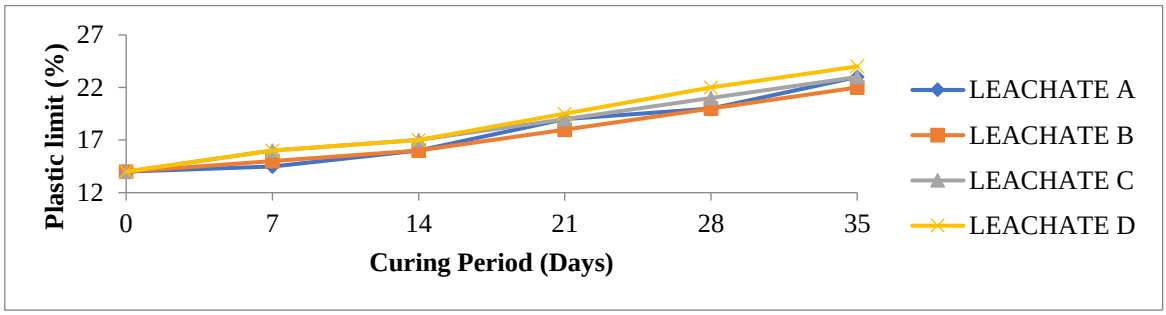

Figure 3: Variation of plastic limit with curing period

The plastic limit also increased with curing period, from 14% for the natural soil to 22-24% after 35 days. The increase was larger proportionally than the increase in liquid limit, amounting to approximately 57-71% across the four leachates. This indicates that leachate exposure shifted the lower boundary of the plastic state to substantially higher water contents. Plastic-limit changes can arise from modified particle associations, altered adsorbed-water conditions, and chemical reactions at clay surfaces. Pore-fluid chemistry has been shown to influence fine-grained soil fabric and macroscopic consistency through changes in electrical interparticle forces (Jang et al., 2018), while leachate-exposed clays have demonstrated time-dependent changes in index and microstructural properties (Oztoprak & Pisirici, 2011; Bahaa et al., 2024). The similarity of the trend for all four leachates suggests that exposure duration was an important controlling factor, although the slightly higher final plastic limit for leachate D indicates that differences in leachate composition also influenced the response.

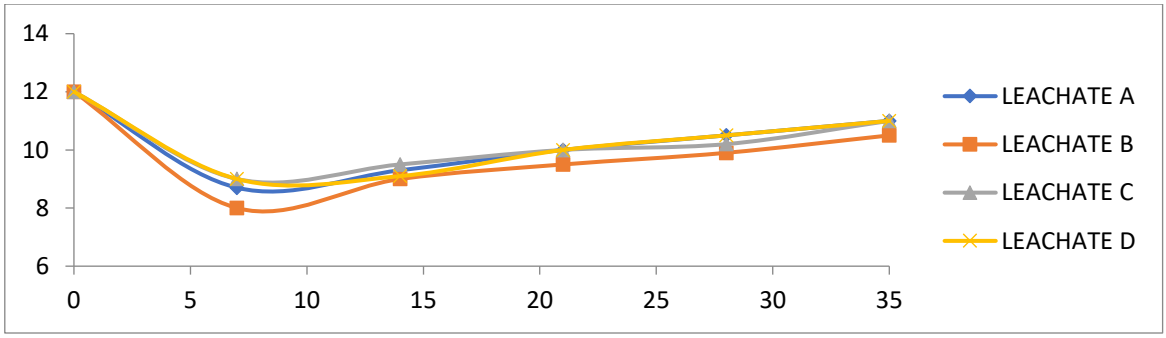

Figure 4: Variation of shrinkage limit with curing period

Shrinkage-limit behaviour differed from the liquid and plastic limits. The natural shrinkage limit of 12% fell sharply after 7 days of leachate exposure to approximately 8.0-9.0%, after which it gradually increased to 10.5-11.0% by 35 days. Thus, although partial recovery occurred with continued curing, the shrinkage limit remained below the uncontaminated value for all four leachates. A lower shrinkage limit means that volume reduction can continue to a lower water content before further drying ceases to cause shrinkage. The observed decrease-then-partial-recovery pattern is consistent with time-dependent physicochemical adjustment of the soil-leachate system, for example changes in ion exchange, diffuse-double-layer conditions, particle aggregation/dispersion, and fabric rearrangement reported for chemically exposed clays (Di Maio, 1996; Di Maio et al., 2004; Mitchell & Soga, 2005). However, these mechanisms are inferential in the present study rather than directly demonstrated, because the clay mineralogy, cation-exchange capacity, and post-exposure soil chemistry were not measured. The result should therefore be interpreted as an observed consistency change whose controlling mechanism remains to be verified by XRD, CEC, and related microstructural or chemical characterization. Similar studies of leachate-clay interaction have reported that index and volume-change characteristics evolve with exposure time rather than changing instantaneously (Ouria & Farsijani, 2019; Priya & Thyagaraj, 2025).

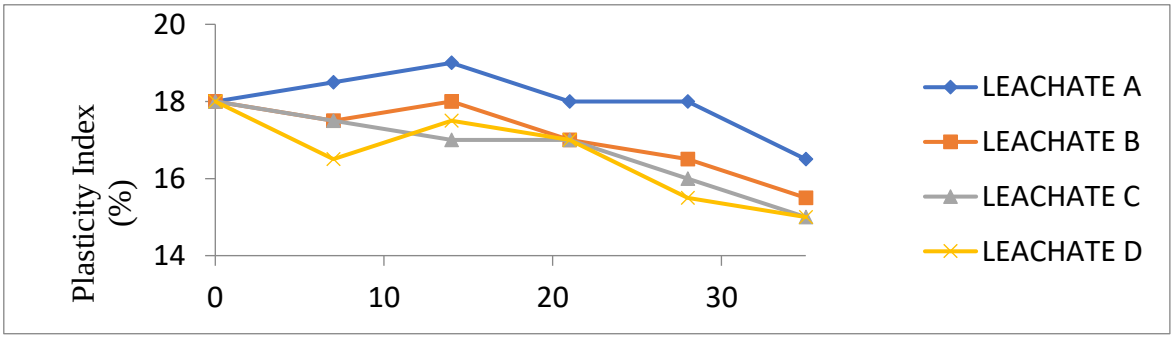

Figure 5: Variation of plasticity index with curing period

The plasticity index, calculated as LL-PL, showed a small early fluctuation but an overall decrease with prolonged exposure. From an initial value of 18%, the PI after 35 days decreased to 16.5%, 15.5%, 15.0%, and 15.0% for leachates A-D, respectively. This occurred because the plastic limit increased more rapidly than the liquid limit, thereby narrowing the range of water contents over which the soil remained plastic. The result is important because it differs from an interpretation based only on the increase in liquid limit: leachate exposure did not increase the overall plasticity range of this soil. Similar variability in the response of clay index properties to chemical pore fluids has been reported and depends strongly on mineralogy, electrolyte concentration, and cation valence (Sridharan & Prakash, 2000; Spagnoli & Sridharan, 2012; Curtin et al., 1994). Importantly, the reduction in PI should not be interpreted as improved engineering performance. In the companion Bauchi study of Chinade et al. (2017), unconfined compressive strength of compacted tropical soil generally decreased as MSW-leachate permeation time increased, despite the fact that strength behaviour cannot be inferred directly from PI alone. Taken together, the two studies suggest that leachate exposure can narrow the plasticity range while still degrading mechanical resistance. The practical implication is that a contaminated clay may become less plastic by the LL-PL measure yet simultaneously experience changes in strength, compressibility, hydraulic conductivity, or fabric that are adverse for foundations

and landfill barriers (Frempong & Yanful, 2008; Emami et al., 2019; Bahaa et al., 2024). Direct strength and compressibility testing of the same specimens would be required to quantify those consequences.

From a waste-containment perspective, the combined changes in liquid limit, plastic limit, shrinkage limit, and plasticity index demonstrate that the tested Bauchi clay is sensitive to the chemistry of the four MSW leachates. Clay-barrier performance is controlled not only by initial classification but also by how the soil responds to the actual permeant; chemical-compatibility testing is therefore important before a clay is adopted as a landfill liner or relied upon as a natural attenuation layer (Bowders et al., 1985; Katsumi et al., 2001; Jo et al., 2005). Nevertheless, the present findings are specific to one clay soil and four leachates collected within Bauchi metropolis. They should not be generalized quantitatively to other soil mineralogies, landfill ages, or leachate chemistries without additional testing. Broader applicability would require replicate testing across multiple soil types, chemical/mineralogical characterization, and direct measurements of strength, compressibility, and hydraulic conductivity.

3.4 Study Limitations and Practical Implications

The principal limitation is the absence of replicate Atterberg-limit measurements and associated standard deviations, which prevents formal assessment of experimental scatter and statistical significance. In addition, XRD mineralogy, cation-exchange capacity, and post-exposure soil chemistry were not measured, so the mechanisms proposed for the observed consistency changes remain literature-supported hypotheses rather than directly verified processes. The study also considered only one Bauchi clay and four local leachates over a maximum curing period of 35 days. Future work should therefore include replicate testing, longer exposure periods, mineralogical and chemical characterization, and paired strength/compressibility/hydraulic-conductivity measurements. Such data would allow the observed plasticity changes to be linked quantitatively to engineering performance and would improve the basis for landfill-liner design or foundation assessment in contaminated ground.

CONCLUSION

From the results of the study, the following conclusions were drawn:

i. The natural soil was classified as A-6(11) under AASHTO M 145-2012 and CL under ASTM D2487-11, with 89% passing the No. 200 sieve, liquid limit of 32%, plastic limit of 14%, plasticity index of 18%, shrinkage limit of 12%, and free swell of 45%.

ii. The four MSW leachates were alkaline (pH 8.1-10.3) and contained high dissolved-solids and organic loads. BOD5/COD ratios of approximately 0.17-0.25 indicate low biodegradability and a relatively stabilized leachate character.

iii. Leachate contamination caused systematic, time-dependent changes in the consistency characteristics of the clay soil.

iv. Liquid limit increased from 32% to 37.5-39.5% and plastic limit increased from 14% to 22-24% after 35 days of exposure. In contrast, plasticity index generally decreased from 18% to 15-16.5% because the plastic limit increased more rapidly than the liquid limit.

v. Shrinkage limit decreased sharply during the first 7 days of contamination and then partially recovered with curing, but remained below the natural-soil value after 35 days. This demonstrates that the effect of leachate on clay consistency is not monotonic and depends on the duration of soil-leachate interaction.

vi. The observed changes are consistent with modification of clay-water interactions through effects such as ionic strength, cation exchange, pH, organic constituents, and time-dependent fabric rearrangement. Because mineralogy, cation-exchange capacity, and post-exposure soil chemistry were not measured, these mechanisms remain inferential and should be verified in future work.

vii. For the tested Bauchi clay and the four local leachates, the results show that consistency properties are sensitive to leachate exposure and that chemical compatibility should be considered in waste-containment applications. The numerical trends should not be generalized to other clays or leachate chemistries without site-specific testing. Properly engineered landfill systems should incorporate effective liners, leachate collection and treatment, surface-water control, and routine monitoring of surrounding soil and groundwater.

ABSTRACT

Concrete performance is strongly influenced by the quality of its constituent materials. Hydrocarbon contamination of aggregates, mixing water, or concrete during handling and service can alter workability, cement hydration, strength development, permeability, and durability. This review synthesizes experimental evidence on the effects of crude oil, diesel, gasoline, and used engine oil on fresh and hardened concrete. The review focuses on the mechanisms through which hydrocarbons interact with cement paste and aggregate surfaces, the resulting changes in mechanical and durability properties, and approaches for mitigating the effects of contamination. The reviewed evidence indicates that the magnitude of deterioration depends on hydrocarbon type, contamination level, mode of contamination, water-to-cement ratio, curing regime, and testing age. Low levels of some hydrocarbons may increase slump through a lubrication or plasticizing effect, but this does not necessarily indicate improved structural performance. At moderate and high contamination levels, disruption of hydration and interfacial bonding generally results in reduced strength and, in many studies, increased porosity and permeability. The review also identifies gaps concerning long-term field performance, standardized permissible contamination limits, microstructural characterization, and sustainable remediation. These issues are particularly relevant to sustainable construction and infrastructure development in hydrocarbon-producing and industrial areas.

Keywords: *Concrete; hydrocarbon contamination; diesel; crude oil; used engine oil; compressive strength; durability; cement hydration*

1.0 INTRODUCTION

Concrete remains one of the most widely used construction materials because of its strength, durability, versatility, and availability (Neville,2011). Nevertheless, its performance can be compromised by environmental and chemical contaminants, including petroleum hydrocarbons. Hydrocarbon contamination may occur through oil spills, leakage from storage facilities, industrial discharges, transportation, construction-site handling, or the use of contaminated aggregates and water (Ajagbe et al., 2012; Osuji and Nwankwo, 2015).

Hydrocarbons such as crude oil, diesel, gasoline, kerosene, and used engine oil can interact with concrete at different stages of production and service. Their effects depend strongly on the type and concentration of the hydrocarbon and whether it is introduced through aggregates, mixing water, curing water, or external exposure. In contaminated aggregates, hydrocarbon films can alter the aggregate–paste interface and interfere with effective bond formation. During mixing, some petroleum products may also increase fluidity at low dosage because of lubrication or plasticizing effects, while simultaneously interfering with hydration and cohesion (Ajagbe et al., 2012; Elinwa & Mahmoud, 2023; Tetteh et al., 2025).

The consequences of contamination are important for sustainable construction because premature deterioration increases repair, replacement, material consumption, and environmental burdens. In Nigeria, where hydrocarbon production, transportation, storage, and industrial activities are significant, understanding the performance of contaminated concrete is relevant to resilient infrastructure development and sustainable management of polluted construction materials.

This review therefore synthesizes published evidence on hydrocarbon–concrete interactions, with emphasis on cement hydration, fresh properties, mechanical strength, density, durability, microstructural changes, mitigation strategies, and areas requiring further investigation.

1.1 Problem Statement

The use of hydrocarbon-contaminated construction materials can compromise concrete reliability. Experimental studies have reported reductions in compressive and flexural strength as contamination increases, although the magnitude of deterioration varies considerably with hydrocarbon type, contamination route, mix design, and curing conditions (Ajagbe et al., 2012; Ejeh and Uche, 2009; Oyelami et al., 2024). Despite the growing body of research, findings are dispersed across studies using different materials and experimental conditions. A structured synthesis is therefore required to distinguish general trends from condition-specific results and to identify practical mitigation and research needs.

1.2 Aim and Objectives

Aim

To critically review the effects of hydrocarbon impurities on concrete strength and durability.

Objectives

1. To examine the mechanisms through which hydrocarbons influence cement hydration and interfacial bonding.
2. To evaluate their effects on fresh and hardened concrete properties.
3. To compare reported experimental findings while accounting for hydrocarbon type, contamination level, and test conditions.
4. To identify practical mitigation strategies and priority areas for future research.

2.0 REVIEW METHODOLOGY

This paper adopts a structured narrative-review approach. Literature was identified from major scholarly and publisher platforms, including Google Scholar, ScienceDirect, SpringerLink, MDPI, institutional repositories, and journal websites. The principal search terms included combinations of hydrocarbon contamination concrete, crude oil contaminated concrete, diesel contaminated concrete, used engine oil concrete, oil contaminated sand concrete, concrete strength, concrete durability, cement hydration, and hydrocarbon concrete microstructure. The research emphasized literature published from 2009 to 2026, while allowing foundational earlier work where it directly informed the subject.

Studies were considered eligible when they reported experimental or review evidence directly related to petroleum hydrocarbons and concrete, mortar, aggregates, mixing/curing water, or concrete durability. Preference was given to peer-reviewed journal articles and traceable scholarly sources containing sufficient information on contamination type, dosage or exposure condition, and measured concrete properties. Sources were excluded when they did not address concrete or cement-based materials, lacked sufficient bibliographic information for verification, or merely mentioned hydrocarbons without reporting relevant performance evidence.

The selected literature was synthesized thematically under cement hydration, fresh properties, hardened properties, durability, microstructure, experimental evidence, mitigation, and research gaps. Quantitative results were not pooled statistically because the reviewed studies used substantially different hydrocarbon types, contamination routes, mix proportions, specimen sizes, curing regimes, and test ages. Instead, reported values are presented with their study conditions to avoid misleading direct comparisons.

3.0 CONCEPT OF HYDROCARBON CONTAMINATION IN CONCRETE

Hydrocarbon contamination occurs when petroleum-based substances such as crude oil, diesel, gasoline, kerosene, or used engine oil are present in concrete constituents or come into contact with concrete during production or service. Depending on the contamination route, hydrocarbons may coat aggregate surfaces, alter the liquid phase of the mixture, affect cement hydration, or modify pore structure (Ajagbe et al., 2012; Osuji and Nwankwo, 2015).

3.1 Cement Hydration

Cement hydration involves reactions between cement compounds and water that produce hydration products, particularly calcium silicate hydrate (C–S–H), which contributes substantially to

strength development. Hydrocarbons can interfere with this process by coating cement particles or aggregate surfaces and reducing effective contact between cement, water, and aggregate. The extent of interference depends on the hydrocarbon and its concentration. Consequently, contaminated concrete may show slower strength development or lower ultimate strength than uncontaminated concrete (Ajagbe et al., 2012; Osuji and Nwankwo, 2015; Oyelami et al., 2024).

3.2 Effects on Fresh Concrete Properties

Hydrocarbon contamination can change the rheology and stability of fresh concrete. At low dosages, some petroleum products can increase slump because their lubricating or plasticizing action reduces interparticle friction. However, increased slump should not be interpreted as evidence of improved concrete quality. At higher contamination levels, hydrocarbon films may reduce cohesion and promote segregation, while interference with cement–water interaction may delay hydration and setting. Thus, the apparent increase in workability and the delay in hydration are not contradictory: they represent different effects of the same contaminant acting on fresh-mixture rheology and cement chemistry, respectively (Tetteh et al., 2025).

1. Workability (slump): Low levels of some hydrocarbons can increase slump through lubrication or plasticizing action; excessive contamination may reduce cohesion and mix stability.
2. Segregation and bleeding: Disruption of cohesion can increase the tendency for non-uniform distribution of constituents.
3. Setting time: By reducing effective cement–water interaction, hydrocarbons may delay hydration and setting, although the magnitude depends on contaminant type and dosage.
4. Cohesion and stability: Oil films at particle surfaces can weaken interparticle interaction and make compaction and uniform placement more difficult.
5. Mechanism: The combined effects arise from surface coating, hydrophobicity, altered rheology, and interference with hydration.

3.3 Effects on Hardened Concrete Properties

Hydrocarbon contamination generally has a more pronounced effect on hardened concrete when contamination is sufficiently high to disrupt hydration and aggregate–paste bonding. Reported outcomes include reductions in compressive, tensile, and flexural strength, changes in density, and deterioration in selected durability indicators. However, the magnitude and even direction of individual properties can vary at low contamination levels and under different exposure conditions.

3.3.1 Effect on Compressive Strength

Compressive strength is one of the properties most consistently affected by hydrocarbon contamination. Ajagbe et al. (2012) reported an 18–90% strength loss for concrete made with sand contaminated with 2.5–25% crude oil, with the larger losses occurring at the higher contamination levels. The study also found that contamination above 5% caused more than 50% strength reduction. These values should not be interpreted as a universal range for all hydrocarbons; they describe a specific crude-oil-contaminated-sand system and its test conditions. Other studies have reported smaller or different losses because they used different hydrocarbons, contamination routes, dosages, water-to-cement ratios, and curing conditions (Oyelami et al., 2024; Mmonwuba et al., 2025; Abbas, 2026).

3.3.2 Strength Development

Hydrocarbon-contaminated concrete may develop strength more slowly than control concrete because early hydration and interfacial bond formation are disturbed. The literature indicates that early-age strength can be particularly sensitive to contamination. Nevertheless, strength development is not governed by contamination alone; curing duration, mix proportions, hydrocarbon type, and contamination route also influence the observed rate of strength gain (Ajagbe et al., 2012; Oyelami et al., 2024).

3.3.3 Effect on Durability

Durability describes the ability of concrete to maintain acceptable performance under anticipated environmental exposure. Hydrocarbon contamination can modify porosity, permeability, water absorption, and resistance to aggressive exposure. Ajagbe et al. (2018), found that crude-oil-impacted-sand concrete showed changes in electrical resistivity and water absorption with contamination level, while fire exposure caused additional strength deterioration. These findings demonstrate that durability responses are not always uniformly negative across every indicator and should be interpreted in relation to the particular contaminant and test method (Adesina et al., 2021; Elinwa & Mahmoud, 2023).

3.3.4 Long-Term Strength and Integrity

Long-term performance remains less consistently documented than early-age strength. Available studies suggest that contamination can continue to influence strength development and durability, but reported magnitudes vary. Therefore, a single percentage reduction should not be presented as a universal long-term loss. Long-term behavior should instead be reported with the contamination type, exposure condition, curing age, and test method explicitly stated.

3.4 Tensile and Flexural Strength

Hydrocarbon contamination can reduce tensile and flexural performance by weakening the cement paste–aggregate interface and increasing internal discontinuities. Ajagbe et al. (2012) reported reductions in flexural strength as crude-oil contamination increased. Similar mechanisms have been associated with reductions in splitting tensile strength, including weaker interfacial transition zones, reduced cohesion, and increased susceptibility to crack initiation.

1. Reduced splitting tensile strength.
2. Increased susceptibility to crack initiation and propagation.
3. Weakening of the interfacial transition zone (ITZ).
4. Reduced flexural capacity where contamination significantly affects internal bonding.

3.5 Density

Density is influenced by particle packing, compaction, entrapped air, and the composition of the concrete matrix. Hydrocarbon contamination can alter these factors by affecting cohesion, compaction, and pore structure. However, changes in density are not necessarily identical across all hydrocarbon types and dosages; therefore, density trends should be interpreted alongside air content, porosity, and the contamination route rather than treated as a direct measure of strength (Abbas, 2026).

3.6 Effect on Concrete Durability

Hydrocarbon contamination may influence durability through changes in hydration, pore connectivity, interfacial bonding, and permeability. Where contamination produces a weaker and more connected pore structure, the ingress of water and aggressive agents may increase. However, some low-level hydrocarbon exposures have produced mixed results for individual durability indicators. Ajagbe et al. (2018) reported improved electrical-resistivity-related durability indicators with increasing crude-oil contamination in their particular test system, while also observing reduced strength after fire exposure. This illustrates why durability conclusions must be tied to the specific indicator and exposure condition rather than generalized across all hydrocarbons.

3.7 Microstructural Effects of Hydrocarbon Impurities

At the microstructural level, hydrocarbon contamination can modify cement hydration and the aggregate–paste interface. Reported mechanisms include incomplete development of hydration products, weak ITZs, altered pore structure, and microcracking. These changes provide a mechanistic explanation for many observed reductions in strength and durability, although microstructural evidence remains less extensive than conventional strength testing in the literature.

1. Reduced or altered development of C–S–H and other hydration products.
2. Weakening of the aggregate–paste interfacial transition zone.

3. Changes in porosity and pore connectivity.
4. Formation or propagation of microcracks and discontinuities.

3.8 Experimental Studies on Hydrocarbon-Contaminated Concrete

Experimental studies differ substantially in hydrocarbon type, contamination route, dosage, concrete composition, and curing regime. Accordingly, direct numerical comparison must be made cautiously.

Table 3.0: Experimental Studies on Hydrocarbon-Contaminated Concrete

Study	**Hydrocarbon**	**Key condition**	**Main finding**	**Interpretation**
Ejeh & Uche (2009)	Crude oil contamination	Concrete materials	Compressive strength decreased with contamination.	Supports the adverse effect of crude oil on strength.
Ajagbe et al. (2012)	Crude-oil-contaminated sand	2.5–25% oil; 3–168 days	18–90% strength loss; >50% loss above 5% contamination.	Large losses are condition-specific and linked to contaminated sand.
Osuji & Nwankwo (2015)	Crude oil contamination	Concrete constituents	Oil hindered bond formation and affected strength.	Supports hydration/bonding mechanism.
Adesina et al. (2021)	Oil-contaminated concrete	Durability-focused	Reported deterioration in durability-related performance.	Shows that strength and durability should be evaluated together.
Oyelami et al. (2024)	Oil-contaminated sand	Mechanical performance	Strength decreased with increasing contamination; early ages were sensitive.	Confirms concentration- and age-dependent effects.
Ajagbe et al. (2018)	Crude-oil-impacted sand	Durability and fire exposure	Durability indicators changed with contamination; fire exposure caused additional strength loss.	Demonstrates property-specific responses.
Mmonwuba et al. (2025)	Petroleum-contaminated sand	RHA and cassava starch remediation	27.76% strength reduction from contamination; additives improved strength.	Supports sustainable remediation approaches.
Tetteh et al. (2025)	Used engine oil as admixture	0.15–30%; varying water-cement ratio	Low dosages improved workability; higher dosages reduced strength.	Shows that low-dose fluidity effects do not imply improved structural performance.

3.9 Comparative Analysis of Existing Studies

The apparently wide range of reported strength reductions is not necessarily contradictory. The 18–90% range reported by Ajagbe et al. (2012) resulted from 2.5–25% crude-oil contamination of sand and therefore represents a specific experimental system. The more than 50% reduction reported in that study at contamination above 5% is part of the same dataset rather than an independent universal value. By contrast, Mmonwuba et al. (2025) reported a 27.76% reduction for petroleum-contaminated sand under a different experimental design, and Oyelami et al. (2024) reported concentration-dependent strength losses in oil-contaminated sand. These differences arise from hydrocarbon composition, contamination level, whether the aggregate or water was contaminated, water-to-cement ratio, mix proportions, curing age, specimen preparation, and test conditions. The review therefore avoids presenting 18–90%, 25%, 50%, or 27.76% as universal strength-loss values.

Another important distinction concerns low-level hydrocarbon addition as an admixture versus accidental contamination of concrete constituents. Some used-engine-oil studies report increased slump at low dosages, while higher dosages reduce strength. Such findings should not be generalized to contaminated aggregates or uncontrolled field exposure because the mechanisms, dispersion, and dosage basis are different (Tetteh et al., 2025).

4.0 MITIGATION STRATEGIES

Mitigation should prioritize preventing contaminated materials from entering structural concrete. Where contamination is detected, appropriate cleaning or treatment of aggregates should be considered, subject to verification by laboratory testing. Other measures include strict material quality control, protection of aggregates during storage, avoidance of contaminated mixing or curing water, and site monitoring in areas exposed to petroleum products.

Supplementary cementitious materials and other remediation additives may provide additional benefits in selected applications. Mmonwuba et al. (2025), reported improved mechanical performance when rice husk ash and cassava starch were used with petroleum-contaminated sand. However, such approaches should be validated for the specific contamination type and structural application before adoption.

5.0 CONCLUSION

The reviewed literature demonstrates that hydrocarbon contamination can significantly alter concrete performance, particularly when contamination is moderate to high or when aggregate surfaces are substantially coated. The dominant mechanisms include disruption of cement hydration, alteration of aggregate–paste bonding, and changes in pore structure. These mechanisms commonly lead to reduced compressive and flexural strength and can impair durability, although individual durability indicators may respond differently depending on the hydrocarbon and exposure condition.

The review also shows that quantitative strength losses reported in the literature cannot be treated as universal constants. Ajagbe et al. (2012) reported a 18–90% range corresponds specifically to 2.5–25% crude-oil contamination of sand, whereas the 27.76% reduction reported by Mmonwuba et al. (2025) arose from a different petroleum-contaminated-sand system. Consequently, future studies should report contamination route, dosage basis, hydrocarbon composition, mix design, curing conditions, and testing age in sufficient detail to permit meaningful comparison.

5.1 Recommendations

1. Avoid using visibly or demonstrably hydrocarbon-contaminated aggregates and water in structural concrete unless an appropriate treatment and laboratory verification demonstrate suitability.
2. Introduce routine quality-control testing of aggregates and water in areas exposed to petroleum products.
3. Investigate washing, treatment, or other remediation methods before considering contaminated aggregates for reuse.
4. Evaluate supplementary cementitious materials and sustainable additives as potential remediation strategies, with structural performance verified experimentally.

5. Develop evidence-based guidance on permissible contamination levels for different hydrocarbon types and concrete applications.

5.2 Further Research Focus

1. Long-term durability and field exposure: Most available studies are laboratory-based and use limited curing or exposure periods. Long-term field studies are needed to establish how contaminated concrete performs under realistic wetting, drying, chemical, thermal, and loading cycles.

2. Standardized contamination limits: Reported strength losses vary widely because studies use different contamination bases and hydrocarbon types. Standardized procedures for defining contamination level and reporting dosage are needed before regulatory limits can be developed.

3. Advanced microstructural characterization: More coordinated SEM, XRD, porosity, permeability, and chemical analyses are needed to link observed strength loss directly to hydration products, ITZ changes, and pore connectivity.

4. Sustainable remediation: The promising results obtained with agricultural and supplementary materials warrant further work on low-cost, environmentally responsible methods for recovering contaminated aggregates without compromising structural safety.

ABSTRACT

Emerging technologies are reshaping engineering safety and environmental protection, yet evidence on their cross-sectoral effectiveness and applicability in resource-constrained economies remains fragmented. This study synthesises peer-reviewed evidence on artificial intelligence (AI), the Internet of Things (IoT), digital twins and BIM, virtual reality and sensor fusion, drones, and nanomaterials across construction, mining, and oil and gas operations. A systematically informed narrative-review approach was adopted, combining a reported search and screening process with manual verification and an operationalised evidence-grading rubric. The discovery platform reported 8,652,714 cumulative topical matches across 23 searches and one citation-graph expansion, reflecting corpus scale rather than individually retrieved records; 250 records were then surfaced for human screening and progressively verified to identify the final 37-study evidence corpus. The synthesis indicates the strongest convergent evidence for IoT- and AI-enabled monitoring and hazard detection, while evidence for digital twins/BIM, immersive technologies, and nanotechnology-based remediation remains comparatively limited. Reported quantitative effects of 18–22% risk reduction and 58–70% safety improvement are treated as single-case findings rather than generalisable technology effects. The study further develops a twelve-dimension, indicative Nigerian technology-adoption framework covering cost, infrastructure, skills, maintenance, regulatory readiness, data governance, cybersecurity, organisational readiness, technology maturity, and safety and environmental benefits. The framework is presented as an analytical proposition requiring empirical validation rather than as evidence of current Nigerian conditions. Directly supporting ICESID 2026's theme of harnessing engineering for Nigeria's sustainable growth, the findings support phased adoption of scalable monitoring and predictive technologies alongside strengthened regulatory, cybersecurity, occupational-exposure, and workforce-development measures.

Keywords: *emerging technologies; engineering safety; environmental protection; artificial intelligence; Internet of Things*

1. INTRODUCTION

Engineering safety and environmental stewardship have historically been treated as compliance obligations layered onto production activity rather than as design objectives in their own right. This posture is changing. Artificial intelligence, the Internet of Things, digital twins, and automation are transforming safety management and environmental protection across construction, mining, and energy industries, reshaping how hazards are anticipated, monitored, and controlled (Adio et al., 2025; Dimkpa et al., 2025; Gobbo et al., 2018). The scale of the underlying problem is considerable: Gupta, Singh, Asari, and Nguyen (2026) report that construction, framed in their review as among the most hazardous industries globally, experiences a worker fatality approximately every ninety-nine minutes; their source does not further disaggregate this figure by country or region, and it is reported here exactly as framed in that review rather than with additional geographic precision the citing source does not itself provide. This statistic has nonetheless driven accelerating adoption of machine learning, robotics, wearable sensors, and immersive visualisation as complements to conventional safety management (Gupta et al., 2026). Parallel pressure is building on the environmental side of engineering practice, where Industry 4.0 concepts, the Internet of Things, big data, and cyber-physical systems, are increasingly framed as

opportunities to integrate process safety with environmental protection rather than treat them as competing priorities (Gobbo et al., 2018).

For Nigeria, these global dynamics intersect with structural realities that make emerging-technology adoption both more urgent and more difficult. The Nigerian economy remains heavily anchored on extractive and heavy-industry activity, oil and gas production in the Niger Delta, solid minerals mining, and an expanding construction sector, each carrying elevated occupational-safety and environmental-protection burdens. Environmental regulation is administered principally through the National Environmental Standards and Regulations Enforcement Agency (NESREA) and sector-specific upstream petroleum regulators, within an institutional environment that, as in many developing economies, faces resource and enforcement constraints. The oil and gas industry continues to contend with greenhouse gas emissions, spills, and process accidents that drive demand for more sustainable protection technologies across upstream, midstream, and downstream operations (Akerele et al., 2024; Alamutu, 2025; Okolie et al., 2024).

Despite this relevance, the literature on emerging technologies for engineering safety and environmental protection remains fragmented along sectoral and disciplinary lines, with comparatively little cross-sector synthesis and even less explicit engagement with the adoption conditions of developing economies. This paper addresses that gap and makes three specific contributions.

Knowledge contribution: a cross-sectoral, evidence-graded synthesis of six technology categories, AI and predictive analytics, IoT and real-time monitoring, digital twins/BIM, VR and sensor fusion, drones, and nanomaterials, against safety and environmental functions. Methodological contribution: an operationalised evidence-grading rubric applied transparently to a heterogeneous corpus, together with a reported search and screening protocol. Practice and policy contribution: a twelve-dimension technology-adoption framework that translates global evidence into a prioritisation logic for resource-constrained Nigerian engineering sectors, explicitly presented as a proposition for empirical validation. The objectives are to: (i) map the six technology categories against safety and environmental functions; (ii) characterise sector-specific applications and quantified impacts; (iii) grade the evidence using the stated rubric; and (iv) derive bounded implications for engineering practice, regulation, and workforce development in Nigeria.

2. LITERATURE REVIEW

2.1 Theoretical Foundations

The theoretical anchor for this review is the Industry 4.0 paradigm, which frames the convergence of cyber-physical systems, IoT, big data, and smart objects as a basis for simultaneously improving process safety and environmental performance rather than treating the two as a trade-off (Gobbo et al., 2018). Complementing this technological framing is a risk-governance perspective associated with the responsible-development literature, which holds that anticipation of hazards, precautionary approaches where occupational exposure limits are undefined, and transparent communication with exposed workers should accompany the introduction of any new technology into industrial practice (Schulte et al., 2024). A third theoretical strand, drawn from the Safe and Sustainable-by-Design (SSbD) literature, argues that environmental and health risk assessment should be embedded across a technology's full life cycle rather than appended after deployment (Cassee et al., 2024; Köhler & Som, 2014).

2.2 Classification Principle and Technology-Function Overlaps

The six technology categories used throughout this review, AI and predictive analytics, IoT and real-time monitoring, digital twins/BIM, VR and sensor fusion, drones, and nanomaterials, are organised by primary sensing, computation, or material function rather than by strict technical independence, because the underlying literature does not treat these as mutually exclusive systems. AI models frequently operate on data streams generated by IoT sensor networks; digital twins depend on both IoT inputs and analytics engines to remain synchronised with the physical asset they represent; drones increasingly embed AI-based computer vision for autonomous inspection; and VR/sensor-fusion training platforms can draw on the same spatial data underlying a digital twin. Nanomaterials are the clear exception, differing fundamentally from the other five categories as a materials-science rather than

a digital/computational technology. Table 1 presents a technology-function matrix that makes this overlap explicit, classifying each category by its dominant function rather than treating the six categories as structurally independent silos.

Table 1: Technology-Function Matrix, Showing Dominant and Secondary Functions

Technology	Dominant Function	Secondary/Overlapping Function	Principal Sectors
AI & predictive analytics	Computation / prediction	Embedded within IoT and drone systems	Mining, construction, oil & gas
IoT & real-time monitoring	Sensing	Supplies data to AI, digital twins	Industrial, mining
Digital twins & BIM	Visualisation / simulation	Depends on IoT + analytics inputs	Construction, oil & gas
VR & sensor fusion	Visualisation / training	Overlaps with digital-twin spatial data	Mining, occupational safety
Drones	Sensing (remote/aerial)	Increasingly AI-embedded (computer vision)	Industrial, environmental
Nanomaterials	Materials intervention	None (non-digital category)	Environmental remediation, oil & gas

2.3 AI and Predictive Analytics

AI-enabled predictive analytics is among the most consistently reported technology categories in the corpus, applied to hazard detection, predictive maintenance, and environmental-risk forecasting across construction, mining, and oil and gas operations (Adio et al., 2025; Dimkpa et al., 2025; Arjunan et al., 2025). In oil and gas operations, machine-learning-based predictive analytics forecasts potential equipment failures and schedules proactive maintenance, complementing continuous IoT-based condition monitoring (Akpe et al., 2024). Systematic reviews of construction-safety technologies identify AI-based topic modelling and smart-technology integration as tools that proactively identify hazards, reduce accidents, and improve resource allocation, while simultaneously contributing to lower carbon emissions through better energy optimisation on site (Seo & Yoon, 2025).

2.4 IoT and Real-Time Monitoring

IoT-based sensing underpins much of the reported progress in both safety and environmental monitoring. In underground mining, an IEEE review documents IoT architectures purpose-built for simultaneous environmental, safety, and production monitoring, addressing persistent challenges such as limited battery life and unreliable underground communication (Zhang et al., 2023). Low-cost sensor networks are identified as a foundational enabling layer for Industry 4.0 digital transformation in mining, supporting real-time monitoring through wireless networks in combination with AI, machine learning, and digital twins (Cacciuttolo et al., 2023). More broadly across industrial operations, digital HSE technologies, encompassing IoT-enabled compliance monitoring alongside AI-based analytics, are reported to strengthen health, safety, and environmental management practice (Adikwu et al., 2024). A single regional mining-complex case study reports that integrating information technologies with environmental monitoring data was associated with an 18–22% reduction in overall industrial and environmental risk at that site; this figure derives from a before–after design at one location without independent replication, and should be read as a case-specific reported effect rather than an expected or generalisable improvement (Kukartsev et al., 2025).

2.5 Digital Twins, BIM, and Robotics

Digital twin technology, providing virtual replicas of physical assets, is reported to enable risk-free simulation and optimisation of plant operations in oil and gas contexts (Akpe et al., 2024). In construction, BIM, robotics, wearable devices, and AI are each positively and significantly associated with improved safety performance, with BIM and wearable technologies showing the strongest individual effects in comparative analysis (Dobrucalı et al., 2022; Yap et al., 2021). The principal safety-enabling mechanisms identified are improved hazard identification, reinforced safety planning, and enhanced monitoring and supervision (Yap et al., 2021). A systematic review of 129 journal articles published between 2018 and 2023 organises construction safety technologies across four functional areas, prevention through design, safety management, safety culture and awareness, and computing in construction safety (Maali et al., 2024). BIM, drones, and prefabrication techniques together enable real-time monitoring, hazard detection, and improved stakeholder coordination, with reported reductions in accident likelihood in high-rise construction (Kumar et al., 2025).

2.6 VR, Drones, and Immersive Technologies

VR and sensor-fusion technologies are applied principally to hazard-scenario training and ergonomic assessment, with secondary applications in pollution visualisation and ecological education (Strzałkowski et al., 2025). Review evidence spanning geodesy and geomatics, mining, environmental protection, and occupational safety identifies sensor-integrated immersive training as a growing sub-field with demonstrated training value, though empirical evidence on transfer to real-world safety outcomes remains comparatively thin (Strzałkowski et al., 2025). Drones are reported primarily as tools for remote inspection and large-scale environmental monitoring, extending the geographic reach of safety and compliance surveillance without placing personnel in hazardous locations (Dimkpa et al., 2025).

2.7 Nanotechnology, Advanced Materials, and Environmental Remediation

Environmental engineering is increasingly linked to Industry 4.0 through intelligent monitoring, low-carbon processes, and data-driven environmental management. Emerging technologies can support emissions, water, pollution, and ecological monitoring, but the environmental evidence is less mature than the safety evidence. Sensor networks and AI offer scalable monitoring and prediction, while nanomaterials provide remediation pathways but introduce exposure and life-cycle concerns (Ateia et al., 2024; Liu et al., 2024; Wu et al., 2024).

These exposure and life-cycle concerns are well documented at the level of individual nanomaterial applications. Advanced in vitro and in silico safety-assessment tools are increasingly used to characterise the hazard profile of engineered nanomaterials ahead of deployment, reducing reliance on animal testing while improving mechanism-based risk characterisation (Fadeel et al., 2018). Life-cycle-oriented reviews of the nano-world more broadly identify environmental risk as distributed across a material's full production-to-disposal pathway rather than concentrated at the point of use, reinforcing the case for safe-and-sustainable-by-design approaches introduced in Section 2.1 (Glišović et al., 2017). Sector-specific evidence extends this concern to oil and gas operations directly relevant to the Nigerian context examined in this review: nanoparticle additives used in drilling muds improve technical performance but carry environmental, health, and safety implications that remain incompletely characterised, underscoring the need for occupational-exposure guidance to accompany, rather than follow, adoption (Martin et al., 2023).

2.8 Distinguishing Safety and Environmental Protection Outcomes

The review therefore distinguishes environmental monitoring from broader environmental protection. Monitoring applications have comparatively direct evidence, whereas pollution prevention, remediation, and governance remain more dependent on laboratory studies, reviews, and conceptual work. Forward-looking technology-forecasting reviews frame environmental engineering itself as entering a period of disruptive innovation, driven by sensing, data, and materials advances converging on pollution-prevention applications (Huang, Lu, Jin, & Ren, 2024), while membrane-based separation technologies illustrate the more laboratory-proximate evidence base typical of remediation applications specifically, with emerging directions targeting pollutant removal and degradation in aqueous systems

(Zhao et al., 2024). This distinction is retained in the evidence grading and in the Nigerian adoption framework.

Table 2: Depth of Empirical Coverage Across Safety and Environmental Outcome Categories

Outcome Category	Representative Evidence	Predominant Evidence Type
Occupational safety	Akinlolu et al. (2020); Yap et al. (2021); Dobrucalı et al. (2022)	Systematic reviews; site-level observational studies
Process / industrial safety	Di Martino et al. (2021); Benson et al. (2023); Akpe et al. (2024)	Case studies; conceptual frameworks
Environmental monitoring	Zhang et al. (2023); Cacciuttolo et al. (2023); Kukartsev et al. (2025)	Technical reviews; single-site case study
Pollution prevention	Huang et al. (2024); Ateia et al. (2024)	Conceptual / technology-forecasting reviews
Environmental remediation	Liu et al. (2024); Wu et al. (2024); Zhao et al. (2024)	Laboratory-scale evidence; narrative reviews
Environmental risk governance	Schulte et al. (2024); Cassee et al. (2024); Köhler & Som (2014)	Policy/framework papers

Table 2a complements this outcome-based view with a technology-based one, tracing each of the six technology categories through to its specific environmental application, the evidence maturity behind that application (using the same strong/moderate/weak logic operationalised in Table 4), and its plausible relevance to the Nigerian sectors discussed in Section 4.4. This technology-to-environmental-function view is intended to strengthen the environmental half of the review's dual safety/environmental scope without duplicating the outcome-category analysis in Table 2.

Table 2a. Technology-to-Environmental-Function Synthesis, with Evidence Maturity and Indicative Nigerian Relevance

Technology	Environmental Application	Evidence Maturity	Indicative Nigerian Relevance
IoT	Emissions, water, and ambient environmental monitoring	Strong–moderate	High — low-cost, scalable entry point (Section 5)
AI	Environmental-risk prediction and forecasting	Moderate	High — pairs naturally with IoT data streams
Drones	Remote environmental surveillance over large or hazardous areas	Moderate	High — extends monitoring reach without fixed infrastructure
Digital twins / BIM	Process optimisation and emissions reduction	Moderate	Moderate — constrained by capital cost and infrastructure (Table 8)
Nanomaterials	Soil, water, and pollutant remediation	Moderate	Potentially high, but safety-constrained pending exposure-limit clarity
VR / sensor fusion	Environmental and safety training, pollution visualisation	Limited	Moderate — training value plausible; outcome evidence thin

2.9 Critical Synthesis and Identified Gap

Across the six technology categories, the literature reports measurable safety and environmental benefits, but the evidence is dominated by reviews, conceptual frameworks, and single-site case studies rather than large empirical trials. Emerging technologies can also introduce new failure modes, occupational exposures, cybersecurity risks, and governance gaps (Salmon et al., 2024; Schulte et al., 2024). Technological-forecasting perspectives on environmental innovation caution more broadly that emerging technologies diffuse unevenly across institutional and economic contexts, so that global evidence of technical feasibility does not, by itself, predict the pace or pattern of adoption in any specific setting (Kargı & Coccia, 2024), a caution directly relevant to the Nigerian adoption framework developed in Section 4.4. Adoption barriers include cost, infrastructure, skills, organisational resistance, and regulatory capacity, with limited evidence from developing economies. The central gap is therefore not the absence of technological capability, but the limited empirical basis for determining how emerging technologies should be prioritised and governed in Nigerian engineering contexts.

3. MATERIALS AND METHODS

3.1 Review Design and Terminology

The review is designated a systematically informed narrative review rather than an unqualified systematic review. The latter typically requires dual independent screening, inter-rater reliability, and formal quality appraisal, which were not fully available here. The present design instead combines a reported search and screening process, manual verification, and an explicit evidence-grading rubric suited to a heterogeneous cross-sector corpus.

This hybrid label requires clarification given that Section 3.3 presents a four-stage, structured study-selection flow table styled after common systematic-review reporting conventions, and Section 3.5 presents a structured evidence-grading rubric, both of which are apparatus more commonly associated with systematic reviews. Three systematic-review elements were adopted: a staged, numerically reported selection process (Table 3); an explicit, reproducible grading rubric applied uniformly across included studies (Table 4); and transparent reporting of exclusion counts between stages. Three systematic-review elements were not adopted, and are flagged as limitations in Section 3.6: dual independent screening with an inter-rater reliability statistic; a pre-registered protocol; and a formal, validated quality-appraisal instrument (e.g., MMAT or CASP) in place of the purpose-built rubric. The review therefore sits deliberately between the two traditions, borrowing the transparency mechanisms of a systematic review while not claiming the full methodological guarantees, particularly independent replicability of the screening decisions, that the unqualified term would imply.

3.2 Search Strategy and Sources

The literature search used Consensus, an AI-assisted academic discovery platform, as a search-support tool. Four term groups were developed around emerging technologies, safety/environmental outcomes, engineering sectors, and developing-economy context. Twenty-three searches and one citation-graph expansion together produced an initial platform-reported count of 8,652,714 cumulative topical matches; the citation-graph expansion is included within, not additional to, this count. This figure warrants explicit clarification: it is the cumulative count of instances the platform's interface reported as topically matching one of the 23 queries or the citation-graph expansion against its full indexed corpus, which spans over 170 million papers, before deduplication, relevance ranking, or any manual review. It should be read as an indicator of the breadth of the underlying indexed corpus and the deliberately broad initial term groups used, not as a set of records that were individually retrieved, inspected, or screened; no claim is made that this number represents discrete, non-overlapping documents, and the figure is not itself labelled or treated as "records retrieved" anywhere else in this paper. The operationally meaningful figure, and the one from which all subsequent screening in Table 3 proceeds, is the 250-record set the platform's relevance-ranking algorithm surfaced for detailed human screening. The platform was used only to identify this manageable screening set; all inclusion decisions from that point forward were checked manually. Because the platform is proprietary, its ranking model and complete search logs are not independently auditable.

3.3 Study Selection Process

Table 3 summarises the four-stage selection process from identification to inclusion, presented as a study-selection flow table rather than a graphical flow diagram.

Table 3: Study Selection Flow, from Initial Identification to Final Inclusion

Stage	N	Process Applied
1. Identification	8,652,714	Cumulative platform-reported topical matches across 23 searches (4 term groups) + 1 citation-graph expansion, against the platform's indexed corpus (>170M papers); not individually retrieved or screened records
2. Screening	250	Platform relevance-ranking algorithm surfaced top-ranked records for detailed screening; deduplication applied
3. Eligibility	198	Records meeting topical relevance and minimum quality signal (peer-reviewed venue; explicit safety/environmental engineering application) after deduplication
4. Inclusion	37	Final selection of records with complete, independently verifiable bibliographic data, applying the explicit rule set out below

Inclusion criteria required that a paper (i) be published in a peer-reviewed journal or conference proceedings, (ii) report on at least one emerging technology applied to engineering safety, environmental protection, or both, and (iii) situate that application within an identifiable industrial sector. Papers addressing emerging technologies purely from a non-engineering perspective were excluded at Stage 3. Reasons for exclusion between Stage 2 and Stage 3 (52 records) were topical irrelevance on full-abstract reading and absence of an identifiable engineering-sector application; a record-level exclusion log was not retained in exportable form and is noted as a reproducibility limitation in Section 3.6. Journal articles and conference proceedings were both eligible and were not differentiated by a separate quality-weighting scheme; this is likewise flagged as a limitation, since venue type can correlate with review rigour.

The Stage 3-to-Stage 4 transition requires clarification, since eligibility (198 records) and final inclusion (37 records) differ substantially and this attrition should not be read as arbitrary. “Complete, independently verifiable bibliographic data” means, concretely, that a record carried a full author list, publication year, journal or proceedings title, volume/issue and page range (or article number), and a resolvable DOI or equivalent stable identifier (e.g., a persistent publisher URL) that could be checked against an independent source rather than taken on the platform's metadata alone. Records were dropped between eligibility and inclusion primarily for three reasons: incomplete platform-exported metadata, most commonly a missing or malformed DOI, common among conference proceedings and recently published articles not yet fully indexed; inability to independently verify the record against a second source, since platform-only metadata was not treated as sufficient on its own after the verification issues discussed in Section 3.4; and, in a smaller number of cases, records that on closer full-text reading did not, in fact, report a specific, attributable technology application meeting the inclusion criteria despite passing automated relevance screening. The 81 percent attrition between eligibility and inclusion is therefore substantially a function of the verification standard applied, deliberately stringent, given the citation-integrity concerns that motivated Section 3.4, rather than of topical irrelevance, which had already been filtered out at the earlier eligibility stage. The platform synthesis referenced a target pool of up to 50 topically relevant records within the eligible set; of these, 37 satisfied the full bibliographic-verification standard above. The final evidence corpus is therefore defined as the 37 fully verified studies. No additional records were inferred, fabricated, or counted without verifiable bibliographic support. Tables and conclusions use 37 as the denominator unless explicitly stated otherwise.

3.4 Role of AI-Assisted Discovery and Human Verification

The Consensus relevance-ranking algorithm narrowed the very large initial pool to a manageable screening set and ranked the eligible records for further consideration. It is treated only as

a search-support mechanism, not as an independent methodological authority. The model is proprietary and its ranking weights are not independently auditable; consequently, manual verification was used for final inclusion. Exact platform query strings, execution dates, and ranking scores were not retained, which limits exact replication.

3.5 Data Extraction and Evidence-Grading Rubric

Data extracted from each retained paper included technology category, sector, reported safety or environmental function, any quantified outcome measures, and stated limitations or barriers. Table 4 sets out the explicit rubric applied. Each claim synthesised in Section 4.3 was scored against five criteria, number of independent supporting studies, predominant study-design quality, presence of replication, geographic diversity of the supporting evidence, and the nature of outcome measurement.

Table 4: Operationalised Evidence-Grading Rubric

Criterion	Low / Weak Signal	Moderate Signal	High / Strong Signal
Number of independent studies	1 study	2–3 studies	4+ independent studies
Study design quality	Conceptual / opinion	Observational / single case study	Multiple observational or quasi-experimental studies
Replication	None	Limited (1 corroborating source)	Multiple independent corroborations
Geographic / contextual diversity	Single site or region	2–3 regions or sectors	4+ regions or sectors
Outcome measurement	Qualitative / descriptive only	Proxy or partial quantitative measure	Direct, quantified outcome measure

The overall strong/moderate/weak grade was not derived from a mechanical count of how many of the five criteria fell into each band. Instead, the default rule was that a grade required at least three of the five criteria to point in the same direction, with the more conservative (lower) grade assigned wherever the criteria diverged. This default was overridden in one specific, explicitly flagged circumstance: where a claim rested on a single case but that case reported a direct, quantified outcome measure (the strongest of the five criteria) rather than a qualitative or proxy measure, the claim was graded moderate rather than weak, on the reasoning that a precisely measured single-case effect carries more evidentiary weight than an equivalently single-source qualitative judgement, while still falling well short of a claim replicated across independent, geographically diverse studies. This override applies to exactly two claims in Table 7, both flagged there with an asterisk and explained in the accompanying note; every other grade in Table 7 follows the default majority rule without exception. This exception-based logic, rather than a strict unweighted vote across the five criteria, is what Table 7 reports, and it is disclosed here explicitly so the grading is reproducible rather than merely asserted.

This rubric was applied retrospectively to the corpus rather than pre-registered, which is itself a limitation relative to full systematic-review practice; it nonetheless represents a substantial improvement in transparency and reproducibility over an unstructured strong/moderate/weak judgement, and the platform's own algorithmically generated evidence-reasoning summaries were cross-checked against, rather than substituted for, this manual rubric.

3.6 Methodological Limitations

The following limitations qualify, but do not negate, the value of the synthesis; they define the boundary of what the review can credibly claim, which is an evidence-graded narrative synthesis that is transparent and reproducible in its reported screening logic and grading rubric, but not fully reproducible at the level of the underlying platform searches themselves, given the search-log limitation noted below, rather than a protocol-registered systematic review with meta-analytic pooling.

- 50-versus-37 record discrepancy: the discovery platform referenced up to 50 relevant records, but only 37 carried complete, independently verifiable bibliographic detail on export; the manuscript therefore uses the 37 verified studies as its evidence corpus.
- Single-analyst screening: no second independent reviewer and no inter-rater reliability statistic is available.
- Proprietary relevance algorithm: the Consensus ranking model is not independently auditable, and false negatives (relevant papers never surfaced) could not be assessed.
- Search-log limitation: exact platform query strings, execution dates, and platform-generated ranking scores for the 23 individual searches were not retained, limiting exact replication of the search process; Section 3.2 reports an illustrative representative formulation in place of a verbatim log.
- No formal quality-appraisal instrument (e.g., MMAT, CASP) was applied; the evidence-grading rubric in Table 4 is a purpose-built substitute, not an equivalent.
- No language restriction was explicitly enforced, and the retained corpus is entirely English-language by outcome rather than by declared protocol.
- Journal articles and conference proceedings were not differentiated by a separate quality weighting.
- A record-level exclusion log for the 52 records dropped between screening and eligibility was not preserved in exportable form.
- Drones, while discussed qualitatively as one of the six technology categories throughout Section 2, were not separately coded in the quantitative outcome-frequency matrix (Table 9) during data extraction, and are therefore absent from that table; no drone-specific frequency counts have been estimated or invented to fill this gap.

4. RESULTS

Table 5 summarises illustrative studies from the retained corpus, selected to represent the range of technology categories, sectors, and evidence types synthesised in Section 2. This table reports only the study-level detail available from the extracted source material; it is presented as a representative subset of the 37 verified included studies rather than an exhaustive table of all 37, since location, sample size, and full methodological detail were not uniformly retrievable for every included paper, itself a data-extraction limitation noted in Section 3.6.

Table 5: Representative Studies from the Reviewed Corpus, by Technology Category and Sector

Study	Technology Focus	Sector / Context	Principal Finding	Evidence Type
Akinlolu et al. (2020)	Construction safety technologies (bibliometric)	Construction	Maps research architecture of 240 construction-safety technology papers	Bibliometric review
Zhang et al. (2023)	IoT architectures	Underground mining	IoT enables simultaneous environmental, safety, and production monitoring	Technical review
Kukartsev et al. (2025)	Integrated IT / environmental monitoring	Regional mining complex	18–22% reduction in industrial/environmental risk (single site)	Case study
Di Martino et al. (2021)	Inherently safer design (ISD) framework	Chemical / process industry	58–70% safety improvement (single case)	Case study
Maali et al. (2024)	Construction safety technologies (taxonomy)	Construction	Categorises 129 articles (2018–2023) into four safety-technology functions	Systematic review
Yap et al. (2021)	BIM, robotics, wearables	Construction (Malaysia)	BIM and wearables show strongest individual safety effects	Empirical / survey study
Cacciuttolo et al. (2023)	Low-cost IoT sensors	Mining	Sensor networks as foundational layer for Industry 4.0 mining transformation	Systematic review
Liu et al. (2024)	Nanoparticle remediation	Soil and water	Nanoparticles function as efficient sorbents/catalysts for pollutant removal	Narrative review
Wu et al. (2024)	Functional nanomaterials	Environmental remediation	Calls for Safe and Sustainable-by-Design given unresolved exposure limits	Narrative review
Kuppula & Bhawani (2025)	Exoskeletons, jobsite technology	Construction	Productivity gains alongside unresolved long-term worker-health concerns	Thematic analysis

4.1 Sector Comparison: Mining and Oil and Gas

Both sectors rely on IoT sensing and automation as a core safety mechanism, but the specific hazard managed, and the quantified impact reported, differ, as summarised in Table 6. In mining, automation and remote-controlled equipment reduce human exposure to hazardous conditions and improve emergency response (Onifade et al., 2023; Arjunan et al., 2025); in oil and gas, offshore drilling safety advances include spill-prediction models, automated safety protocols, and emission-control measures such as carbon capture and flare-gas recovery (Alamutu, 2025). As already noted in Section

2.4, the 18–22% and 58–70% figures reported below are single-case findings and are not to be read as expected sector-wide effects.

Table 6: Comparison of Mining and Oil and Gas Safety Technology Applications

Dimension	Mining	Oil and Gas
Core technology	IoT sensors, automation, remote equipment	Real-time monitoring, predictive analytics, digital twins
Safety mechanism	Reduces human exposure to hazardous conditions	Detects anomalies before escalation
Environmental function	Proactive geotechnical and gas monitoring	Spill prediction, emissions control
Key barrier	Battery life; underground communication quality	Integration with legacy systems
Reported impact (single case; not generalisable)	18–22% risk reduction with integrated IT	58–70% safety improvement with ISD framework

4.2 Construction-Sector Evidence

Construction-sector evidence is comparatively richer in systematic reviews. A bibliometric analysis of 240 construction-safety technology papers establishes the field's overall research architecture (Akinlolu et al., 2020), while a subsequent systematic review of 129 articles (2018–2023) categorises construction safety technologies across four functional areas (Maali et al., 2024). Smart technologies, digital twins, IoT, and big data, are reported to enhance construction-site safety proactively while simultaneously optimising energy use and lowering carbon emissions (Seo & Yoon, 2025). This benefit is not unqualified: emerging construction technologies also introduce sustainability challenges of their own, including high energy consumption, electronic-waste generation, elevated implementation costs, and labour-market disruption, with exoskeletons specifically flagged as improving short-term productivity while raising unresolved questions about long-term musculoskeletal health, a claim graded weak in Table 7 given its reliance on a single thematic-analysis finding (Kuppula & Bhawani, 2025).

4.3 Evidence-Strength Assessment

Applying the operationalised rubric in Table 4 and the exception rule described in Section 3.5, Table 7 grades the strength of evidence behind the review's principal claims and reports the rubric criteria underlying each grade, rather than an unexplained qualitative label. The strongest-graded claim, that IoT and AI improve safety monitoring and hazard detection, is supported by four or more independent, high-quality sources converging across mining, construction, and oil and gas, with quantified outcome measures reported in at least two of those sources (Zhang et al., 2023; Dimkpa et al., 2025; Seo & Yoon, 2025; Akpe et al., 2024). Claims regarding digital twins/BIM and nanotechnology remediation are graded moderate under the default majority rule, reflecting two to three supporting studies with predominantly observational or conceptual designs and limited geographic diversity. The two single-case quantitative claims (18–22% and 58–70%) are graded moderate under the explicit exception described in Section 3.5, since a direct, quantified single-case outcome measure was judged to carry more evidentiary weight than an equivalent single-source qualitative claim, while still falling short of the replication and geographic-diversity needed for a strong grade. The weakest-graded claim, concerning exoskeleton health effects, satisfies none of the five criteria beyond a single qualitative source and receives the default weak grade with no exception applied.

Table 7: Evidence Strength for Key Claims, Graded Against the Rubric in Table 4

Claim	Independent Studies	Design Quality	Replication	Geographic Diversity	Overall Grade
IoT and AI improve safety monitoring and hazard detection	4+	Observational/quasi-experimental (multiple)	Multiple	4+ sectors	Strong
Digital twins/BIM enhance construction safety via proactive hazard identification	2–3	Observational + conceptual	Limited	2–3 contexts	Moderate
Nanotechnology enables remediation but poses toxicity risks requiring SSbD	3+	Laboratory / conceptual	Limited	Single domain (materials)	Moderate
Integrated IT deployment reduces industrial/environmental risk by 18–22%	1	Single case study	None	Single site	Moderate*
ISD framework improves safety by 58–70%	1	Single case study	None	Single site	Moderate*
Exoskeletons raise long-term worker-health concerns	1	Thematic analysis (qualitative)	None	Single context	Weak

*Graded moderate under the explicit exception in Section 3.5: a direct, quantified single-case outcome measure outweighs the single-study and no-replication criteria that would otherwise default to weak, but does not itself constitute evidence of generalisability — see Section 4.1 and the case-specific labelling applied throughout.

4.4 A Conceptual/Indicative Nigeria-Specific Adoption Framework

None of the 37 studies in the final synthesis reported an empirical Nigerian or West African case. The framework in Table 8 is therefore presented as a conceptual/indicative adoption framework, not an adoption index or measured assessment of Nigerian conditions. Its ratings are author judgments derived from the reviewed evidence and contextual reasoning, not Nigerian survey data, Delphi ratings, frequency counts, or weighted scores. The framework is a structured starting point for empirical validation and scores four priority technology groupings against twelve adoption-relevant dimensions using Low/Moderate/High ratings.

Table 8: Conceptual/Indicative Nigeria-Specific Technology-Adoption Framework (Author Judgment, Not a Measured National Readiness Index; Requires Empirical Validation)

Dimension	IoT / AI Monitoring	Digital Twins / BIM	VR Safety Training	Nanotech Remediation
Capital cost	Low–Moderate	High	Moderate	Moderate–High
Technical infrastructure need	Low–Moderate	High	Moderate	Moderate
Electricity/connectivity reliability need	Moderate	High	Moderate	Low
Skills availability (current)	Moderate	Low	Low	Low
Maintenance capacity required	Moderate	High	Moderate	Moderate
Regulatory readiness	Low	Low	Low	Low
Data governance exposure	Moderate	Moderate	Low	Low
Cybersecurity exposure	Moderate–High	Moderate	Low	Low
Organisational readiness	Moderate	Low	Low–Moderate	Low
Technology maturity (global)	High	Moderate–High	Moderate	Moderate
Environmental benefit (global evidence)	Moderate	Low–Moderate	Low	High
Safety benefit (global evidence)	High	Moderate	Moderate	Low

Read across dimensions, the framework indicates that IoT/AI monitoring combines the most favourable near-term adoption profile (comparatively low capital and infrastructure requirements against the strongest global safety-evidence base) with a genuine governance gap (low regulatory readiness, moderate-to-high cybersecurity exposure) that Nigerian regulators would need to address concurrently with, not after, deployment. Digital twins/BIM and nanotechnology remediation both show a wider gap between global technology maturity/environmental promise and local readiness (skills, infrastructure, or regulation), consistent with the near-total absence of developing-economy evidence identified in Section 4.5.

4.5 Research Gaps by Outcome Dimension

The 37-study corpus provides an uneven picture of evidence coverage. Counting, within the verified papers, how many address each of five outcome dimensions per technology category, Table 9 shows comparatively stronger empirical coverage for IoT safety monitoring and nanotechnology remediation, moderate coverage for AI predictive analytics and VR safety training, and less coverage for digital twins. Developing-economy evidence is particularly sparse: AI, VR, and digital twins record no papers specifically addressing such contexts, while IoT and nanotechnology each have only one. Drones are not separately coded in this matrix and are therefore excluded from the frequency counts.

Table 9: Number of Included Papers (of 37) Addressing Each Outcome Dimension, by Technology Category (Drones Not Separately Coded)

Technology	Empirical Validation	Long-Term Safety	Cost-Effectiveness	Developing Economies	Regulatory Frameworks
IoT safety monitoring	8	3	2	1	4
AI predictive analytics	6	2	1	0 (gap)	3
Nanotechnology remediation	9	5	2	1	4
VR safety training	5	1	2	0 (gap)	2
Digital twins	4	1	1	0 (gap)	2

This exclusion has a direct implication for how the gap analysis in this section should be read: because drones are not separately coded in Table 9, the research-gap picture presented here characterises five of the review's six technology categories rather than all six, and the apparent evidence coverage of the reviewed corpus as a whole is correspondingly incomplete rather than exhaustive. Drone-specific applications are still discussed qualitatively in Section 2.6 and appear in the technology-function matrix (Table 1) and the environmental-function synthesis (Table 2a), so the omission is confined to this specific outcome-dimension frequency count rather than to the review's coverage of drones generally; a coded drone row is identified in Section 3.6 as a specific target for the data-extraction protocol in any future update of this analysis.

5. DISCUSSION

The graded evidence supports a bounded set of conclusions. IoT- and AI-enabled monitoring has the strongest convergent evidence in the corpus, while digital twins/BIM, immersive technologies, and nanotechnology remain less mature. The 18–22% and 58–70% figures are single-case findings and should not be interpreted as general technology effects. The evidence therefore supports prioritising scalable monitoring and predictive applications while treating higher-cost or less mature technologies as context-dependent investments.

For Nigeria, the implication is not that globally better-supported technologies should be adopted uncritically. Rather, adoption should be phased according to infrastructure, skills, maintenance, governance, cybersecurity, and regulatory readiness. Read as an indicative, author-judgment proposition rather than as validated guidance, the conceptual framework in Table 8 suggests that IoT/AI monitoring may offer the most accessible near-term entry point, provided governance and cybersecurity measures develop alongside deployment; this reading should be treated as a hypothesis for empirical testing, not as an established prioritisation.

The oil and gas evidence carries a parallel, similarly bounded implication for the Niger Delta context. Offshore and onshore drilling safety advances, spill-prediction models, automated safety protocols, and emissions-control measures including flare-gas recovery, address categories of environmental harm that have historically defined Nigeria's upstream environmental challenges (Alamutu, 2025; Akerele et al., 2024). The inherently safer design (ISD) framework's reported 58–70% safety improvement (Di Martino et al., 2021) illustrates the scale of improvement that engineering-controls-first approaches can plausibly achieve relative to administrative controls or PPE-led interventions alone, consistent with broader process-industry evidence that combining engineering controls, administrative controls, PPE, and behavioural interventions outperforms any single intervention type (Benson et al., 2023), but the specific 58–70% figure itself remains a single-case artefact that should inform expectations only qualitatively, not quantitatively.

The review's risk categories are particularly relevant to Nigerian implementation. Responsible-development principles should accompany deployment so that technologies introduced to improve

safety do not create new occupational, privacy, cybersecurity, or environmental risks. AI and IoT systems require data governance and cyber controls; nanomaterials require exposure and life-cycle safeguards; and digital twins require reliable infrastructure and technical skills. These are governance conditions, not findings measured in Nigeria.

This review's limitations, detailed in full in Section 3.6, bear directly on how its findings should be used. As a single-analyst, platform-assisted synthesis of secondary sources without a formal quality-appraisal instrument, it inherits real reproducibility constraints. The Nigerian policy implications drawn here are, without exception, extrapolations from global evidence rather than findings validated within Nigeria itself, and the framework in Table 8 should be read as a proposed research and investment agenda awaiting empirical testing, not as a confirmed characterisation of Nigerian conditions.

6. CONCLUSIONS

This review synthesised 37 verified peer-reviewed studies on emerging technologies for safety and environmental protection across construction, mining, and oil and gas engineering. Its contributions are threefold: a cross-sectoral evidence-graded map of six technology categories; an operationalised evidence-grading rubric with transparent limitations; and a twelve-dimension, explicitly indicative Nigerian adoption framework. The evidence is strongest for IoT- and AI-enabled monitoring and more limited for digital twins/BIM, immersive technologies, and nanotechnology. The review supports phased adoption of scalable monitoring and predictive technologies, accompanied by regulatory, cybersecurity, occupational-exposure, and workforce-development measures.

For policy, the findings support three concrete actions, each qualified by the review's evidentiary limits and by the conceptual, not empirically validated, status of the Table 8 framework from which the second and third actions draw: strengthening NESREA and sector-regulator capacity to evaluate emerging-technology deployments, guided by the regulatory-readiness gap identified in Table 8 rather than by the single-case quantitative figures reported in Section 4; incentivising phased, low-cost sensor and predictive-analytics adoption among small- and medium-scale mining and construction operators, as the technology category with both the strongest global safety evidence and, on the indicative framework's author-judgment ratings only, the most favourable near-term adoption profile; and establishing local occupational-exposure guidance for engineered nanomaterials ahead of, rather than after, wider deployment, given the unresolved global exposure-limit gap identified in Section 2.7. Each action should be piloted and revisited as the Table 8 ratings are empirically tested, rather than treated as settled by this review alone.

These contributions connect directly to ICESID 2026's conference theme, “Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development.” The twelve-dimension adoption framework operationalises that theme at the level of individual technology-adoption decisions: it gives engineering practitioners and regulators a structured, if indicative, basis for harnessing globally emerging technologies in a manner calibrated to Nigeria's present infrastructure, skills, and regulatory conditions, rather than importing innovation agendas wholesale from better-resourced economies. In that sense, the framework's central proposition, that sustainable engineering-driven growth depends on matching technology adoption to demonstrated local readiness rather than to global technology maturity alone, is offered as a direct, if empirically provisional, contribution to the conference's growth-and-sustainability agenda for Nigerian engineering.

Priority future research includes empirical validation of the Table 8 framework under Nigerian mining, construction, and oil and gas conditions; longitudinal studies of worker-health outcomes for wearable and exoskeleton technologies; techno-economic evaluation of AI predictive-maintenance deployment; and locally grounded governance research on AI monitoring, privacy, and data protection. These studies would address the central limitation of the current literature: the shortage of Nigeria-specific empirical evidence on emerging technologies for safe and environmentally responsible engineering.

ABSTRACT
Coupling a microbial electrolysis cell (MEC) with anaerobic digestion (AD) is an effective approach to improving methane yield from agricultural waste. The current research focuses on the optimization, kinetics, and thermodynamic analysis of the MEC–AD hybrid system using cow dung and poultry dung as substrates. The physicochemical characterization results show that cow dung has higher volatile solids (78.20%) and a C:N ratio of 26.0, while poultry dung contains 62.35% volatile solids and a C:N ratio of 6.26. Based on mass balance calculations, the optimum substrate mixture containing 98.3% cow dung and 1.7% poultry dung is obtained to reach the optimum C:N ratio of 25:1. The optimization process was carried out by applying Response Surface Methodology using Central Composite Design involving applied voltage (0.3–1.5 V), pH (6–8), and C:N ratio (15–35). The proposed quadratic equation showed a high prediction accuracy (R^2 = 0.9997) and obtained the optimum values of 0.97 V, pH 7.0, and C:N ratio of 25 with the optimum methane yield of 350.73 mL CH_4 g^{-1} VS. Based on kinetic analysis using the Modified Gompertz model, the ultimate methane potential, maximum methane production rate, and lag phase were found to be 378.33 mL CH_4 g^{-1} VS, 41.25 mL CH_4 g^{-1} VS day^{-1}, and 1.36 days, respectively. Thermodynamic analysis showed that the process achieved 91.02% energy efficiency, 73.8% exergy efficiency, and an EROI of 29.55, confirming its favorable energetic and thermodynamic performance. Overall, the hybrid MEC–AD process significantly improved the methane yield.

Keywords: *Anaerobic digestion; Microbial electrolysis cell; Cow dung; Poultry waste; Methane production*

1. INTRODUCTION

The growing demand for energy and the environmental effects of fossil fuels have attracted the attention of researchers toward renewable energy generation systems. Anaerobic digestion (AD) is one of the promising approaches to produce methane, the main component of biogas, from organic wastes and address waste management issues (Angelidaki et al., 2009; Mao et al., 2015a). However, the conventional AD process can be affected by low methane production, substrate inhibition, and slow degradation (Appels et al., 2008).

Coupling AD with a microbial electrolysis cell (MEC) has been proposed to overcome the above problems. Low current input can increase the activity of electroactive microorganisms, facilitate direct interspecies electron transfer (DIET), and increase methane formation from organic waste (Ao et al., 2024; Wang et al., 2024). The applied voltage can accelerate the metabolism of microorganisms, increase electron transfer between them, and reduce the lag time before methane generation (Kaneko et al., 2025; Worajo et al., 2025).

Cow dung and poultry dung can be considered as suitable substrates for MEC-AD technology, since these are abundant agricultural wastes which contain biodegradable organic compounds (Kafle & Chen, 2016; Telo & Yigezu, 2025). Nevertheless, each of these substrates has certain drawbacks, which can affect the digestion performance. High nitrogen concentration in poultry dung can cause the accumulation of ammonia and inhibit methanogenic bacteria (Zhao et al., 2021). Moreover, the presence of lignocellulose in cow dung slows down its decomposition and limits the digestion rate (Zhang et al., 2025). The co-digestion process can increase the balance of nutrients and the stability of the microenvironment for methane-producing microorganisms (Mao et al., 2015b).

In this study, the possibility of improvement in methane production in the integrated MEC-AD system was investigated. First of all, the substrates were characterized from physicochemical and elemental perspectives. Additionally, Response Surface Methodology (RSM) was used for optimization of the operational parameters of the system. Kinetics of methane production was modeled using the Modified Gompertz model and validated with independent experiments (Sheron et al., 2026). Finally, energy, thermodynamic, and exergy analysis of the MEC-AD system was conducted.

2. METHODOLOGY

2.1 Substrate Collection and Preparation

Fresh cow dung and poultry dung were obtained from the Teaching and Research Farm at Ahmadu Bello University in Zaria, Nigeria. The poultry dung included both droppings and bedding materials used in poultry houses. The samples were placed in sealed containers, taken to the lab, and kept at 4°C to prevent changes before testing. Before starting the experiments, each type of material was mixed well. The mixture was passed through a 2 mm sieve to remove large fragments. Distilled water was added to dilute the solids to between 8% and 10%. This range is known to be good for digestion (Chojnacka & Moustakas, 2024).

2.2 Physicochemical and Elemental Analysis

The physicochemical tests followed the methods from APHA (2017). Total solids were found by drying the samples in an oven at 105°C. Volatile solids were measured by burning the dried samples at 550°C. Chemical Oxygen Demand was tested using the reflux titrimetric method. Total Organic Carbon was found with the Walkley- wet oxidation method (Nelson & Sommers, 1996). Total Nitrogen (Kjeldahl) was measured using Kjeldahl digestion and distillation (Evers & Hughes, 2002). The carbon-to-nitrogen ratio was calculated from the values of total organic Carbon and total Nitrogen as:

$$C:N = \frac{\%TOC}{\%TKN} \quad (1)$$

To get a carbon-to-nitrogen ratio of 25 to 1, the amounts of cow dung and poultry waste were estimated using this mass-balance equation:

$$\frac{M_{CD}}{M_{PW}} = \frac{N_{PW}\times 25 - C_{PW}}{C_{CD} - N_{CD}\times 25} \quad (2)$$

2.3 MEC-AD Reactor Design and Setup

Experiments were carried out on a lab-scale apparatus that coupled microbial electrolysis with anaerobic digestion. The reactor consisted of a double-chamber configuration with a working volume of 1.5L. A graphite rod (10 × 100 mm) was used as the anode, while a 50 × 50 mm 304 stainless-steel mesh was used as the cathode. Both parts were connected to a power supply that could provide 0-2 V to maintain a steady voltage. The anode was inserted into the substrates to help transfer electrons through the microbes. The cathode was placed in the part of the reactor where hydrogen formed and then was used by other microbes to make methane (Shao et al., 2025). All experiments were done in batch mode at a temperature of 30 to 37 degrees Celsius.

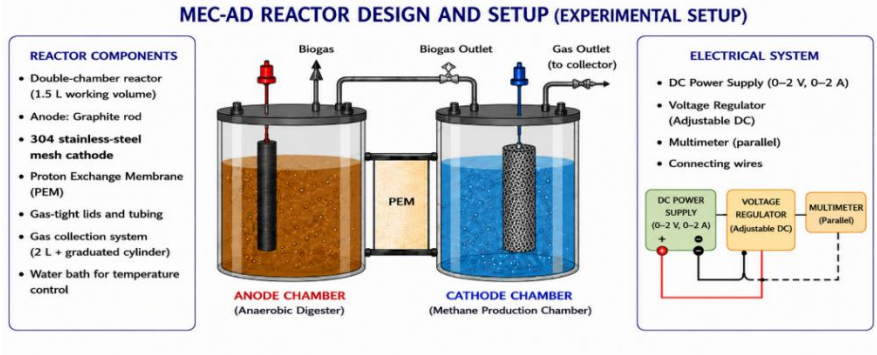

Figure 1: Schematic Diagram of the Coupled MEC–AD Reactor and Experimental Setup

2.4 Experimental Design and Optimization

The process was optimized using Response Surface Methodology based on a Central Composite Design. Three factors were considered: voltage (0.3 to 1.5), pH (6 to 8), and C:N (15 to 35). There were 20 runs in total. These included eight factorial points, six axial points, and six center points. The amount of methane produced was the response.

The data were fitted into a second-order model that had the equation:

$$Y = \beta_0 + \sum_{i=1}^{3} \beta_i X_i + \sum_{i=1}^{3} \beta_{ii} X_i^2 + \sum_{i=1}^{2} \sum_{j=i+1}^{3} \beta_{ij} X_i X_j + \epsilon \quad (3)$$

Analysis of variance was done at a 95% confidence level to check how good the model was and which factors were important. This was done using Design-Expert® Version 13 (Stat-Ease Inc.).

2.5 Kinetic Modeling

The methane production was described using the Modified Gompertz model:

$$B(t) = B_0 \times \exp\left\{-\exp\left[\frac{R_{max} \times e}{B_0}(\lambda - t) + 1\right]\right\} \quad (4)$$

where **B(t)** is the total methane produced at time **t, B_0** is the maximum methane possible, R_{max} is the maximum rate of methane, **λ** is the lag phase, and **e** is Euler's constant.

The model parameters were estimated using nonlinear regression in Python Version 3.9. with optimization carried out using the Levenberg-Marquardt algorithm

2.6 Development of Enhancement Factors and Global Model Integration

Voltage, pH, and carbon-to-nitrogen ratio all influence methane production. To account for changes in reactor performance across operating conditions, explicit enhancement factors were fitted and integrated into the Modified Gompertz parameters (B_0, $R_{\max}$, and λ).

2.6.1 Voltage Enhancement Factors

Raw experimental data for ultimate methane potential (B_0) and production rate ($R_{\max}$) at different applied voltages ($0.3 - 1.5$ V) obtained from the literature were fitted using polynomial regression in Python (Version 3.9)(Zou et al., 2021). The resulting unnormalized polynomial models showed strong coefficients of determination ($R^2 = 0.9897$ for B_0 and $R^2 = 0.9884$ for $R_{\max}$) To derive dimensionless enhancement multipliers ($f(V)$), the raw curves were normalized to their baseline values at the optimal reference voltage (V_{ref} = 1.0 V, where $B_{0,raw}(1.0)$ = 328.9 mLCH_4 g^{-1}VS and $R_{max,raw}$ (1.0) = 24.312 mLCH_4 g^{-1}VS day^{-1})

$$f_{B0}(V) = -1.207V^4 + 4.504V^3 - 6.815V^2 + 4.520V \quad (5)$$

$$f_{R\max}(V) = 3.933V^5 - 17.315V^4 + 27.680V^3 - 19.827V^2 + 6.525V \quad (6)$$

For the lag phase (λ), applied voltage reduces adaptation time at lower voltages ($V \leq 1.0$ V) but induces electrochemical stress at higher voltages ($V > 1.0$ V). A hybrid piecewise function was developed:

$$\lambda(V) = \begin{cases} \frac{1}{k(1+\alpha V+\beta V^2)}, & V \leq V_{\text{opt}} \\ \frac{1+\left(\frac{V-V_{\text{opt}}}{K_I}\right)^n}{k(1+\alpha V+\beta V^2)}, & V > V_{\text{opt}} \end{cases} \quad (7)$$

A two-step regression approach was applied: linear transformation ($y = \frac{1}{\lambda}$) determined quadratic growth constants (k, α, β), while non-linear regression fitted the inhibition threshold (K_I) for $V > 1.0$ V, before normalizing relative to $\lambda(1.0\text{ V})$.

2.6.2 pH and C:N Ratio Enhancement Factors

The effects of pH and C:N ratio were modeled using Gaussian functions centered around their optimal values ($\mu = 7.0$ for pH; $\mu = 25$ for C:N) to reflect symmetric performance decay away from ideal conditions:

$$f_{B0}(\text{pH}) = \exp\left(-0.5 \times \left[\frac{\text{pH}-7.0}{0.8}\right]^2\right) \quad 8$$

$$f_{B0}(\text{C:N}) = \exp\left(-0.5 \times \left[\frac{\text{C:N}-25}{7.0}\right]^2\right) \quad 9$$

Standard deviations (σ) for $R_{\max}$ were set to 0.7 (pH) and 9.0 (C:N), while σ values for λ were 1.0 (pH) and 11.0 (C: N).

2.6.3 Global Kinetic Integration

Following autonomous multiplicative bioprocess modeling frameworks (such as IWA ADM1), the individual enhancement factors modify baseline kinetic parameters ($B_{0,\text{base}} = 498$ mL g^{-1} VS, $R_{\text{max,base}} = 23$ mL g^{-1} VS day^{-1}, $\lambda_{\text{base}} = 3.2$ days):

$$B_{\text{total}} = B_{0,\text{base}} \times f_{B0}(V) \times f_{B0}(\text{pH}) \times f_{B0}(\text{C:N}) \quad 10$$

$$R_{\text{total}} = R_{\text{max,base}} \times f_{R\text{max}}(V) \times f_{R\text{max}}(\text{pH}) \times f_{R\text{max}}(\text{C:N}) \quad 11$$

$$\lambda_{\text{total}} = \lambda_{\text{base}} \times f_{\lambda}(V) \times f_{\lambda}(\text{pH}) \times f_{\lambda}(\text{C:N}) \quad 12$$

Substituting these into Equation (4) yields the global predictive kinetic equation:

$$B(t, V, \text{pH}, \text{C:N}) = B_{\text{total}} \cdot \exp\left(-\exp\left[\frac{R_{\text{total}} \cdot e}{B_{\text{total}}}(\lambda_{\text{total}} - t) + 1\right]\right) \quad 13$$

2.7 Thermodynamic and Exergy Analysis

Methane energy was calculated using:

$$E_{CH_4} = V_{CH_4} \times \rho_{CH_4} \times LHV_{CH_4} \quad 14$$

where the lower heating value (**LHV**) of methane was taken as **50 MJ/kg**, while methane density was taken as **0.716 kg/m³** (Nindhia et al., 2021).

Overall energy efficiency was determined from:

$$\eta_{energy}(\%) = \left(\frac{E_{CH_4}}{E_{in}}\right) \times 100 \quad 15$$

Exergy analysis was also performed to determine how effectively the available energy was converted into useful work. Electrical energy was assigned an exergy factor of **1.0**. Methane was assigned an exergy factor of **0.94**, making it possible to evaluate energy losses occurring within the coupled MEC-AD system (Dinçer & Rosen, 2021).

3. RESULTS AND DISCUSSION

3.1 Substrate Characterization

Table 1: Substrate Characterization

Parameter	**Cow Dung**	**Poultry Dung**
Total Solids (TS, %)	9.85	8.40
Volatile Solids (VS, % TS)	78.20	62.35
COD (g L^{-1})	95.40	68.20
Ash Content (% TS)	21.80	37.65
Carbon (%)	38.5	31.3
Nitrogen (%)	1.48	5.00
C:N ratio	26.0	6.26

Cow dung demonstrated higher volatile solids (VS) content (78.20%) and chemical oxygen demand (COD) (95.40 g/L) compared to poultry dung (62.35% and 68.20 g/L), indicating the presence of a greater amount of biodegradable organic matter that could be used to produce methane. The VS content of cow dung fits the typical 70-85% range of ruminant manure, reflecting the partial

lignocellulosic breakdown before being excreted. The C:N ratio of cow dung is 26.0, falling within the recommended 20-30 range of anaerobic digestion. On the contrary, poultry dung possessed a C:N ratio of 6.26 because of its increased nitrogen content (5.00%), which could promote the formation of ammonia and inhibit methanogenesis. Mass balance shows that 98.3% of cow dung and 1.7% of poultry dung satisfied the requirement of the target C ratio of 25:1.

3.2 Optimization of MEC-AD Operating Parameters

In the 20 central composite design (CCD) experiments, methane yield ranged from 50.69 to 350.73 mL CH4/g VS, showing a strong dependence on process conditions. The six center-point runs at 0.90 V, pH 7.0, and C:N ratio of 25 produced the maximum methane yield of 350.73 mL CH_4 g^{-1} VS, with a standard deviation below 0.01, demonstrating excellent reproducibility. The quadratic model proved to be highly significant ($F = 3201.86$; $p < 0.0001$), with $R^2 = 0.9997$, Adjusted $R^2 = 0.9993$, Predicted $R^2 = 0.9982$, and Adequate Precision = 128.074, which demonstrates a good correlation and ratio of signal to noise. The reduced quadratic model in coded variables was expressed as:

$$\ln(Y) = 5.85 + 0.0669A - 0.4013A^2 - 0.9378B^2 - 0.5261C^2$$

Denoting Y as the methane yield (mL CH4 g^{-1} VS), A, B, and C stand for the coded values of applied voltage, pH, and C:N ratio, respectively. Since there is a positive linear coefficient related to voltage, the initial increase in methane yield with the increase in applied voltage can be expected. However, due to the presence of the negative quadratic coefficients, it can be deduced that there are optimal operation ranges after which the methane production decreases.

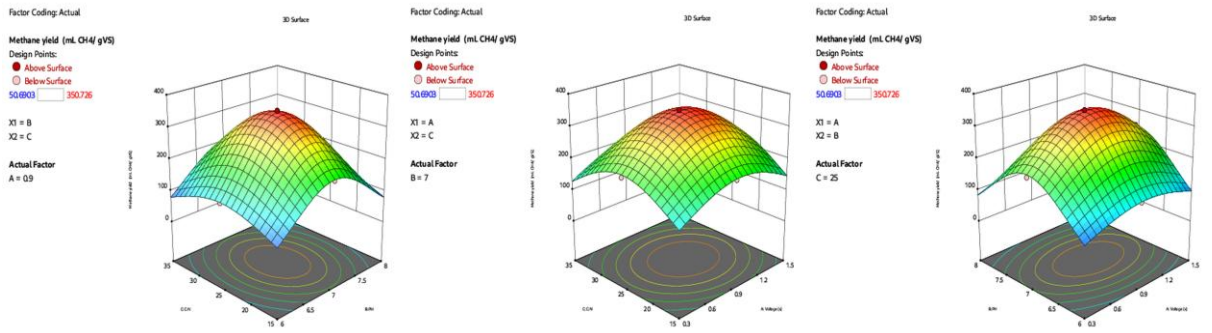
3.3 Interactive Effects of Process Variables

3.3.1 pH and Carbon-to-Nitrogen Ratio

The pH–C response surface revealed a dome-shaped graph, characterized by a sharp peak. Maximum methane production happened at pH 6.8-7.2; pH lower than 6.5 caused the accumulation of volatile fatty acids and inhibited methanogenesis, whereas pH higher than 7.5 shifted the ammonium-ammonia equilibrium towards the inhibitory free ammonia (NH_3).

Methane yield was higher than 300 mL CH_4/g VS in the range of C 25. The C ratios lower than 20 contributed to ammonia formation due to the excess of nitrogen, whereas those higher than 30 inhibited microbial growth because of the deficiency of nitrogen.

3.3.2 Applied Voltage and Carbon-to-Nitrogen Ratio

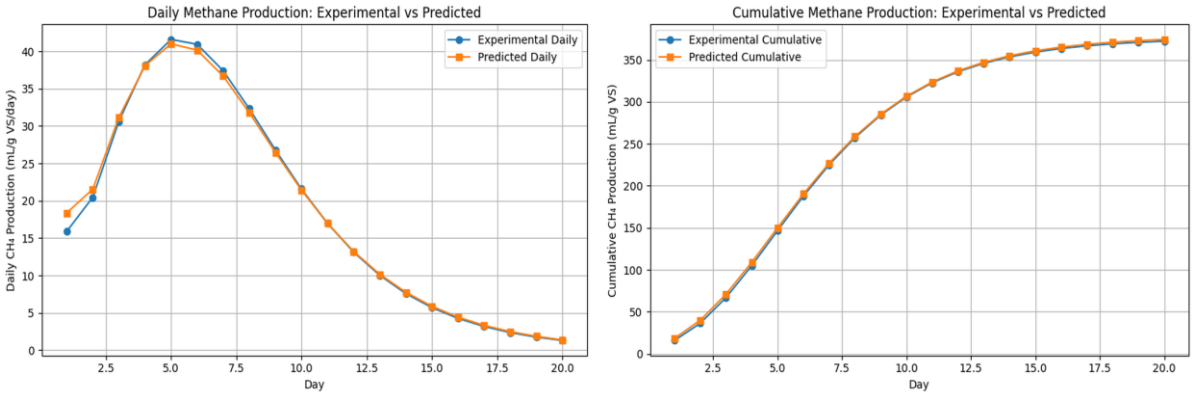


The voltage range optimal for methane production was about 0.6-1.2 V, where the electrical stimulation promoted electron transfer and organic matter degradation.

Below 0.6V, the thermodynamic driving force was not sufficient to stimulate the electroactive microorganisms, and above 1.2 V, the performance decreased probably due to electrochemical stress and water electrolysis.

3.3.3 Applied Voltage and pH

The voltage–pH response showed that electrical stimulation was most effective under favorable microbial conditions.



The combination of 0.9 V and pH 7.0 facilitated the methanogenic activity. Increasing the voltage without appropriate pH weakened the electrochemical effects; thus, it was necessary to optimize both voltage, pH, and C:N ratio.

3.4 Kinetic Modeling

The Modified Gompertz model was built under optimized conditions (0.97 V, pH 7.0, C 25) based on the cumulative, daily, and joint methane data. The joint fit revealed the true behavior of the reactor better than the cumulative and daily ones and provided the ultimate methane potential (P) of 378.33 mL CH_4/g VS, maximum production rate (R_{max}) of 41.25 mL CH4/g VS/day, and lag phase (λ) of 1.36 days. The R^2 values of the cumulative and daily fits were 0.99965 and 0.99497, respectively. Methane production attained 10%, 50%, and 90% of the calculated potential after 1.92, 5.97, and 12.33 days, respectively.

Compared with conventional anaerobic digestion reported in the literature, the MEC–AD system increased methane yield by approximately 17–40%, increased methane production rate by 64–118%, and reduced the lag phase by approximately 55–82%. These comparisons were based on literature-reported conventional AD performance rather than a parallel conventional-AD control experiment conducted in the present study

3.5 Model Validation

Three independent experiments out of the data set used for the model development provided the average prediction error of 6.26%. The R^2 value of the model validation of 0.9987 proves that the model explained 99.87% of the variance in the methane yield, which means a good predictive ability within the investigated operating range.

3.6 Thermodynamic Performance

For optimal working conditions, the consumption of electrical and thermal energies per batch in the MEC-AD process was 6.70×10^{-4} MJ and 0.0627 MJ, respectively. However, for substrate chemical and methane energy yields, these values were 1.99374 MJ and 1.87234 MJ, respectively. As a result, the net energy obtained is 0.18477 MJ, and an efficiency of 91.02% has been observed. The energy return on investment (EROI) is 29.55, and it is evident that there is significantly more energy yield from methane than the electrical energy input into the system. The total exergy of input was 2.381 MJ, where the contribution from the substrate was 2.380 MJ, 0.00067 MJ was attributed to the electrical input, and 0.000267 MJ was attributed to the thermal input. The exergy of methane energy output was 1.758 MJ, whereas that of irreversibility destruction was 0.623 MJ. Therefore, the exergy efficiency

was 73.8%, while the ratio of exergy destruction was 26.2%. This is because the exergy balance fulfilled the equation 1.758 + 0.6.

4. CONCLUSIONS

This study demonstrated the potential of coupling microbial electrolysis with anaerobic digestion for enhanced methane recovery from cow dung and poultry dung. Cow dung contained 78.20% VS, 38.5% carbon, 1.48% nitrogen, and a C:N ratio of 26.0, while poultry dung contained 62.35% VS, 31.3% carbon, 5.00% nitrogen, and a C:N ratio of 6.26. Carbon–nitrogen balancing produced an optimum mixture of 98.3% cow dung and 1.7% poultry dung at a target C:N ratio of 25.

RSM optimization identified 0.97 V, pH 7.0, and C:N 25 as the optimum operating conditions, with a maximum observed methane yield of 350.73 mL CH_4 g^{-1} VS. The reduced quadratic model provided an excellent fit with R^2 = 0.9997, adjusted R^2 = 0.9993, and predicted R^2 = 0.9982. The Modified Gompertz model gave an ultimate methane potential of 378.33 mL CH_4 g^{-1} VS, maximum methane production rate of 41.25 mL CH_4 g^{-1} VS Day^{-1}, and lag phase of 1.36 days. Independent validation produced an average prediction error of 6.26% and R^2 = 0.9987.

The thermodynamic analysis indicated 91.02% energy efficiency and an EROI of 29.55. The corrected exergy analysis gave 2.381 MJ total input exergy, 1.758 MJ methane exergy, 0.623 MJ exergy destruction, 73.8% exergy efficiency, and 26.2% exergy destruction ratio. These results demonstrate that the system was energy-positive and achieved substantial conversion of substrate exergy into methane.

For Nigeria, the approach has practical potential because livestock production generates large quantities of manure that can be difficult to manage safely and productively. A decentralized MEC–AD system could provide a pathway for converting manure into renewable methane while reducing uncontrolled decomposition and improving nutrient management. Nevertheless, the present work was conducted at laboratory scale and should not be interpreted as proof of immediate commercial viability. Scale-up challenges include electrode and membrane cost, electrode durability and fouling, electrical-control requirements, mixing, feedstock variability, continuous-operation stability, heat management, and the economics of integrating the MEC subsystem with existing digesters.

Future work should therefore include pilot- and semi-continuous-scale testing, long-term electrode performance assessment, optimization of electrode configuration, process automation, techno-economic analysis, and life-cycle assessment under Nigerian agricultural conditions. Such studies are needed to determine whether the observed laboratory-scale performance can be maintained at practical scale and under variable real-world feedstock conditions.

ABSTRACT

This study presents the flood inundation risk evaluation of the dam formerly called Kubanni, an earthen dam with a water catchment area of 57 km^2, situated in Zaria area, Kaduna State, Nigeria. The research aims to explain the pattern of dam breach by modeling it in three different return periods, (30, 50, and 100 years) and the hazard posed by the dam. HEC-RAS with QGIS software was used to run unsteady flow simulation of the dam break for piping failure. The breach parameters like the width of the bottom, the slope on the sides, and the time to formation were all obtained using empirical regression equations of Froehlich (2008), and as a result, the downstream hazard was mapped in several risk zones. The discharges during breach were 1,426.56m^3/s, 1,697.71 m^3/s, and 1,758.04 m^3/s respectively for the three events. The flood events lasted for approximately 1 hour (30 and 50 year return periods) and 3 hours (100-year return period). The floodwater covered a distance of more than 10 km with Zango, Hanwa, Yan Karfe, and parts of Northeast Tudun Wada showing high flood vulnerability. Approximately 2,705 residences and several croplands located along the floodplain are in great danger from floods. The flood water took the minimum time of 10 sec reaching the nearest zone against the farthest zone where the water reached after 20min at the fastest depth level of 16.3m. These findings can assist dam safety management, land use regulation, and even the establishment of an early warning system at community level in other regions with similar challenge not monitored well.

Keywords: *dam break analysis; piping failure; flood inundation mapping; ABU Dam*

1 INTRODUCTION

Dams are probably the most strategically important of all hydraulic structures. By controlling the river flow, they provide irrigation, domestic water supply, industrial water use and downstream flood attenuation services, which together form the basis of livelihoods for the million people around the world. (Alhassan et al., 2019) stated the benefits of dams in the provision of these water services. However, it is the very energy that the reservoir releases that the structural failure would have devastated effect. There is dam failure recorded on all inhabited continents, and some have had only crop losses, while others have resulted in total destruction of communities in the downstream areas (Aureli et al., 2021). More exactly, in Nigeria, the majority (>81%) (Umaru et al., 2010), the dam types vulnerable to two dominant failure mechanisms: overtopping and internal erosion (piping). Piping is very dangerous because the failure might even pass unnoticed until a catastrophic collapse happens. (Foster et al., 2000) From the study and analysis of dam failure databases on a worldwide scale, the percentage of internal erosion in embankment dam failures is around 40% (Jandora & Riha, 2009). This amplifies more the impacts in cases of dam failures in the West Africa due to factors like: downstream urban settlements being more dense; agricultural plots close to floodplains; and unavailability of an early warning system and associated infrastructure(Okeola et al., 2025).

Kubanni Dam was originally known as ABU Dam before being incorporated into the water supply system of Ahmadu Bello University (ABU). The dam is a simple earthwork built along the Kubanni River in Zaria, Kaduna State, Nigeria (Latitude: 11°08′03.18″ N Longitude: 7°39′15.67″ E). Given that the dam has a catchment area of 57 km², average water depth of 6 m, and a reservoir volume

of more than 2.6 million m^3 of water at normal water level, it gives the main water resource for the university campus and various nearby communities. Even though this dam is very essential for the people who are getting settled in the city at a fast pace, prior research on the topic of dam breaks and quantitative risk of downstream floods was not published about the structure until this study. As a result, emergency planners, Dam safety engineers, and community heads are unable to develop reliable response strategies without the relevant information.

This study addresses the identified research gap by developing an integrated dam-break assessment framework for Zaria Dam using HEC-RAS unsteady-flow hydraulic modelling and QGIS-based spatial analysis. The study simulates a piping-induced dam failure under 30-, 50-, and 100-year return-period inflow conditions to evaluate potential downstream flood hazards. Unlike previous studies, this research provides the first comprehensive dam-break assessment for Zaria Dam by integrating HEC-RAS hydraulic modelling with GIS-based inundation mapping and google satellite basemap imagery to improve the delineation, visualization, and interpretation of flood-prone areas. Furthermore, the study incorporates community-level risk characterization to support dam safety assessment, emergency planning, and informed decision-making for downstream communities. It further evaluates multiple hydrological return periods to capture the influence of increasing flood magnitude on downstream hazard, thereby offering a more comprehensive assessment than studies based on a single design event. The adopted framework is consistent with recent applications of HEC-RAS and GIS for dam-break assessment in data-scarce environments (Beza et al., 2023; Mo et al., 2023), while extending their application through a site-specific multi-scenario risk assessment for eleven downstream communities. Consequently, the study provides a practical decision-support framework for dam safety management, land-use planning, and emergency preparedness in the Zaria region.

1.1 Historical Context of Earthen Dam Failures

Today in Africa, most earthen dams that were poorly maintained, have been built in the 1960s to 1980s through post-independence development programs, pose a growing safety threat as they confront changing rainfall patterns through their deteriorating infrastructure(Moreno-Rodenas et al., 2025).

In the country, a failed Cham Dam incident at Gombe State is a notable example: an inadequate spillway capacity coupled with seepage-induced internal erosion caused a sudden major breach, which resulted in the large death toll downstream and damage of property (Umaru et al., 2010). Generally, a major problem with many dams in the sub-Saharan area is lack of maintenance or safety checking of dams and only slow adoption of quantitative methods for predicting breaches so that local residents living near old embankment dams rarely know how much danger they face (Okeola et al., 2025).

1.2 Mechanisms of Embankment Dam Failure

Two failure mechanisms dominate embankment dam loss: overtopping and internal erosion. Overtopping occurs when reservoir levels surpass the dam crest, typically during inflow floods that exceed spillway design capacity or when debris blocks the spillway. The uncontrolled flow of water over and down the downstream face rapidly initiates erosion of the embankment material, a process that accelerates non-linearly until breach formation is complete (Jandora & Riha, 2009). For small catchment dams such as ABU Dam, a single extreme precipitation event can generate inflows that exceed the design discharge standard, making overtopping a credible scenario even at moderate return periods.

The second type of failure mechanism -internal erosion- occurs through a form of internal "piping". It typically starts in those parts where the permeability of materials is higher or in case the dam is built on an impermeable layer (Jandora & Riha, 2009) (e.g. in case of leakage). It is the so called "piping." The fine soils particles get washed from the source location and are taken further downstream until a bigger and bigger channel is created. At a certain point the velocity of the flow of the particles is so high that the particles themselves help in forming the channel, making the process almost endless until the failure of the dam structure (Foster et al., 2000).

In reality, this piping failure mode has a reinforcing loop to the dam can go from a perfectly good working condition to complete failure in a matter of seconds. As (Zhang, et al., 2007) researched,

if the reservoir level is raised then there is an enhancement in the hydraulic gradient resulting in an increase in the likelihood of the pipe starting. This is mainly important for ABU Dam, where the reservoir capacity is always near full during the rainy season. Piping was the primary failure mechanism considered for this dam because the spillway has adequate capacity for the design flood, based on (Bharath et al., 2021); as a result, spillway overtopping due to flood was not considered a likely failure mode. That means internal erosion like piping is much more likely scenario for triggering the failure in this dam than the external ones like overtopping.

1.3 Dam Break Analysis

One of the most popular platforms for performing both steady and unsteady flows in one-dimensional (1D) and two-dimensional (2D) cases is HEC-RAS developed by and under the control of US Army Corps of the Engineers Hydrologic & Hydraulic Engineering Center. The breach modeling capacity of this tool has been found applicable to various dam types and locations including earthen dams in Africa (Beza et al., 2023; HEC, 2023). Newer research shows that for rivers having clearly defined cross-sectional geometry, it is still valid to rely on 1D HEC-RAS model to simulate flows and that the results it generates are detailed enough to help with EAP creation even when further GIS processing is done on them (Mo et al., 2023)

GIS-based spatial analysis Mostly through QGIS is being increasingly used for creating risk maps that can be used for risk reduction and management efforts. HEC-RAS outputs together with satellite images and digital elevation maps can be used as reference inputs for inundation areas classification and quantification in the GIS environment, about land use types and settlement density (Aureli et al., 2021)

2 MATERIALS AND METHODS

ABU Dam (Kubanni Dam), a gravity earth dam, was built in 1970s in the Kubanni River Zaria Kaduna State, Nigeria of Ahmadu Bello University (Yusuf, 2013). The dam is located in a watershed which is covered mainly in savannah vegetation, rolling hills, and seasonally changing water flow regime. (Yusuf, 2013) After the dam, the Kubanni valley becomes a narrow flood plain and then extends to a peri-urban area with a high population density, residential houses shops market places gardens small farms and schools. This study did not include overtopping failure as a consideration. The Kubanni (ABU) Dam has a central spillway that is sufficient to carry design flood inflows so overtopping would be practically impossible failure pathway for the scenarios presented. Piping failure was, because of this, considered as the main failure mechanism that matches the dam's physical condition and that is in line with practice for embankment dams whereby internal erosion is the more likely failure mode than crest overtopping. Table 1 describes the main structural and geometric features of the dam.

Table 1: Key structural and geometric parameters of ABU Dam (Kubanni Dam), Zaria

Parameter	**Value**
Location	Latitude: 11°08′03.18″ N Longitude: 7°39′15.67″ E, Zaria, Kaduna State, Nigeria
Dam Classification	Earthen embankment
Top of Dam Elevation	645.38 m a.s.l.
Breach Bottom Elevation	632.53 m a.s.l.
Dam Crest Width	5 m
Mean Water Depth	6 m
Crest Length	122 m
Catchment Area	57 km²
Reservoir Capacity	~2.6×10^6 m³
Upstream Face Slope (Z1, H:V)	1:2.5
Downstream Face Slope (Z2, H:V)	1:2
Pool Volume at Failure	$22{,}600 \times 10^3$ m³

2.1 Data Acquisition and Terrain Representation

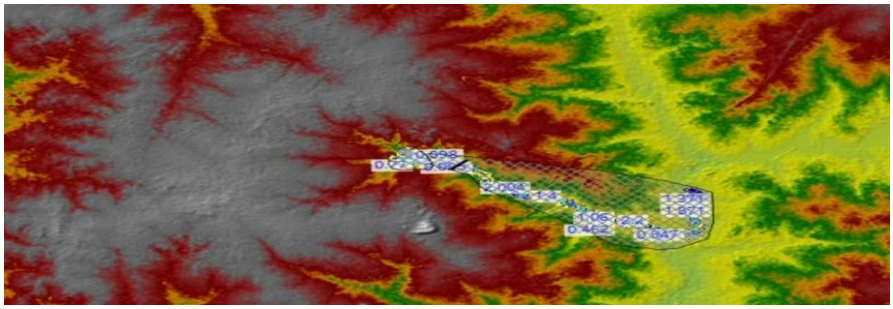

Figure 1: DEM of ABU Dam

The datasets and model inputs used in the hydraulic simulation are summarized in Table 2. A 30 m Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM) was adopted to represent the terrain (Farr et al., 2007)). The DEM was georeferenced in ArcGIS 10.8 to match the HEC-RAS coordinate system following established georeferencing procedures. River cross-sections and overbank geometries were extracted from the processed DEM and incorporated into the HEC-RAS geometry file. Manning's roughness coefficients for the channel and floodplain were assigned based on field observations and published values for similar savanna environments (Salah Abd Elmoaty & T. A, 2020) The reservoir elevation–storage relationship required for level-pool routing was generated from DEM-derived contours and imported into HEC-RAS as a Storage Area Elevation–Volume table initialized at the normal operating level.

Table 2: Summary of inputs

Input	**Purpose in the Study**	**Source**	**Reference**
Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (30 m)	Extraction of terrain elevation, watershed topography, channel geometry, and reservoir characteristics	NASA Shuttle Radar Topography Mission (SRTM)	Farr et al. (2007)
River cross-sections and overbank geometry	Development of HEC-RAS geometric model	Extracted from the georeferenced SRTM DEM using ArcGIS 10.8	Derived from SRTM DEM (Farr et al., 2007)
Manning's roughness coefficient	Hydraulic resistance assignment for channel and floodplain	Field observations and published values for comparable savanna environments	Salah Abd Elmoaty & T.A. (2020)
Elevation–Storage (Elevation–Volume) relationship	Level-pool routing and reservoir storage definition	Derived from DEM contours and entered into HEC-RAS as a Storage Area Elevation–Volume table	Derived from SRTM DEM (Farr et al., 2007)

2.2 Breach Parameter Estimation

The HEC-RAS parameter calculator is used for comparing five empirical formulas for predicting breach of pipe failure by failure modes: MacDonald and Langridge-Monopolis (1984), Froehlich (1995), Froehlich (2008), Von Thun and Gillette, and Xu and Zhang. The dam geometry and reservoir features were put up in the connection data editor. HEC-RAS calculated internally the reservoir volume and the breach height needed for each regression method; the estimated breach parameters are displayed in Table 2. The Xu and Zhang method resulted in unrealistic numbers of a

breach width of 6080 m, and a negative side slope for a rather small reservoir size that was discarded from further consideration.

The equations by Froehlich (2008) have been accepted as the design-reference parameters mainly because they stem from the most substantial checked failure database that the methodological independence of these formulas has been proven through reliable operation for earthy dams having approximately the same geometry in recent papers (Beza et al., 2023; Bharath et al., 2021) the formulas are the only ones formally acknowledged by the US Army Corps of Engineers for standard dam safety assessments. The average breach width (B_{avg}) and the breach formation time is:

$$B_{avg}=0.27K_oV_w^{0.32}h_b^{0.04} \qquad \textit{equation I}$$

$$t_f = 63.2\sqrt{\frac{V_w}{g\,h_b^2}} \qquad \textit{equation II}$$

Table 3: Breach parameters for ABU Dam estimated by five empirical methods (piping failure mode)

Method	Breach Bottom Width (m)	Side Slope (H:V)	Formation Time (hrs)
MacDonald & Langridge-Monopolis (1984)	2	0.5	0.26
Froehlich (1995)	126	0.9	6.83
Froehlich (2008) — Selected	132	0.7	2.99
Von Thun & Gillette	49	0.5	0.25
Xu & Zhang (excluded)	6,080*	—*	—*

** Xu & Zhang result is physically implausible for this dam geometry and was excluded from further analysis.*

2.3 HEC-RAS Modelling Framework

The one-dimensional unsteady flow model of HEC-RAS version 6.3.1 follows recent practice for comparable earthen dam analyses (Beza et al., 2023; Mo et al., 2023) The simulation setup covered the whole system from the reservoir storing area going through the connecting structure of breach between storage areas, and ending at downstream channel outflow boundary. Cross-section spacings were 100 to 500 m varying with topographic complexity. The storage area for the reservoir was bridged by an inline breach structure to the downstream routing reach through which boundary conditions for the upstream inflow hydrograph and downstream normal depth were provided. Separate unsteady flow simulations were run for return periods of 30, 50, and 100 years, each started from a steady-state base flow condition. The model variables that were exported for post-processing were mainly the breaching width, breaching flow, time-series records of velocity and water surface elevations at headwater and tailwater reference points; while flood depth raster, velocity, and elevation outputs at water surface were produced through RAS Mapper tool.

2.4 QGIS Spatial Analysis and Inundation Mapping

Raster outputs from RAS Mapper were exported and imported into QGIS version 3.61 for spatial classification and risk mapping. Google Satellite Hybrid imagery, accessed via the QuickMapServices plugin, provided high-resolution visual context for identifying built-up areas and land use types. (QGIS.org, 2019) Flood-depth rasters were classified into risk bands and overlaid on satellite imagery to produce flood inundation maps for each return period. Eleven downstream risk zones Areas 1 through 11 were manually delineated by digitizing visible residential and agricultural extents, with boundaries validated against available administrative boundary data. For each zone, maximum flood depth, inundated area, estimated number of exposed residential structures, and flood arrival time were extracted from the QGIS attribute table and compiled into the risk assessment matrix presented in the results section. This spatial analytical approach is consistent with current best practice for inundation mapping in data-scarce African contexts (Ekeu-Wei & Blackburn, 2018).

Figure 2: Satellite view of the area

3 RESULTS AND DISCUSSION

3.1 Breach Hydrograph Characteristics

Unsteady flow simulation produced time-series outputs for each return period scenario capturing the complete breach sequence from initial piping to recession. In all three scenarios, the breach progression follows a consistent three-phase pattern: (i) an initial quiescent period during which the piping orifice is small and outflow is limited; (ii) a rapid intensification phase during which breach width and outflow accelerate to their respective peaks; and (iii) a recession phase in which the depleted reservoir is unable to sustain peak discharge and outflow gradually diminishes. This tripartite temporal structure is consistent with the theoretical piping failure process described by (Jandora and Riha 2009) and with empirical hydrograph patterns documented in recent HEC-RAS dam break studies (Mo et al., 2023; Beza, 2023).

For the 30-year return period, the breach peak occurred at 0:59:52 hours, at which point breach width measured 31.14 m, total flow reached 1,426.56 m³/s, and velocity through the breach was 4.51 m/s. By the recession phase at 02:59:45 hours, breach width had expanded to its maximum of 40 m as the breach stabilized, outflow had fallen to 454.00 m³/s, and velocity had declined to 2.77 m/s.

The 100-year scenario exhibited a qualitatively different character. While initial and recession conditions were broadly comparable to the shorter return periods, the peak discharge of 1,761.71 m³/s occurred much later, at 02:59:45 hours. This delayed peak reflects the substantially larger reservoir volume accumulated during the 100-year inflow event prior to failure initiation; notably, it is the timing of the peak that shifts markedly with return period, while its magnitude increases only modestly relative to the 50-year event. This is consistent with (Aureli et al. 2023), who documented that breach-outflow timing can be more sensitive to antecedent pool volume than peak magnitude at the upper end of the return period range. Table 4 summarizes the peak hydrograph values across all three scenarios.

Table 4: Summary of peak breach hydrograph characteristics by return period

Return Period	Peak Discharge (m³/s)	Peak Velocity (m/s)	Breach Width at Peak (m)	Time to Peak	Headwater Elevation (m)	Tailwater Elevation (m)
30-year	1,426.56	4.51	31.14	00:59:52	642.91	637.41
50-year	1,697.71	4.56	31.14	00:59:52	643.16	637.48
100-year	1,761.71	4.44	31.14	02:59:45	643.00	637.15

3.2 Flood Inundation Extent

Across all three return periods, the flood wave propagated approximately 10 km downstream from the dam face, inundating communities from Zango in the immediate downstream reach to Sabon Gari Zaria at the distal limit of the modelled domain. This spatial extent is consistent with the travel distances documented for comparable small-to-medium earthen dam failures in West Africa (Salimon et al., 2023) and with analytical wave-celerity estimates for the observed peak discharges and channel geometry.

As expected, higher return periods produced greater inundation depths and slightly broader flood extents. The velocity and water-surface elevation rasters from RAS Mapper show that energy dissipation over the lower-gradient sections of the downstream reach generates the deepest inundation in mid-to-distal zones, where the flood wave encounters the widening valley floor. This pattern is present across all three scenarios, with the modestly higher peak discharge and delayed timing of the

100-year event generating somewhat deeper inundation in several zones relative to the 30- and 50-year events. The inundation maps produced for the three return periods (30-year, 50-year, and 100-year) show distinct flood depth, velocity, and water-surface-elevation layers, each providing spatially explicit information for emergency planning purposes.

Figure 3: Flood Inundation extent.

3.3 Downstream Risk Assessment

Table 5 presents the comprehensive risk assessment results for the eleven delineated downstream zones. Two findings are particularly significant for emergency planning. First, flood arrival times are extremely short. Even in the most distant zone (Area 11), located approximately 10 km downstream of the dam, the flood wave arrives in under 20 minutes under the 30-year return period scenario, while the nearest communities (Areas 1–3) experience inundation within the first minute. These results indicate that downstream residents would have little or no opportunity for spontaneous evacuation following a dam breach, making real-time monitoring and automated warning systems essential. Arrival times in some zones (e.g., Areas 4 and 5) converge or remain nearly identical between the 50- and 100-year scenarios rather than continuing to decrease; this is consistent with the flood wave in these zones approaching the channel's hydraulic capacity, beyond which additional inflow increases depth and discharge more than it increases wave-front speed. This finding is consistent with previous Nigerian dam-break studies. Comparable Nigerian dam-break studies have applied HEC-RAS to downstream reaches of approximately 11–12 km, including the Oyan River and Asa Dam systems, highlighting the importance of short downstream reaches in assessing potential flood impacts and emergency preparedness (Balogun & Ganiyu, 2016; Olanipekun et al., 2026)

Table 5: Inundation risk metrics for eleven downstream zones under three return period scenarios (Arrival columns give incremental travel time between consecutive zones, not cumulative time from the dam)

Area	Inund. Area (km^2)	Houses at Risk	Max Depth 30yr (m)	Max Depth 50yr (m)	Max Depth 100yr (m)	Arrival 30yr	Arrival 50yr	Arrival 100yr
1	0.79	325	9.01	11.57	11.34	00:00:16	00:00:10	00:00:10
2	0.19	47	5.05	8.47	8.24	00:00:42	00:00:35	00:00:34
3	0.20	30	4.92	8.27	8.12	00:00:56	00:00:50	00:00:46
4	0.63	18	4.60	8.19	10.51	00:01:15	00:01:07	00:01:07
5	0.57	35	9.04	11.74	11.06	00:01:39	00:01:33	00:01:07
6	0.50	250	6.32	9.13	8.03	00:02:10	00:01:47	00:01:22
7	0.32	500	4.00	7.49	10.25	00:02:41	00:02:00	00:01:38
8	0.88	400	8.81	10.40	10.48	00:03:38	00:02:13	00:02:02
9	2.55	300	8.49	10.33	10.04	00:04:00	00:02:30	00:02:22
10	3.21	600	14.88	13.20	12.87	00:06:37	00:03:20	00:03:13
11	0.46	200	15.00	16.26	16.31	00:07:08	00:06:00	00:04:05

The second major finding is the severity of downstream inundation. Maximum flood depths exceed 9 m in Areas 1, 5, 8, 9, and 10 under the 30-year scenario and increase to over 15 m in Areas 10 and 11 under the 100-year scenario, indicating catastrophic flooding capable of causing extensive

damage to buildings, infrastructure, and critical facilities. (Aureli et al., 2021) These results agree with recent HEC-RAS-based dam-break investigations, which consistently show that higher inflow scenarios generate greater breach outflows, deeper inundation, and substantially increased downstream hazard.

Similarly, (Bharath et al., 2021) demonstrated through HEC-RAS modelling of the Hidkal Dam in India that overtopping failures produce deep inundation and rapid flood propagation, posing severe risks to downstream settlements. These studies corroborate the present findings, confirming that flood depth and flood-wave travel time are critical indicators of dam-break hazard. Consequently, the combination of extremely short warning times and very high inundation depths observed in this study underscores the urgent need for automated early warning systems, well-rehearsed evacuation procedures, and strict land-use planning to minimize flood risk in downstream communities.

Figure 4: Map showing affected zones downstream

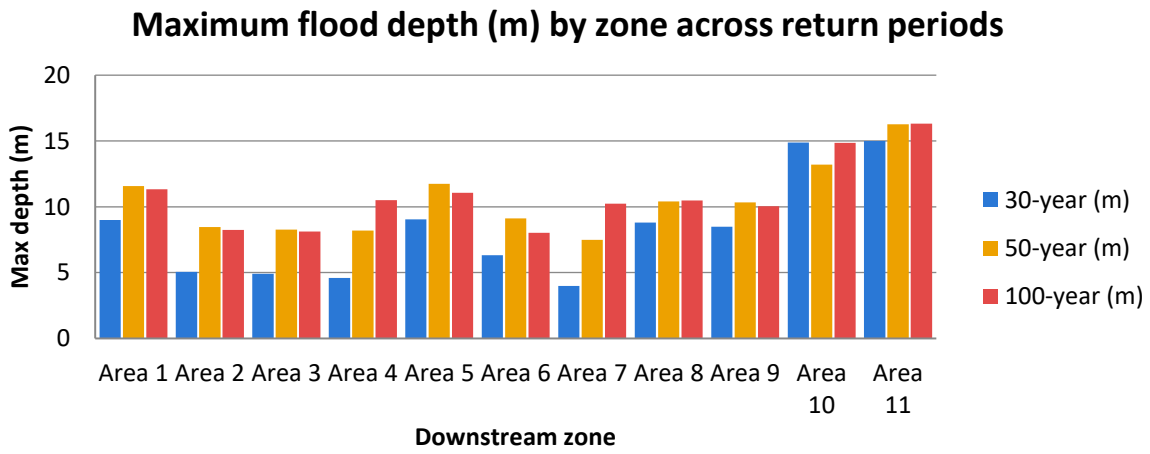

Figure 5: Maximum flood depth (m) by zone across return periods

As depicted in Figure above, maximum flood depths don't uniformly increase with the return period in all zones. Zones 1,4,5 and 9 actually have their maximum simulated depths for the 50-year scenario and not the 100-year scenario, a result that is not obvious under any assessment based on a single design return period rather than comparing several scenarios would miss completely. Zones 9 and 10 have the largest inundated areas (2.55 km and 3.21 km respectively) indicating floodplain widening when flood wave uses its energy slowly on lower gradient terrain farther from the dam site. This pattern has been found by other comparative return-period dam-break studies, for example, (Leoul, 2015) also found on the case of Kesem Dam in Ethiopia that flood risk is by no means proportional with return periods, the dam was safe under 50-year inflow conditions but failed catastrophically under 100-year and 200-year inflows and between these scenarios, both inundated area and depth increased sharply and non-linearly. Such findings highlight why the reliance of dam safety assessments on a single return period leads to substantial risk underestimation.

4 LIMITATIONS

This investigation was affected by multiple limitations. For example, only a pipe burst failure was considered in our modelling, and overtopping was not considered because a dam's central spillway is sufficiently designed to convey very heavy floods. This way, the scenario is considered highly unlikely unless spillway capacity is updated to reflect changing rainfall intensities. The second

shortcoming is that breach characteristics were taken from Froehlich's (2008) empirical regression equations, which although validated against the largest database of failures, the equations are subject to inherent uncertainty of the parameters. The third factor is that our hydraulic simulation was based on a relatively low-resolution DEM (30 m SRTM) which results in a decreased precision of capturing the smallest variations (microtopography) of a floodplain, so possibly changing how deep and far the floodwater is spreading at individual places. Because the 2,705-residence exposure estimate is derived directly from the extent of these depth rasters, it carries the same resolution-dependent uncertainty: at a 30 m cell size, individual structures and narrow drainage features smaller than one pixel cannot be resolved, so the true count of exposed residences in the actual floodplain likely deviates from this estimate, with the direction and magnitude of that deviation unverified without a finer-resolution DEM (e.g., LiDAR or sub-10 m satellite-derived terrain data) for comparison. Fourth, in our assessment of downstream people exposed (i.e. houses and farmlands) we only considered static land-use data which Yet, cannot record recent or informal residential or commercial development with Zaria floodplain.

5 RECOMMENDATIONS

Based on the findings, the recommendations to be considered are: (i) Installing automated, real-time, early-warning systems at the dam and downstream for the limited warning windows, Mostly in the nearest zones, which were extremely short; (ii) Drawing up and testing community-level Emergency Action Plans regularly, including holding evacuation drills for each of the eleven identified risk zones; (iii) Enforcement of land-use zoning to disallow more residential and agricultural development in the high-risk floodplain area determined; (iv) Regular safety inspection and equipping the dam (e.g. installation of piezometers, seepage monitoring) to detect signs of piping and structural problems in the building of the dam at an early stage; and (v) The future studies should combine overtopping failure scenarios, higher resolution terrain data, and updated land-use/population datasets to refine the risk estimates.

6 CONCLUSIONS

This research paper is the first to report a dam-break, breach-modelling-based flood inundation risk assessment of Kubanni (ABU), a Dam in Zaria, Nigeria. It uses a HEC-RAS, QGIS model under a scenario when water is escaping through a pipe or any small opening (piping failure mode) and considering return periods of 30, 50, and 100 years. Breach factors (width 132 m, side slope 0.7H:1V, formation time 2.99 hours) came from Froehlich's (2008) equations, chosen following a joint assessment with four other empirical models. Peak breach discharges of 1,426.56 m^3/s, 1,697.71 m^3/s, 1,761.71 m^3/s were modelled for these scenarios giving rise to a flood that swelled so much that it reached settlements downstream from Zango to Sabon Gari, which were about 10.3 km large (through 11 risk zones), and where 2,705 houses as well as vast areas of cropland have been identified as being at risk of high flood. The shortest duration of flood arrival, as fast as 10 seconds, was in a zone very close to the dam while in the farthest zone it took about 20 minutes. These results demonstrate a very limited time margin in case of emergency evacuation of the population. So, such work should be useful not only for dam safety but also for regulation of land use besides community-level early-warning systems in Zaria and similar less-observed river basins in the area.

ACKNOWLEDGEMENTS

The authors express sincere gratitude to Dr. A.D. Bello (Project Supervisor) for his guidance throughout this research, and to the staff of the Department of Water Resources and Environmental Engineering at Ahmadu Bello University, Zaria. The encouragement of family and colleagues is likewise warmly acknowledged.

ABSTRACT

Heavy metal contamination of soil and groundwater is an escalating environmental and public health threat in rapidly urbanizing settlements, where overlapping anthropogenic activities complicate risk assessment and constrain effective management. In Funtua, Katsina State, Nigeria, limited geospatial evidence linking contamination sources to observed pollution patterns has hindered evidence-based groundwater conservation. This study spatially characterized anthropogenic heavy metal contamination in soil and groundwater across Funtua metropolis and identified priority zones for intervention. An integrated geospatial framework combining field surveys, systematic sampling and atomic absorption spectrophotometry was employed, and concentration profiles, source-clustering patterns, contamination levels and composite indices were computed and mapped using a Geographic Information System. Anthropogenic pollution sources exhibited statistically significant spatial clustering, including auto-mechanic workshops ($z = -11.10$, $p < 0.001$), filling stations ($z = -12.36$, $p < 0.01$) and dumpsites ($z = -19.84$, $p < 0.01$). Soil concentrations ranged from 0.19-0.26 mg/kg (Cd), 1.80-3.02 mg/kg (Cu), 1.74-7.46 mg/kg (Pb), 4.41-18.90 mg/kg (Fe) and 0.14-0.84 mg/kg (Ni). Groundwater analysis returned markedly elevated lead (up to 74.37 mg/L) and nickel (up to 560.10 mg/L) at several locations; these two extreme values exceed drinking-water guideline values by three to four orders of magnitude and are reported as provisional pending confirmatory re-analysis. The Metal Index ranged from 0.02 to 63.86, with 12.40% of the study area (17.09 km²) classified as contaminated, while the combined high- and very-high-risk zones occupied 0.68% (0.93 km²) and coincided with dense source overlap. Heavy metal contamination in Funtua is spatially structured and driven primarily by clustering of anthropogenic activities. Targeted monitoring, land-use control and regulatory enforcement at identified hotspots are recommended, and a low-cost biochar-based groundwater treatment system is proposed as a direction for future work.

Keywords: *Heavy metal contamination; Anthropogenic sources; Soil pollution; Groundwater quality; Geospatial analysis*

1. INTRODUCTION

Heavy metal contamination of soil and groundwater is recognized globally as one of the most intractable forms of environmental degradation, owing to the persistence and bioaccumulative behaviour of metallic pollutants (Kabata-Pendias, 2011). While natural weathering establishes baseline metal concentrations, the sharpest increases are anthropogenically driven, arising from industrial activity, waste disposal, vehicular traffic and unplanned urban expansion (FAO, 2017; Alloway, 2013). Urban and peri-urban settlements are disproportionately affected because informal pollution sources such as auto-mechanic workshops, filling stations and dumpsites are typically spatially concentrated and inadequately regulated.

Studies in China show that soil metal accumulation is governed primarily by land-use intensity and proximity to the urban core (Fang et al., 2011; Huang et al., 2018; Yang et al., 2020), while Nigerian studies in Ijebu-Ode, Lagos and Nsukka have linked localized soil contamination to differential land use, industrial estates and clustered mechanic workshops, respectively (Adedeji et al., 2019; Ololade et al., 2022; Duru et al., 2024). Groundwater, which supplies nearly half of global freshwater withdrawals,

is especially vulnerable once surface contaminants infiltrate through permeable soils and inadequate drainage (Jain, 2023), and aquifers underlying Africa's Sahelian belt, including northern Nigeria, face considerable and spatially heterogeneous pollution risk (Podgorski et al., 2024).

Despite this growing body of research, most existing studies focus on large metropolitan centres and treat soil and groundwater contamination as discrete processes, leaving medium-sized, rapidly urbanizing towns characteristic of northern Nigeria, and integrated source-to-contamination frameworks, comparatively understudied. In Funtua, Katsina State, no such framework has yet been applied, which constrains environmental planning, groundwater protection and risk-based regulatory decision-making.

The present study addresses this gap. It integrates a field-based source inventory, systematic soil and groundwater sampling, laboratory analysis and GIS-based spatial and contamination-index modelling in order to characterize the spatial distribution of the three major anthropogenic heavy metal sources in Funtua auto-mechanic workshops, filling stations and dumpsites — to quantify the associated soil and groundwater contamination, and to identify the priority zones for intervention that follow from their spatial coincidence.

2. METHODOLOGY

2.1 Study Area

Funtua town lies between latitudes 11.390279°N and 11.580643°N and longitudes 7.244443°E and 7.358793°E in Katsina State, north-western Nigeria, covering approximately 137.72 km² across eight wards (Makera, Nasarawa, Anguwan Musa, Sabon Gari, Anguwan Ibrahim, Dandutse, Maigamji and Kusami/Yankwani). As a major commercial and transit hub, the town hosts a dense concentration of filling stations, auto-mechanic workshops and informal dumpsites clustered along its road network and market areas, making it a suitable case for examining the linkage between anthropogenic activity and soil/groundwater contamination. Locality names follow a single gazetteer, applied consistently across the text, tables and figures of this paper; variant spellings encountered in the field records were reconciled to this gazetteer before analysis.

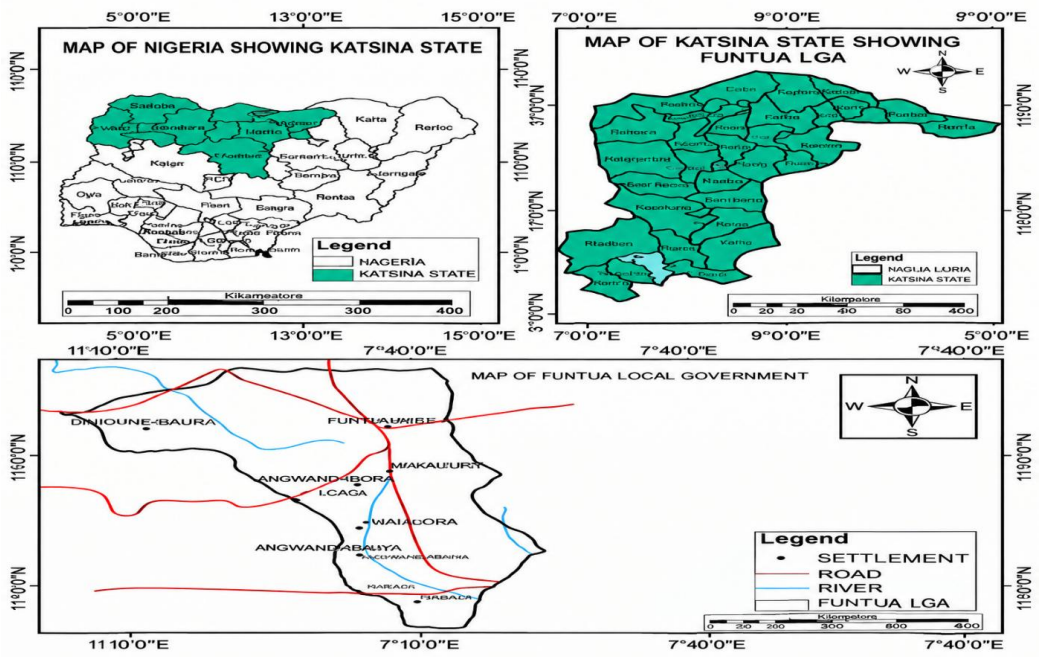

Figure 1: Map of the study area.

2.2 Sampling and Laboratory Analysis

Source coordinates for filling stations, auto-mechanic workshops and dumpsites were captured with a hand-held GPS, imported into Microsoft Excel, converted to shapefiles, and overlaid on the study-area base map in ArcMap 10.3/ArcGIS 10.8. A 50 m buffer was delineated around all mapped

contaminant sources, and sampling was stratified across the eight wards. Within each ward, four soil samples (0–25 cm depth) and four groundwater samples (from hand-dug wells and boreholes) were collected inside the buffer zone, yielding 32 source-proximal soil samples and 32 source-proximal groundwater samples. A further four soil and four groundwater control samples were collected from areas of comparably low anthropogenic activity outside all buffers, giving an overall total of thirty-six soil samples (S1–S36) and thirty-six groundwater samples (W1–W36). The control samples supplied the local geochemical background value used in the geo-accumulation index and the baseline against which source-proximal enrichment was judged.

Soil and groundwater samples were digested by the nitric acid–sulfuric acid procedure of Standard Methods for the Examination of Water and Wastewater, Method 3030 G (APHA, AWWA & WEF, 2005), and analysed for Al, Cd, Cu, Fe, Ni and Pb using an atomic absorption spectrophotometer (Unicam Model 969) at the National Water Quality Reference Laboratory, Sokoto. Groundwater physicochemical parameters (temperature, pH, electrical conductivity, salinity, turbidity and hardness) were determined on separate unacidified aliquots. Analytical quality was controlled through multi-point calibration ($r^2 > 0.995$), reagent blanks, and duplicate and matrix-spike analysis; the numerical QA/QC outcomes are not reported in this paper, so the two extreme groundwater Pb and Ni values discussed in Section 3.3 are treated as provisional pending confirmatory re-analysis.

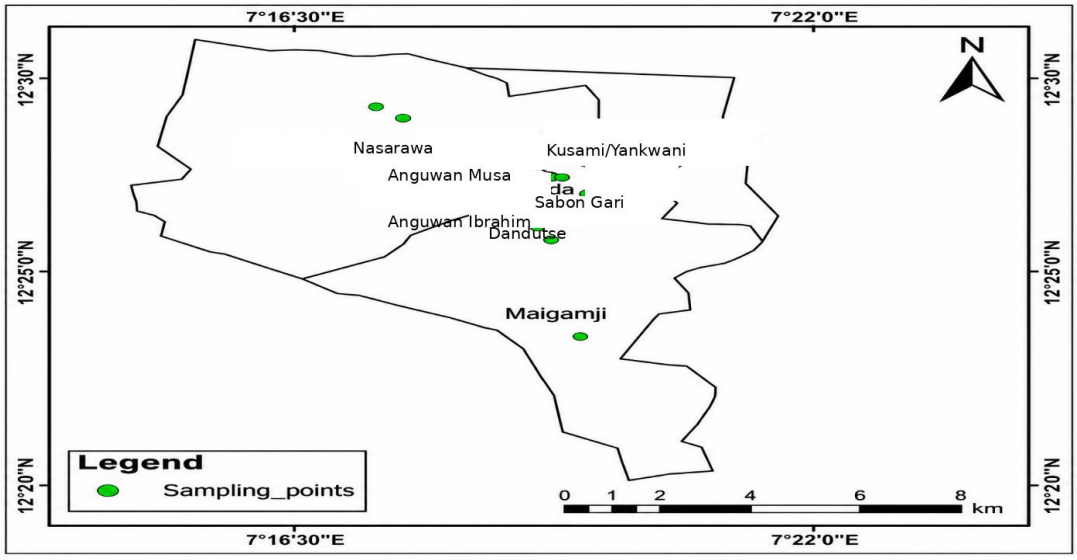

Figure 2: Spatial distribution of soil and groundwater sampling points across the wards of Funtua.

2.3 Geospatial and Statistical Analysis

Spatial analysis comprised point mapping, Average Nearest Neighbour (ANN) analysis, buffering, overlay/intersect analysis, and raster interpolation and reclassification in ArcGIS. The ANN statistic compares the observed mean nearest-neighbour distance among source points with the value expected under complete spatial randomness (Clark & Evans, 1954), yielding a Nearest Neighbour Ratio (NNR) and an associated z-score; ratios substantially below 1.0 with large negative z-scores indicate statistically significant spatial clustering (Ebdon, 1976; Mitchell, 2005). Where the NNR was unavailable for a source category, inference in this paper is confined to the significance of the departure from randomness rather than the ranking of clustering intensity.

Soil contamination was assessed using the Geo-accumulation Index (Igeo), computed as:

$$Igeo = \log_2 (C_m / 1.5B_n) \quad (1)$$

where C_m is the measured concentration of the metal and B_n is the local geochemical background value, taken as the geometric mean of its concentration in the control soils; the factor 1.5 corrects for lithogenic variation (Müller, 1969). Values were classified into seven standard Müller classes, from uncontaminated (Igeo ≤ 0) to extremely contaminated (Igeo > 5).

Groundwater contamination was assessed using the Metal Index (MI), computed as:

$$MI = \Sigma (C_i / MAC_i) \quad (2)$$

where C_i is the measured concentration of metal i and MAC_i is the WHO maximum allowable concentration for that metal (Table 1); MI > 1.00 denotes contaminated groundwater and MI ≤ 1.00 denotes uncontaminated groundwater (Tamasi & Cini, 2004). Fifty-metre source buffers were also intersected to classify groundwater risk zones as low, high or very high according to the degree of overlap among source-influence zones.

Table 1: *WHO maximum allowable concentrations (MAC) used for Metal Index calculation.*

Metal	Cu	Ni	Cd	Pb	Fe	Al
WHO limit (mg/L)	2.00	0.07	0.003	0.05	3.00	2.90

3. RESULTS AND DISCUSSION

3.1 Spatial Clustering of Anthropogenic Sources

The ANN analysis showed that anthropogenic sources within the study area are not randomly distributed but exhibit statistically significant spatial clustering (Table 2), concentrated around Anguwan Musa, Sabon Gari, Dandutse, Kusami/Yankwani and the surrounding central corridor (Figure 3). Auto-mechanic workshops returned an NNR of 0.42 (z = -11.10, p < 0.001), indicating strong clustering consistent with Nigerian GIS-based studies of workshop clusters (Ajeh et al., 2022; Duru et al., 2024; Iwegbue et al., 2024). Filling stations (z = -12.36, p < 0.01) and dumpsites (z = -19.84, p < 0.01) also departed significantly from randomness, although their NNR values were unavailable in the ANN output, so inference for these two categories is limited to statistical significance rather than clustering intensity or ranking. Sabon Gari, Anguwan Ibrahim and Nasarawa together accounted for approximately 77% of the mapped source density, indicating that environmental pressure is concentrated in a small part of the study area rather than evenly distributed, and that monitoring based on the area-wide average could underestimate conditions within these clusters.

Table 2: *Average Nearest Neighbour (ANN) results for anthropogenic source categories.*

Source category	NNR	z-score	p-value	Pattern
Auto-mechanic workshops	0.42	-11.10	< 0.001	Highly clustered
Filling stations	—	-12.36	< 0.01	Significantly clustered
Dumpsites	—	-19.84	< 0.01	Significantly clustered

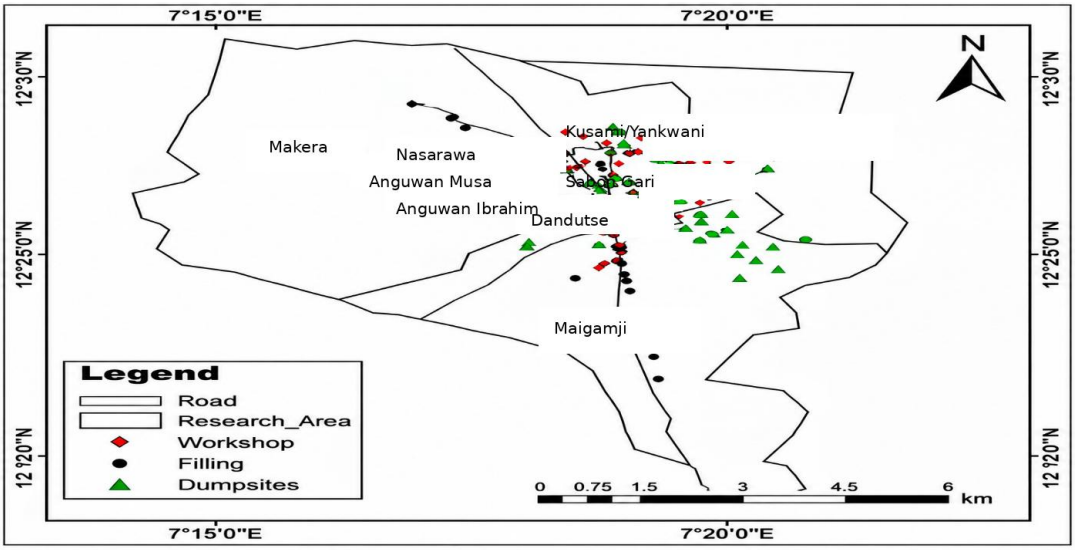

Figure 3: Spatial clustering of anthropogenic sources — auto-mechanic workshops, filling stations and dumpsites — in Funtua.

3.2 Soil Contamination (Geo-accumulation Index)

Soil Pb concentrations ranged from 1.74 to 7.46 mg/kg, with 92.13% of the study area (126.90 km²) classified as uncontaminated by Igeo (Figure 4); higher contamination was localized around

Kusami/Yankwani, consistent with Nigerian studies linking metal enrichment to automobile-related activities (Ajeh et al., 2022; Duru et al., 2024; Iwegbue et al., 2024). The remaining metals fell within comparatively narrow ranges (Cd 0.19–0.26 mg/kg, Cu 1.80–3.02 mg/kg, Fe 4.41–18.90 mg/kg, Ni 0.14–0.84 mg/kg). Elevated soil Pb values coincided spatially with the wards of highest anthropogenic-source density, supporting an anthropogenic rather than purely geogenic origin, although a lithogenic contribution cannot be entirely excluded for Fe and Ni.

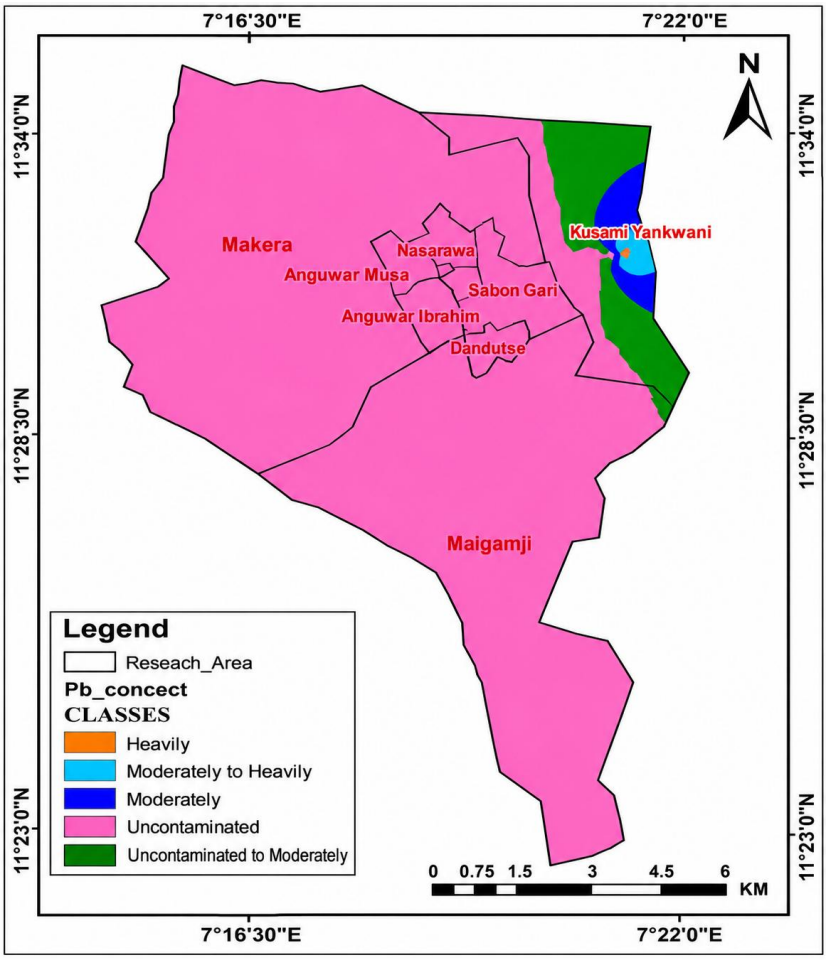

Figure 4: Spatial distribution of lead (Pb) contamination in soil across the study area, classified by the geo-accumulation index (Igeo).

3.3 Groundwater Contamination Level (Metal Index)

The groundwater Metal Index ranged from 0.02 to 63.86, with 87.60% of the mapped area (120.63 km²) classified as not-contaminated (MI ≤ 1.00) and 12.40% (17.09 km²) classified as contaminated (MI > 1.00) (Table 3, Figure 5). The contaminated zone was tightly concentrated in the north-eastern sector, coinciding with the densest aggregation of mapped sources and with the 700–740 m topographic band, suggesting that topographically controlled infiltration compounds the anthropogenic signal (Podgorski et al., 2024).

Maximum groundwater Pb (74.37 mg/L) and Ni (560.10 mg/L) exceeded current WHO drinking-water guidelines (0.01 mg/L and 0.07 mg/L, respectively) by three to four orders of magnitude (World Health Organization, 2022). These concentrations lie above the calibrated working range of the analytical method and were drawn from wells with turbidity up to 169 NTU, so unfiltered, particulate-rich digestion may have inflated the apparent dissolved concentration; both values are therefore reported as provisional pending confirmatory resampling with filtered/unfiltered splits, duplicate digestion and graphite-furnace AAS or ICP-MS analysis. No management or health-risk conclusion is drawn from their absolute magnitude until that confirmatory analysis is completed; the spatial pattern to which they contribute is corroborated independently by the buffer-overlay risk zoning in Section 3.4.

Table 3: *Groundwater contamination level in the study area (Metal Index classification).*

Class	MI range	Area (km²)	Percentage (%)
Not contaminated	≤ 1.00 (0.02–1.00)	120.63	87.60
Contaminated	> 1.00 (1.01–63.86)	17.09	12.40
Total	—	137.72	100.00

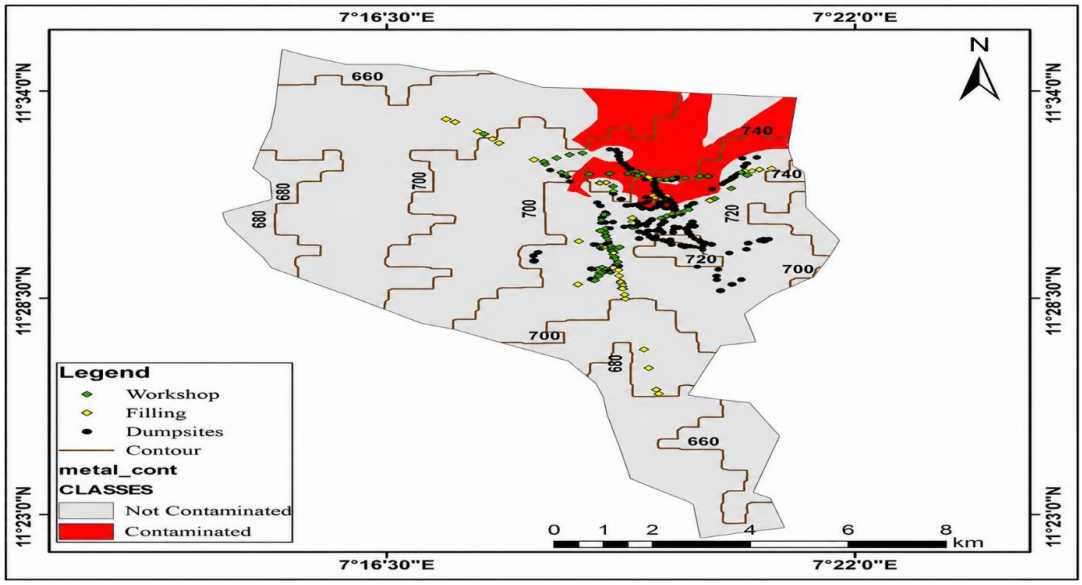

Figure 5: Groundwater contamination level (Metal Index classification) in the study area.

3.4 Groundwater Contamination Risk Zones

Buffer-overlay risk classification (Figure 6) showed that the low-risk class dominates the landscape (99.32%, 136.78 km²), while the high-risk and very-high-risk classes occupy 0.53% (0.73 km²) and 0.15% (0.20 km²) respectively, a combined footprint of 0.68% (0.93 km²) concentrated in and around Sabon Gari, Dandutse and Anguwan Ibrahim. This footprint coincides with both the highest source density (Section 3.1) and the Metal-Index-defined contaminated zone (Section 3.3); the convergence of these independently derived indicators provides internal validation that these three wards constitute genuine, high-confidence contamination hotspots (Duru et al., 2024; Guan et al., 2013). The small areal extent of the high-risk classes reflects the point-source-driven nature of urban groundwater risk rather than an absence of contamination pressure, consistent with continental-scale assessments of Sahelian aquifer vulnerability (Podgorski et al., 2024).

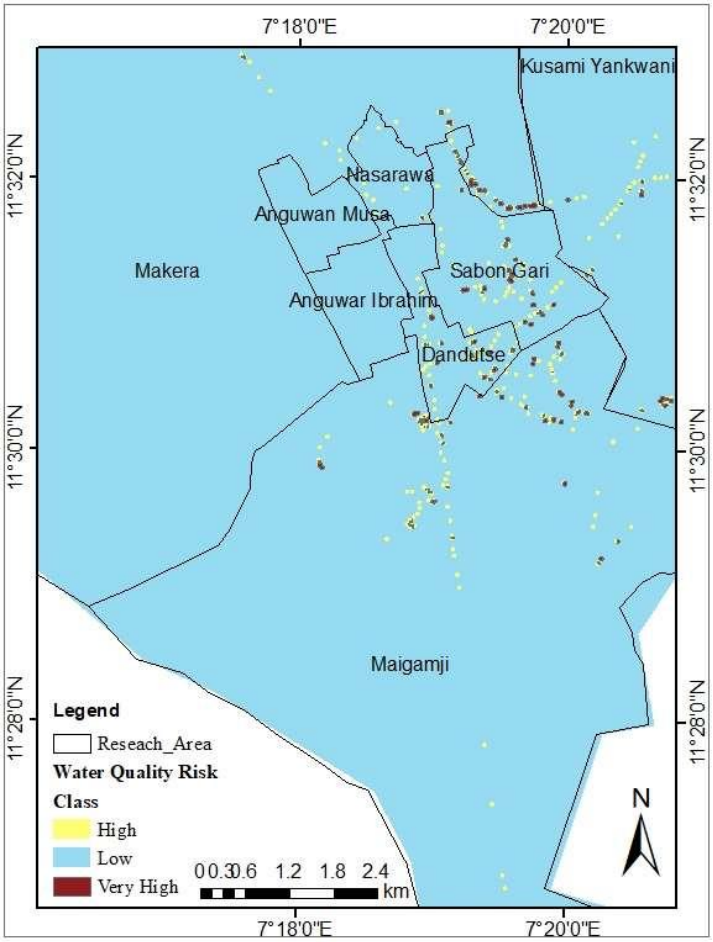

Figure 6: Delineation of groundwater contamination risk zones in the study area.

3.5 Groundwater Physicochemical Characteristics

Table 4 summarizes five physicochemical parameters across the thirty-six groundwater samples (W1–W36) relative to WHO (2017) and NSDWQ (SON, 2015) guideline values. pH (6.94–8.33, mean 7.8) fell entirely within guideline limits, and this near-neutral to slightly alkaline regime favours reduced solubility of Pb^{2+}, Cd^{2+} and Ni^{2+}, suggesting that the elevated Pb and Ni concentrations reported in Section 3.3 more plausibly reflect direct, source-proximal loading than pH-driven mobilization. Electrical conductivity (112–1,624 µS/cm, mean 500 µS/cm) exceeded the guideline in only 6% of samples, while turbidity (0–169 NTU, mean 20 NTU) exceeded the 5 NTU guideline in approximately 50% of samples the most significant deficiency identified consistent with the shallow, structurally unprotected nature of hand-dug wells (Jain, 2023). Total hardness (64–414 mg/L as $CaCO_3$, mean 180 mg/L) remained below the 500 mg/L guideline throughout. Overall, Funtua groundwater is predominantly fresh and near-neutral, with turbidity representing the principal water-quality concern and a plausible additional pathway for particulate-bound metal transport.

Table 4: *Summary statistics of groundwater physicochemical parameters (n = 36).*

Parameter	Min	Max	Mean	WHO limit	% exceeding
Temperature (°C)	33.2	35.2	33.8	N/A	N/A
pH	6.94	8.33	7.8	6.5–8.5	0
EC (µS/cm)	112	1624	500	1500	6
Turbidity (NTU)	0	169	20	5	50
Total hardness (mg/L as $CaCO_3$)	64	414	180	500	0

4. CONCLUSIONS

This study provides a GIS-based assessment of anthropogenic heavy-metal contamination in Funtua, integrating source mapping, laboratory analysis and contamination-index modelling. Auto-mechanic workshops, filling stations and dumpsites showed statistically significant spatial clustering (workshops: NNR = 0.42, z = -11.10, $p < 0.001$; filling stations: z = -12.36, $p < 0.01$; dumpsites: z = -19.84, $p < 0.01$), concentrated around Sabon Gari, Anguwan Ibrahim, Nasarawa, Dandutse and Kusami/Yankwani. Soil Pb ranged from 1.74–7.46 mg/kg, with 92.13% of the study area classified as uncontaminated by Igeo; groundwater showed greater concern, with Metal Index values of 0.02–63.86 and 12.40% (17.09 km²) classified as contaminated. Maximum groundwater Pb (74.37 mg/L) and Ni (560.10 mg/L) exceeded WHO guideline values by three to four orders of magnitude but remain provisional pending confirmatory analysis. Risk mapping identified a combined high-risk and very-high-risk footprint of 0.68% (0.93 km²) around source-overlap zones, particularly Sabon Gari, Dandutse and Anguwan Ibrahim. Overall, contamination in Funtua is spatially heterogeneous and driven primarily by the clustering of anthropogenic activities rather than by diffuse regional processes. Priority monitoring should focus on Kusami/Yankwani, Sabon Gari, Dandutse and Anguwan Ibrahim, supported by improved land-use regulation, confirmatory sampling of the extreme groundwater values, and seasonal monitoring. A limitation of this study is that batch-level QA/QC metrics for the analytical procedure are not reported here; a low-cost biochar-based groundwater treatment system is identified only as a direction for future work, not as a system designed or evaluated in the present study.

ABSTRACT

Dam infrastructure occupies a central position in water resource management; and dam failure can produce severe consequences, especially in data-scarce regions where observed hydrological and failure data are limited. This study assesses a hypothetical piping failure of Zobe Dam, an earthen embankment with a documented history of seepage on the Karaduwa River in Katsina State, Nigeria, utilizing coupled HEC-HMS and 2D HEC-RAS modelling software. A terrain-delineated HEC-HMS model comprising five subbasins and two Muskingum-Cunge-routed reaches was used to generate inflow hydrographs for 30-, 50-, and 100-year design storms. Global Curve Number 250 (GCN250)-derived curve numbers and Soil Conservation Service (SCS)-derived lag times were used for hydrologic simulation, while breach parameters were estimated using Froelich (2008) formulation. Breach initiation was fixed at the documented Full Supply Level of 493.00 m across all scenarios. Peak basin-outlet discharge increased from 4,616.3 to 5,333.4 m^3/s between the 30- and 100-year events, while peak breach discharge increased from 2,377.24 to 2685.35 m^3/s. Flood depth, velocity, and inundation extent were from RAS Mapper and mapped in QGIS, with downstream hazard classified using the Australian Institute for Disaster Resilience (AIDR) Guideline 7-3 depth-velocity framework. Hazard classification remain unchanged across the three scenarios: Garhi was classified H6; Hakazama, Safana and Kunamawa as H5; and Dogon Ruwa and Makwanshi as H2/H3. The Water Treatment Plant and Bodole remained outside the modeled inundation extent. Sensitivity testing indicated limited variation in routed and breach discharges within the tested parameter ranges, while floodplain roughness produced a localized change in hazard classification at Safana. Garhi and the downstream road corridor linking Dutsin-Ma toward Kankara were identified as priorities for emergency preparedness and evacuation planning.

Keywords: *Dam breach; piping failure; flood hazard mapping; HEC-RAS; HEC-HMS; QGIS*

1. INTRODUCTION

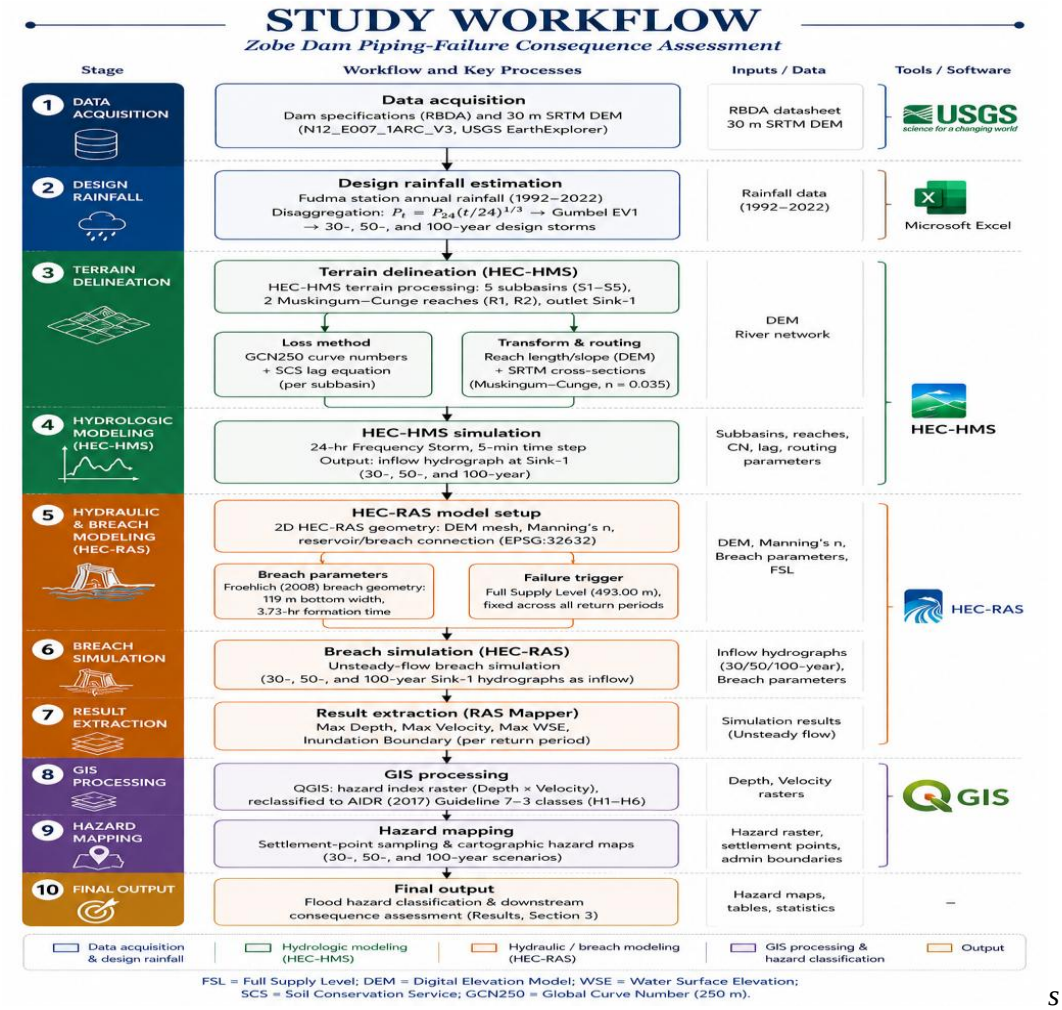
Dams provide water security, irrigation, hydropower, and flood control, but can also become sources of catastrophic loss when they fail. More than 2,000 dam failures have been recorded globally over the past century, causing over 200,000 deaths (Nasser et al., 2025; Hariri-Ardebili, 2018). Earthen embankment dams are especially prone to failure because of their lower structural rigidity relative to concrete or masonry dams (Planès et al., 2016; Tang et al., 2022), and their collapse generates flood waves capable of altering downstream morphology and devastating riparian communities (Zhou et al., 2026). Failure typically results from piping, overtopping, seepage, or seismic loading (Chen et al., 2023). Piping, or internal erosion, occurs when seepage through the dam or its foundation progressively entrains fine soil particles, enlarging internal voids until a mass collapse of the overlying material sharply increases outflow (Saliba et al., 2019; de Paula Barreto et al., 2024). Because piping failures develop internally and can remain undetected until collapse is

imminent, they pose a distinct and often underappreciated risk relative to overtopping, which is more readily anticipated from reservoir stage alone (Chen et al., 2023). Understanding this mechanism, and quantifying the flood wave it would generate, is essential for downstream disaster preparedness.

Historical events such as the Teton (1976) and Banqiao (1975) dam failures catalyzed the development of formal breach-hydrograph and inundation-mapping methods (Bezerra and Eleuterio (2026). An estimated one to two significant dam-breach events occur globally each year, disproportionately affecting populations near the failed structure (Rana et al., 2022); the 2015 Swar Chaung sluice-gate breach in Myanmar and the 2023 Derna cascading dam failures in Libya illustrate how quickly such disasters unfold when settlements lie close to the source, and hydraulic simulation is the principal means of quantifying breach discharge, depth, velocity, and inundation extent in advance of an actual failure. While empirical regression relationships developed by MacDonald and Langridge-Monopolis (1984) and Froehlich (1995, 2008) now allow breach geometry and discharge to be estimated quantitatively from dam and reservoir characteristics. Combined with GIS-based terrain processing, coupled hydrologic-hydraulic software such as HEC-HMS and HEC-RAS enables engineers to simulate breach initiation, progression, and downstream flood propagation even where ground-survey data are limited (Peker et al., 2024). Most published applications of this coupled approach emphasize overtopping scenarios, however, with piping treated, at best, as a secondary comparison; site-specific, piping-focused assessments using locally derived design-storm hydrology remain comparatively scarce, particularly for embankment dams in West Africa. This emphasis partly reflects the greater modelling uncertainty associated with piping failure, which depends on poorly constrained internal erosion processes, initiation conditions, and breach progression that are difficult to characterize without detailed geotechnical and dam monitoring data; however, overtopping failure can be more readily represented using hydraulic loading and established breach-parameter relationships. Zobe Dam, an earthen embankment impounding the Karaduwa River in Katsina State, Nigeria, illustrates this gap directly. The dam has a documented history of foundation seepage (ESIA Report for Zobe Dam and Associated Infrastructures Rehabilitation Works, 2020), a condition mechanistically linked to piping failure (Magawata et al., 2020), yet no piping-specific dam-break analysis using locally derived design-storm hydrology has previously been conducted for the dam. Downstream, several rural settlements, farmland, and a water treatment plant serving the wider Dutsin-Ma and Katsina area remain without a quantitative, hydraulically modeled understanding of the flood hazard they would face in a breach event.

Accordingly, this study evaluates the downstream consequences of a hypothetical piping-induced breach of Zobe Dam under 30-, 50-, and 100-year design-storm conditions using coupled HEC-HMS and two-dimensional HEC-RAS modeling. The specific objectives are to: (i) model the piping-failure scenario using HEC-RAS 2D hydraulic modeling; (ii) estimate 30-, 50-, and 100-year design-storm runoff hydrographs using HEC-HMS with Gumbel frequency analysis; (iii) simulate the resulting flood wave and characterize peak flow, depth, and velocity; (iv) map the spatial distribution of downstream flood risk against defined hazard thresholds; and (v) translate the results into recommendations for dam safety and emergency planning. The analysis estimates breach hydrographs, flood depths, velocities, inundation extent, and spatial hazard levels, with particular attention to the implications for downstream settlements and emergency preparedness, and offers a replicable methodology for comparable earthen dams across Nigeria's Sokoto-Rima Basin. The study is confined to Zobe Dam using HEC-RAS 6.6 for two-dimensional unsteady-flow simulation of a piping failure, with breach parameters from the Froehlich (2008) method.

2. METHODOLOGY



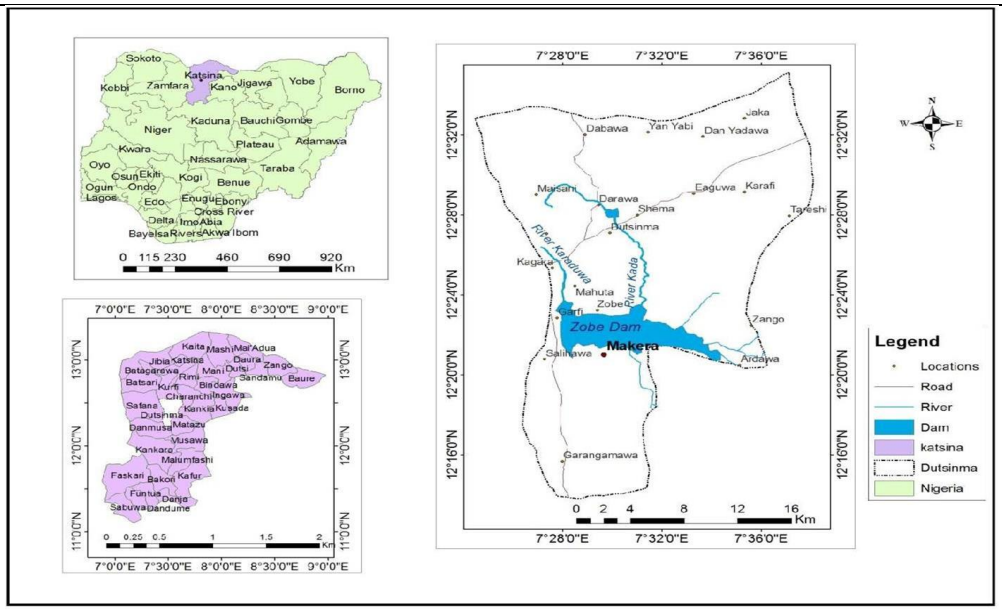


Figure 1: Overall study workflow, from data acquisition through terrain-based HEC-HMS delineation and design-storm hydrograph generation, HEC-RAS breach and unsteady-flow simulation, to GIS-based flood hazard classification.

2.1 Study Area

Zobe Dam is located at Makera, approximately 65km south of the city of Katsina in Katsina State, Nigeria, between longitudes 7^0 27' 57.12" and 7^0 34' 4.68" E and latitudes 12^0 20' 34.62" and 12^0 23' 27.48" N. The reservoir has a design capacity of 177 x 10^6 m^3, fed by the Gada and Karaduwa rivers, and was built to irrigate an 8,000ha command area and supply water to Katsina town and surrounding villages. The embankment is a 2.7km curved earth-fill structure with a 110m free-overflow spillway, reinforced at chainage 0+950 by a concrete intake-tower culvert, impounding a reservoir approximately 15km long and 36.9 km^2 in surface area. The dam supplies water for irrigation, domestic use, livestock, and fisheries (Jamda Saidu et al., 2019), emphasizing the scale of disruption a breach would set on the surrounding population.

Table 2 summarizes the principal structural and hydrological characteristics of Zobe Dam, as documented by the Sokoto-Rima River Basin Development Authority, which formed the core input data for the HEC-RAS geometric model.

Feature	***Value***
Embankment length	*2.75 km*
Embankment height	*18.9 m*
Dam crest width	*5.00 m*
Upstream slope	*1:3.2 (rip-rap, d = 1.00 m)*
Downstream slope	*1:2.2 (rip-rap, d = 0.35 m)*
Freeboard	*2.21 m*
Catchment area	*2,527 km^2*
Active storage capacity	*170 x 10^6 m^3*
Dead storage capacity	*7.0 x 10^6 m^3*
Maximum flood storage capacity	*263 MCM*
Reservoir surface area	*4,500 ha*
Full storage level (FSL)	*493.00 masl*
Dead storage level (DSL)	*484.60 masl*
Spillway No. 1 crest length	*110 m*
Spillway No. 2 crest length	*78 m*
Maximum overflow capacity	*1,087 m^3/s*

The catchment-wide curve number and time of concentration originally reported for the full 2,527 km^2 catchment are substituted, for the delineated Zobe sub-catchment used in the HEC-HMS model, by the subbasin-specific values in Table 2a (Section 2.4).

Table 2a. Subbasin curve numbers, derived from the GCN250 global curve-number dataset, and SCS lag times used in the HEC-HMS model.

Subbasin	*CN*	*Lag time (hrs)*
S1	*70.5*	*5.9*
S2	*70.8*	*5.5*
S3	*70.0*	*7.1*
S4	*73.6*	*2.8*
S5	*70.1*	*5.9*

The Karaduwa catchment lies within the Basement Complex of Katsina State, underlain by granite-migmatite and gneiss overlain by laterite and sandy-gravelly loam (ESIA Report for Zobe Dam and Associated Infrastructures Rehabilitation Works, 2020; Kankara, A., & Shazalli, N. U. 2020); permeable alluvial sand and gravel deposits extend across the river channel and adjacent floodplain, strata recognized as preferential pathways for internal erosion and directly relevant to the seepage vulnerability motivating this study. The catchment is dendritic, covering area of about 2,527km^2 as a tributary of the River Bunsuru, with average rainy-season discharge of 356 m3/s above the dam (Wang et al., 2022). The region receives 600-800 mm of annual rainfall governed by ITCZ migration, concentrated in a May-September wet season (mean 750 mm, peak in August) followed by an eight-month dry season (Geen et al., 2020).

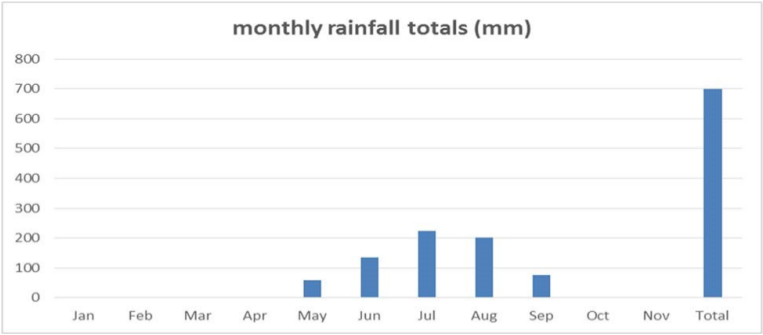

Figure 3: Mean monthly rainfall depth (mm) at the Katsina gauge station (Source: ESIA Report for Zobe Dam and Associated Infrastructures Rehabilitation Works, 2020).

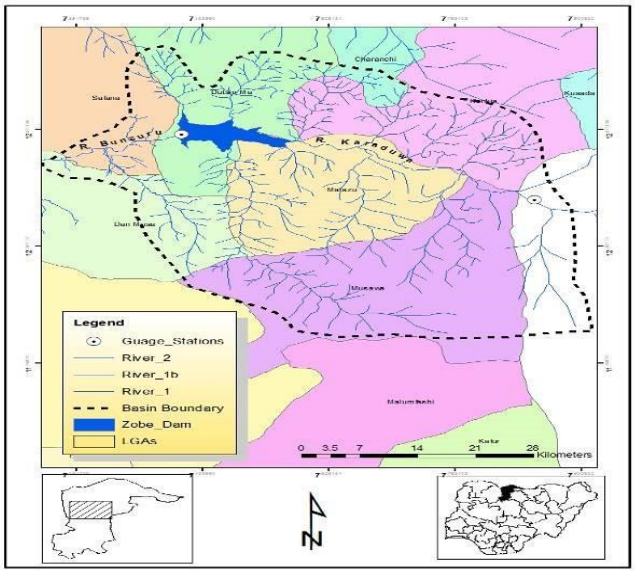

Figure 4: Drainage network of the Karaduwa-Bunsuru catchment showing the Zobe Dam reservoir (Source: Sokoto-Rima River Basin Development Authority).

2.2 Data Sources and Preparation

Table 1 summarizes the data sources used to construct the hydrologic and hydraulic models. Geometric data (dam dimensions, operating levels) were obtained directly from the Sokoto-Rima River Basin Development Authority. A 30m resolution SRTM DEM tile (N12_E007_1ARC_V3.TIF) was obtained from USGS Earth-Explorer and clipped to the study area using ArcGIS Spatial Analyst to provide the terrain surface for the HEC-RAS 2D model. Land-cover information from Landsat imagery and satellite base-map interpretation informed the Manning's roughness assignment described in Section 2.6. These datasets collectively provided the hydrological, topographical, and hydraulic information required to develop, in terms of parameters, and evaluate the joined HEC-HMS and HEC-RAS modelling framework

Data	***Format***	***Source***	***Use***
Rainfall records	*Time series*	*Fudma meteorological station*	*Gumbel frequency analysis / design storms*
DigitalElevation Model	*Raster (30m)*	*USGS EarthExplorer (SRTM)*	*Terrain surface for HEC-RAS 2D mesh*
Dam and reservoir geometry	*Engineering records*	*Sokoto-Rima River Basin Development Authority*	*HEC-RAS geometric model, breach parameters*
Land use / land cover	*Raster*	*Landsat imagery, Google satellite basemap*	*Manning's roughness assignment*
Manning's roughness (n)	*Literature-based estimate*	*Assigned per land-cover class (Section 2.6)*	*Channel and floodplain roughness input*

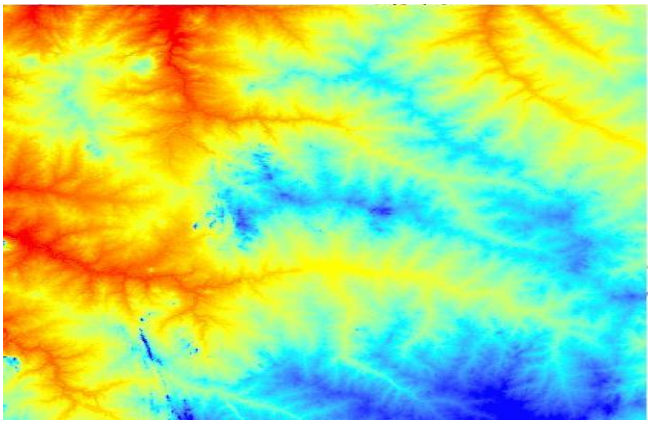

Figure 5: DEM of the Zobe Dam catchment derived from SRTM 30 m data (red = high elevation, blue = low elevation).

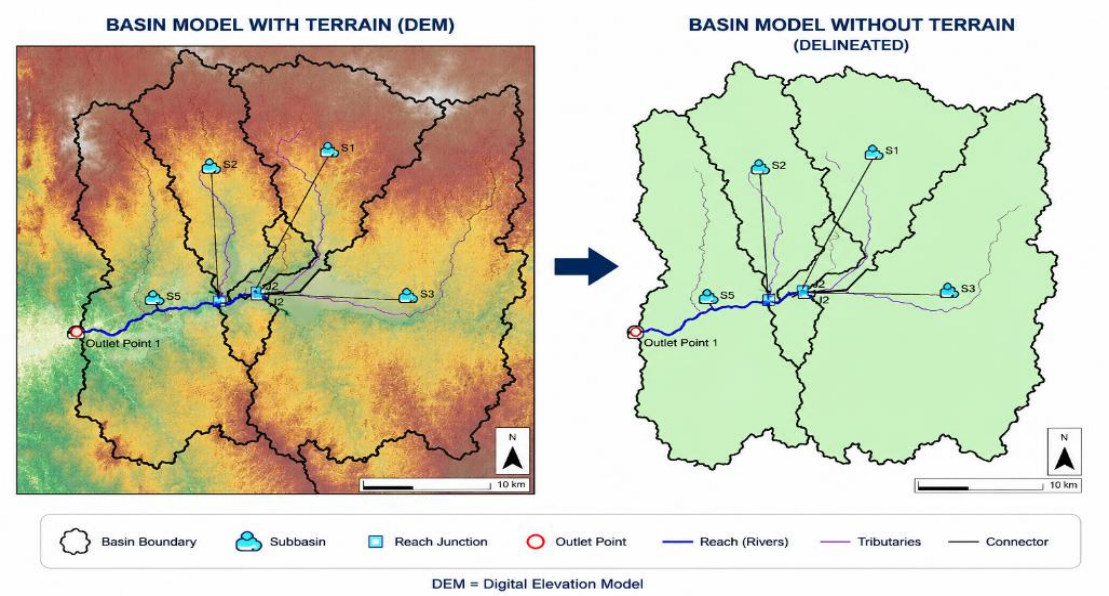

Figure 6: HEC-HMS basin model schematic showing the five terrain-delineated subbasins (S1-S5), the two Muskingum-Cunge-routed reaches (R1, R2), junction elements, and the basin outlet (Sink-1).

2.3 Frequency Analysis and Design Rainfall

Design rainfall depths for 30-, 50-, and 100-year return periods were estimated from the annual maximum rainfall series recorded at the Fudma meteorological station using Gumbel's extreme-value distribution:

$$XT = x - bar + K.sigma$$

Where $K = \left(\frac{yT - yn}{Sn}\right)$

$$yT = -\left[-ln\left(ln\left(\frac{T}{(T-1)}\right)\right)\right]$$

where x-bar and sigma are the sample mean and standard deviation of the annual maximum series and K is the frequency factor for return period T, y_T is the reduced variate, y_n the reduced mean and S_n is the reduced standard deviation. Annual maximum daily depths were first disaggregated to shorter sub-durations (5 minutes-24 hours) using the empirical relation $Pt = P24(t/24)^{1/3}$, and Gumbel's method was then applied at each duration to obtain return-period design rainfall depths for the 30-, 50-, and 100-year return periods. The design rainfall depths were converted to 24-hour design-storm hyetographs at five-minute resolution and used as meteorological input to HEC-HMS (Section 2.4).

2.4 Rainfall-Runoff Modelling

The Zobe sub-catchment was delineated directly from the SRTM DEM using HEC-HMS's terrain-processing tools, yielding five subbasins (S1-S5) connected through two routed reaches (R1, R2) to a single basin outlet (Figure 6). No streamflow gauge exists on the Karaduwa River, so model parameters were derived from physical watershed characteristics and not adjusted to observed hydrographs, consistent with standard practice for ungauged catchments (Section 2.8).

Curve Numbers were obtained per subbasin from GCN250 (Jaafar & Ahmad, 2019), a global 250m curve-number grid combining ESA CCI land cover with the HYSOGs 250m hydrologic soil group dataset, area-averaged for each subbasin by zonal statistics; values ranged from 70.0 to 73.6 (Table 2a), consistent with the mixed cropland, grassland, and scattered woodland cover of this Sudan-savanna catchment. The SCS Curve Number method was selected because it provides a practical and widely adopted approach for estimating rainfall losses in ungauged catchments where observed infiltration measurements are unavailable. GCN250 provides a physically based, spatially distributed alternative to assigning a single empirical CN in such data scarce settings and has shown a reasonable agreement with independent runoff products and global scales, including application in

Africa (Jaafar et al., 2019; Sujud & Jaafar, 2022). However, its use at the local watershed like the Karaduwa carries uncertainty because the derived CNs inherit uncertainties from the developed global land-cover and hydrologic-soil-group datasets and also the generalized CN lookup relationships. Hence, the resulting values were therefore physically valid estimates. The SCS Curve Number loss method,

$$Q = \frac{(P - 0.2S)^2}{(P + 0.8S)}$$

where S = $\left(\frac{25400}{CN}\right) - 254$ *(mm), was applied with these subbasin-specific CN values.*

Subbasin lag times were computed from the SCS lag equation,

$$L = \frac{l^{0.8}(S+1)^{0.7}}{1900\ Y^{0.5}}$$

where l is the hydraulic length (ft), Y is the average subbasin slope (%), and S = (1000/CN) - 10, using length and slope values from the terrain delineation; resulting lag times ranged from 2.8 to 7.1 as presented in (Table 2a) across the five subbasins, applied in the SCS unit-hydrograph transform (PRF-484).

Name	CN	L (km)	Y	S	L (ft)	Y(%)	Tc	Lag(Hr)	Lag(min)
S1	70.47	29.60	0.07	4.19	94984.10	7.25	9.90	5.94	356.54
S2	70.82	26.79	0.07	4.12	85967.45	7.04	9.19	5.51	330.85
S3	70.02	38.24	0.08	4.28	122700.43	7.80	11.86	7.12	426.95
S4	73.55	11.42	0.06	3.60	36649.89	6.02	4.66	2.79	167.67
S5	70.13	30.78	0.08	4.26	98783.66	7.93	9.86	5.92	355.09

Channel routing for R1 and R2 used the Muskingum-Cunge method, which derives routing behavior from channel geometry, slope, and roughness rather than from calibration against observed inflow-outflow pairs. Reach length and slope were taken from the terrain delineation (R1: 12.126 km, 0.00091; R2: 3.111 km, 0.00546). Because the SRTM resolution was not enough to directly resolve channel cross-sectional geometry, two cross-sectional profiles were sketched along each reach using Google Earth Pro v7.36, based on the visible channel trace and elevation profile and the resulting dimensions were averaged for each reach. The Channel cross-sections approximated as trapezoidal, with bank height and top width; gave a representative geometry of approximately 94m and 68m bottom width and 2H:1V assumed side slopes, for R1 and R2 respectively. Manning's n was initially set to 0.035 for a natural earth channel with light vegetation (Chow, 1959). Both this roughness assumptions and the sketched cross-sectional geometry are potential sources of uncertainty in the Muskingum-Cunge routing; their effect on simulated peak discharge was tested and reported (Section 3.6), together with the other parameter sensitivity checks performed in this study.

The three design storms from Section 2.3 were applied as a 24-hour Frequency Storm at a five-minute computational time step, with the simulation window to 72 hours to allow each hydrograph to fully recede to near-baseflow conditions. The resulting hydrographs at the basin outlet were used as HEC-RAS unsteady-flow boundary conditions (Section 2.6). Internal computational consistency was confirmed by verifying that the unit-hydrograph volume equaled 1mm for each subbasin; this check confirms only that the model computes runoff correctly given its inputs. Accordingly, the hydrological model was verified through parameter consistency, comparison with published ranges, and evaluation of the simulated hydrograph characteristics and not direct calibration against observed streamflow.

2.5 Breach Scenario and Breach-Parameter Estimation

Overtopping accounts for approximately 70.9% of documented dam-breach incidents and piping for 14.3% (Zhong et al., 2021); reflecting on Zobe Dam's seepage history (Section 2.1) and not its overall failure-mode base rate, this study models a piping failure occurring during normal reservoir operation. Piping is characterized by a discrete erosional conduit through the embankment interior, in contrast to the progressive crest-downward erosion of overtopping, and this distinction governed the parameters of the HEC-RAS breach module.

Because detailed geotechnical information required to predict the precise onset of piping was unavailable, a hypothetical piping-induced breach was assumed to initiate when the reservoir water surface reached the documented Full Supply Level (FSL = 493.00 m, Table 2). This assumption represents a "sunny-day" piping failure initiated at the normal operating level, transitioning into the design-storm inflow, rather than an overtopping-triggered failure. The same breach-initiation criterion was applied across the 30-, 50-, and 100-year scenarios to maintain a consistent failure condition and allow the effect of convergent storm magnitude on breach response to be compared. The breach invert was set to 489.47 m, which is the dam's documented foundation level. Accordingly, the study evaluates the downstream consequences of an assumed FSL-initiated piping failure subjected to subsequent storm loading, and not predicting the actual onset or probability of piping failure.

Reliable projection of peak discharge and inundation extent requires an accurate characterization of breach geometry and development time. A substantial body of regression research, summarized by Wahl (1998), has produced competing formulations for these parameters, compiled in Table 3; because each equation was justified to a different, generally modest sample of historical failures, and can diverge by a factor of two or more for a given dam, practitioners increasingly favor comparative application of several formulas rather than reliance on one, an approach followed here via the HEC-RAS Breach Parameter Calculator (Section 3.2).

Among these, statistical evaluation has repeatedly identified the Froehlich (2008) equations as the best-performing method for earth-fill dams specifically (Temür et al., 2026; Geremew, 2024), the basis for its adoption in this study. The sensitivity of the simulated peak discharge to the adopted breach formation time was tested and reported in (Section 3.6), together with the other parameter sensitivity checks performed in this study.

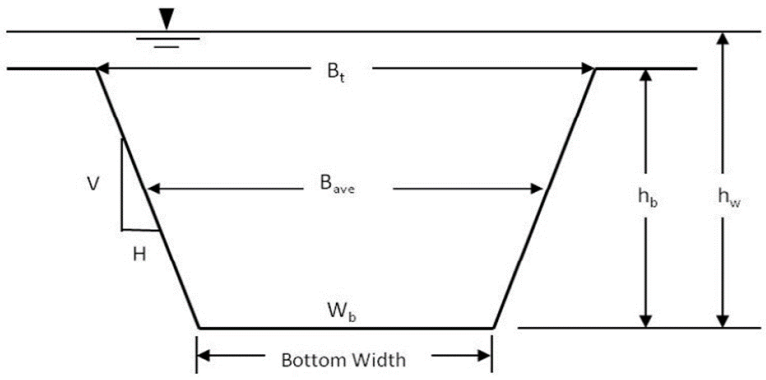

Figure 7: Schematic definition of embankment breach geometry (adapted from the HEC-RAS reference manual).

2.6 Two-Dimensional Hydraulic Modelling

The clipped DEM (Section 2.2) was imported into RAS Mapper at 1/128 rounding precision under the WGS 1984 UTM Zone 32N projection (EPSG: 32632), the correct zone for the study area's longitude (~7.5°E), and the 2D flow area and its connection to the Zobe reservoir storage area were constructed in the geometric editor.

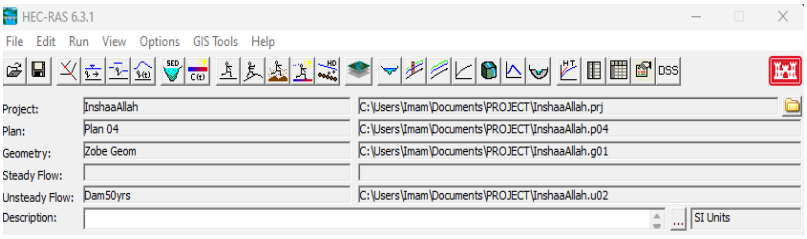

Figure 8: HEC-RAS v6.3.1 project window showing the configured plan, geometry, and unsteady-flow files.

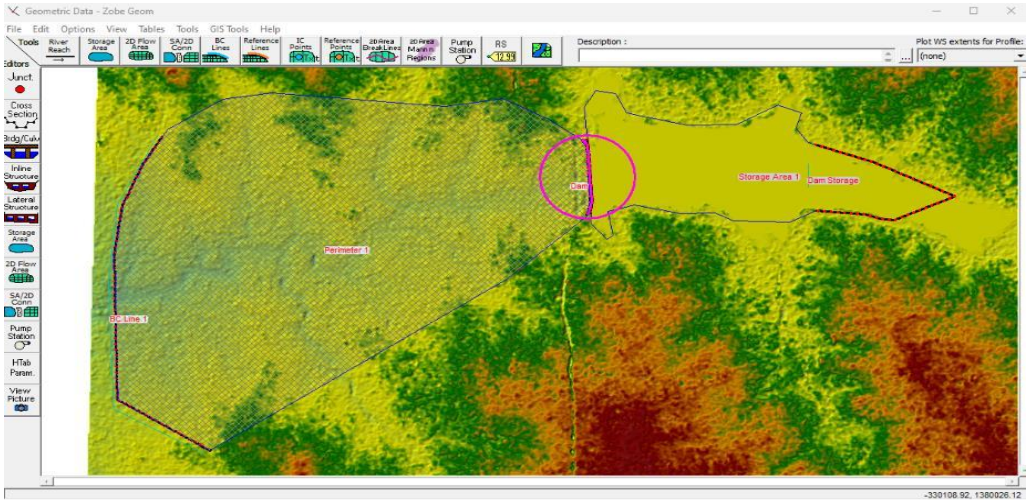

Figure 9: Geometric data editor showing the 2D flow area, storage area, and SA/2D connection (breach location).

A base mesh of cell size of 50x 50m was computationally generated for the polygon of the study area with 44035 grid cells. The selected Manning's roughness coefficients n of 0.035 was set which represent the dominant land-cover conditions within the savannah grassland cover of the Karaduwa-Bunsuru (Section 2.1); but 'Spatially Varied Manning's n on Faces' option was selected; which extracts multiple roughness values along a 2D face rather than depending on a single value at the center. The sensitivity of the resulting depth-velocity hazard classification to this floodplain rougness assumption was tested and is reported in (Section 3.6), together with the other parameter sensitivity checks performed in this study. Unsteady-flow boundary conditions comprised the HEC-HMS design-storm hydrographs at the upstream boundary and normal depth downstream was selected to ensure stable unsteady-flow routing is enough. Simulation used a 30-second computational interval and 5-minute mapping interval over 1 hour of simulated time, within a stable Courant-number range for the HEC-RAS full momentum solver. Depth, velocity, and water-surface-elevation outputs were visualized in RAS Mapper and exported to QGIS for the hazard maps in Section 3.4.

2.7 Flood Hazard Classification

Downstream hazard was classified using the depth-velocity product (D x V) framework of the Australian Institute for Disaster Resilience (AIDR, 2017) Guideline 7-3, Flood Hazard, developed from the vulnerability curves of Cox et al. (2010) and Smith et al. (2014). The adopted classification incorporates the combined influence of flood depth and velocity, thereby providing a more realistic representation of flood risk than either parameter considered independently. This structure defines six hazard classes (H1-H6) from the combined depth and velocity at each location, oriented toward the

stability and safety of people, vehicles, and buildings in floodwater and not directly classifying structural or economic damage assessment specifically.

Class	*D x V limit (m2/s)*	*Limiting depth (m)*	*Limiting velocity (m/s)*
H1	*<= 0.3*	*0.3*	*2.0*
H2	*<= 0.6*	*0.5*	*2.0*
H3	*<= 0.6*	*1.2*	*2.0*
H4	*<= 1.0*	*2.0*	*2.0*
H5	*<= 4.0*	*4.0*	*4.0*
H6	*> 4.0*	-	-

H1 denotes conditions generally safe for people, vehicles, and buildings; H6 denotes conditions under which all building types are considered vulnerable to structural failure and floodwater is unsafe for vehicles and people. Maximum simulated depth and velocity at each downstream location were combined into a single D x V value and classified against these thresholds in QGIS.

3. RESULTS

3.1 Design Rainfall and Rainfall-Runoff Results

HEC-HMS produced peak discharge and time-to-peak at the basin outlet (Sink-1) for the three design storms derived in Section 2.3 (Table 5), confirmed by a unit-hydrograph volume of 1 mm for each subbasin.

Return Period (years)	*Simulated Peak Discharge (m3/s)*	*Time to Peak*
30	*4,616.3*	*19h 20min*
50	*4,773.9*	*19h 15min*
100	*5,333.4*	*19h 15min*

Peak discharge increased from 4,616.3m^3/s (30-year) to 5,333.4m^3/s for the 100-year event, representing an increase of approximately 22% (Table 5). While time-to-peak remains near-constant (~19.25 hours) across all three return periods, indicating that increasing rainfall intensity affected runoff magnitude without altering the watershed's hydrologic response time for these selected rainfall scenarios. The subbasin lag times and reach travel times derived from the terrain delineation (Sections 2.2, 2.4) behavior were consistent, controlled by the catchment characteristics and not storm magnitude. The simulated inflow hydrographs at the Sink-1 were subsequently used as the upstream boundary conditions for the HEC-RAS breach simulations.

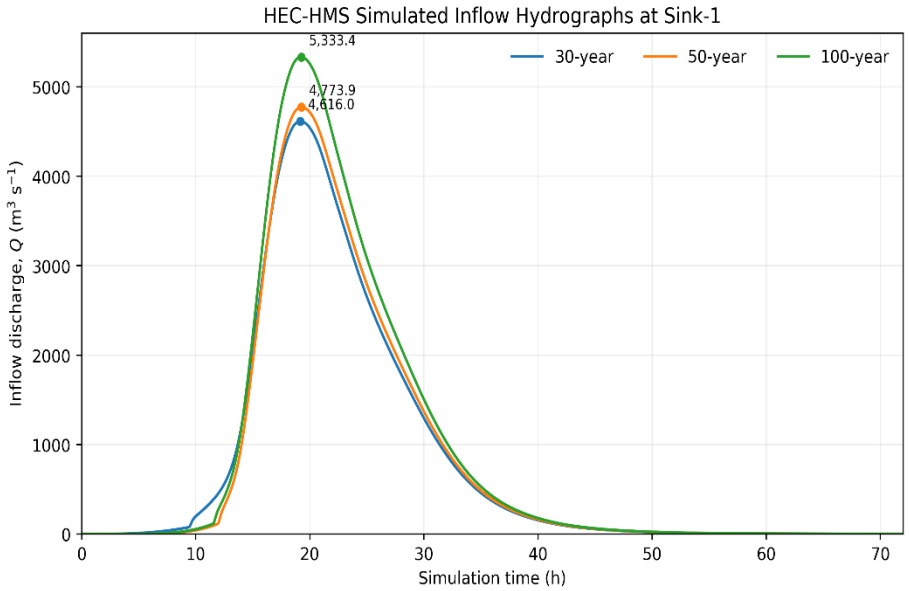

Figure 10: HEC-HMS Simulated Inflow Hydrographs at Sink-1.

3.2 Breach Parameters

Breach parameters were estimated using the HEC-RAS Breach Parameter Calculator based on the empirical relationship of MacDonald and Langridge-Monopolis (1984), Froehlich (1995, 2008), Von Thun and Gillette, and Xu and Zhang formulations listed in Table 3. Following the selection criteria described in section 2.5, the Froehlich (2008) output (Table 6) was adopted for all simulations. Because breach dimensions are primarily by the physical characteristics of the dam and reservoir characteristics not the inflow hydrographs. The Pool Elevation at Failure (493.00m, the documented FSL) and breach invert (489.47m) were similarly held constant across all three scenarios (Section 2.5). This approach ensured that difference in flood response reflected variations of the hydrological inputs not changing breach geometry.

Breach Parameter	***Estimated Value (Froehlich, 2008)***
Breach bottom width	*119 m*
Side slopes	*0.7 (H:V)*
Breach development time	*3.73 hrs*
Pool elevation at failure (FSL)	*493.00 m*
Breach invert elevation	*489.47 m*

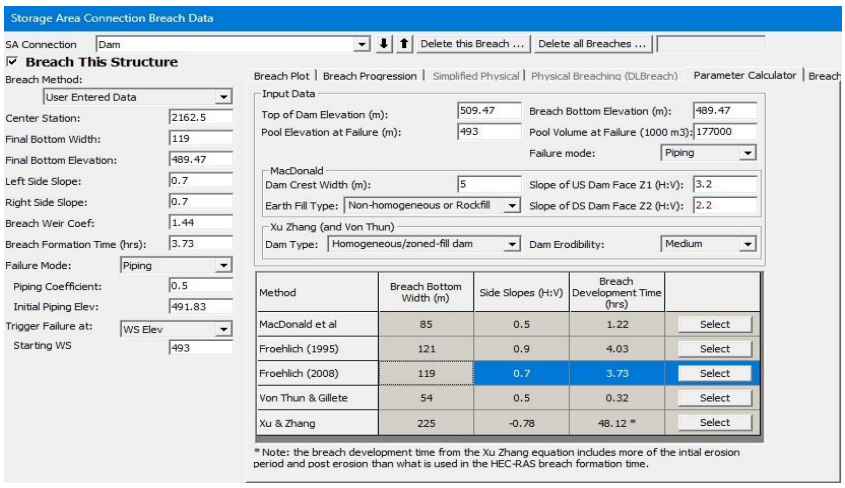

Figure 11: HEC-RAS Parameter Calculator comparing breach parameters across regression methods for Zobe Dam.

The adopted breach geometry corresponds to a moderate piping failure scenario and was treated as a hypothetical but internally consistent representation for all scenarios.

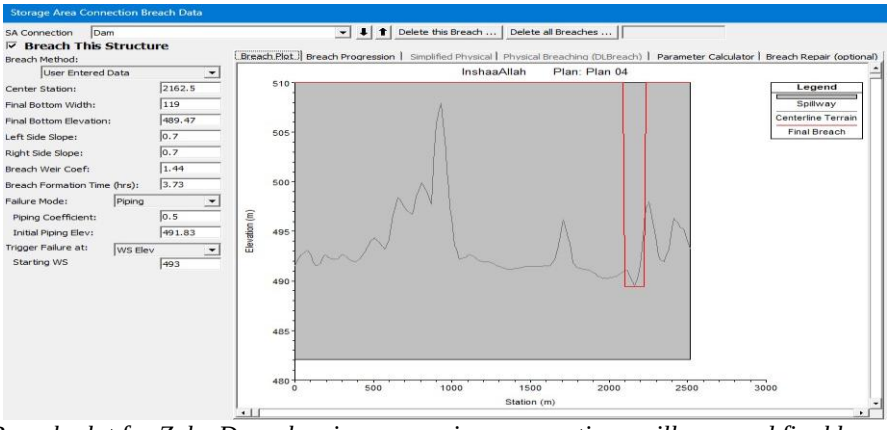

Figure 12: Breach plot for Zobe Dam showing reservoir cross-section, spillway, and final breach geometry.

3.3 Breach Hydrographs and Reservoir Response

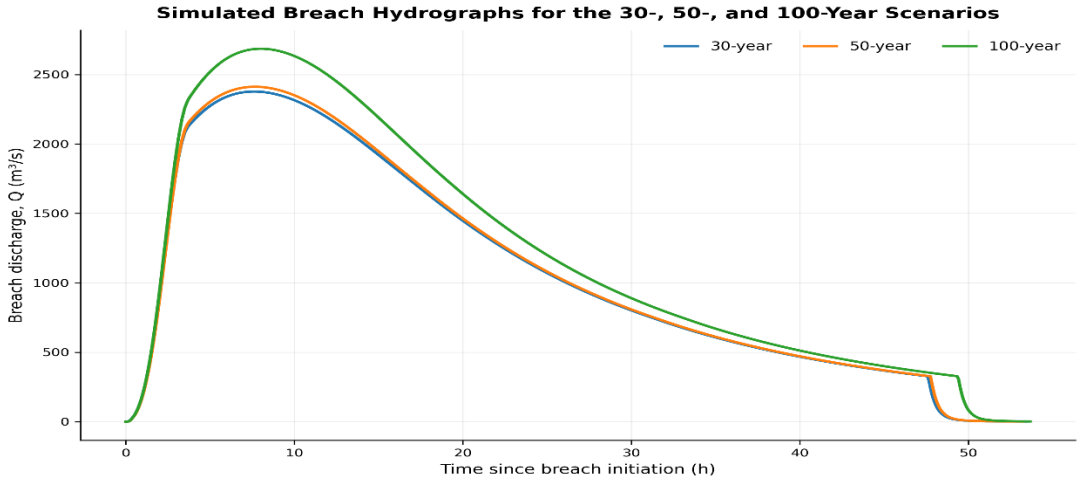

Figure 13a. Breach plot for Zobe Dam showing the outflow Breach Hydrograph for the 30, 50, and 100-year event.

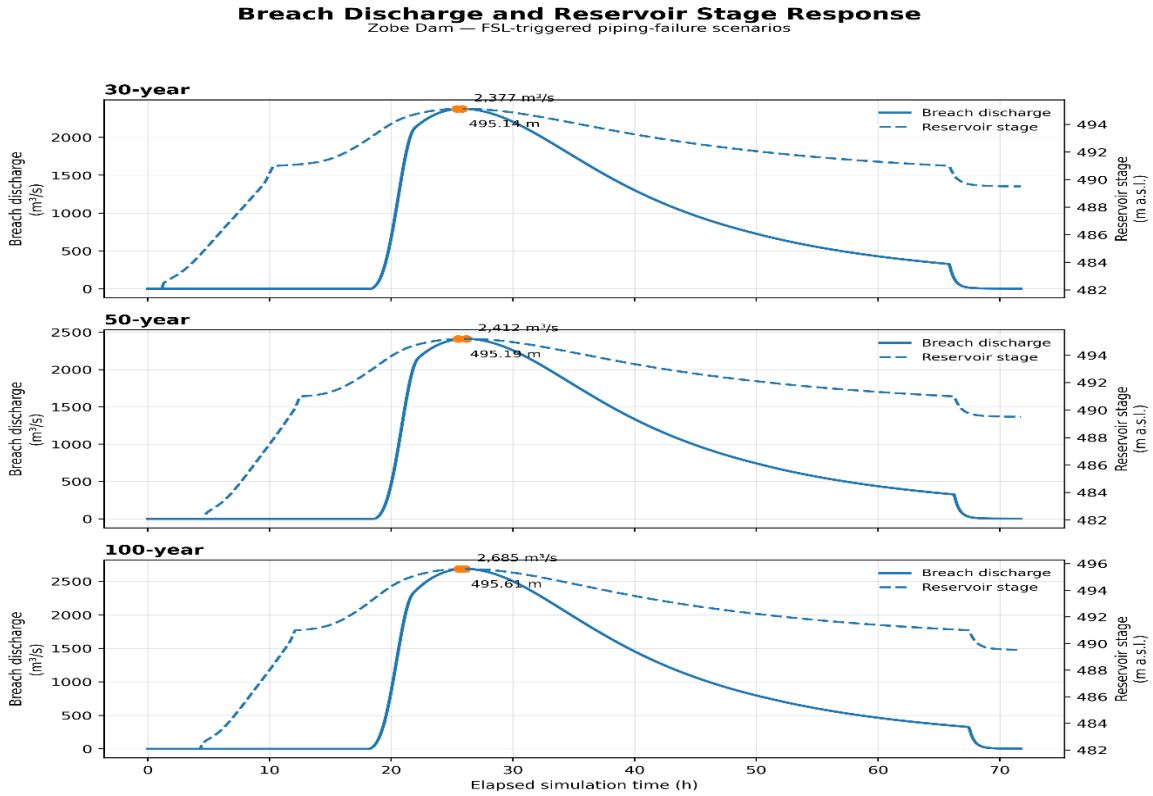

Figure 13b. Breach plot for Zobe Dam showing reservoir stage and Breach Discharge starting at selected Full Supply Level triggered piping scenario.

With the reservoir breach initiating at the documented FSL (493.00m, Section 2.5), Table 7 summarizes the reservoir response by return period.

Return Period	***Peak Inflow (m3/s)***	***Maximum Reservoir Stage (m)***	***Peak Breach Discharge (m3/s)***
30-year	*4,616.3*	*495.13*	*2,377.24*
50-year	*4,773.9*	*495.19*	*2,411.69*
100-year	*5,333.4*	*495.61*	*2,685.35*

The simulated reservoir response and breach hydrograph for the three design storm scenarios are summarised in Table 7 and plotted in Figure 13a. Peak inflow increased from 4,616.3 m³/s for the 30-year event to 5,333.4 m³/s for the 100-year event, producing a corresponding rise in maximum reservoir water level from 495.13 to 495.61 m. Peak breach discharge also increased with return period, ranging from 2,377.24 to 2,685.35 m³/s.

Despite the increase in inflow, peak breach discharge remained substantially lower than peak reservoir inflow in all simulations as shown in Figure 13c. This behaviour reflects the hydraulic control imposed by the adopted breach configuration and the relatively shallow driving head available above the breach invert (489.47 m) following breach initiation at the documented Full Supply Level (493.00 m) shown in Figure 13b. Consequently, a considerable proportion of the incoming flood volume was temporarily attenuated by reservoir storage before being released through the developing breach, resulting in a moderated breach hydrograph.

The modest increase in breach discharge across the three return periods further indicates that, under a fixed breach geometry and failure elevation, downstream flood response is influenced more by reservoir routing and breach hydraulics than by the incremental increase in design storm magnitude. This observation is consistent with the relatively small differences in maximum reservoir stage among the simulated events. More so, the 30-year simulation produced a volume-accounting error of only 0.05%, demonstrating excellent mass conservation and confirming the numerical stability of the hydraulic model (Section 2.8).

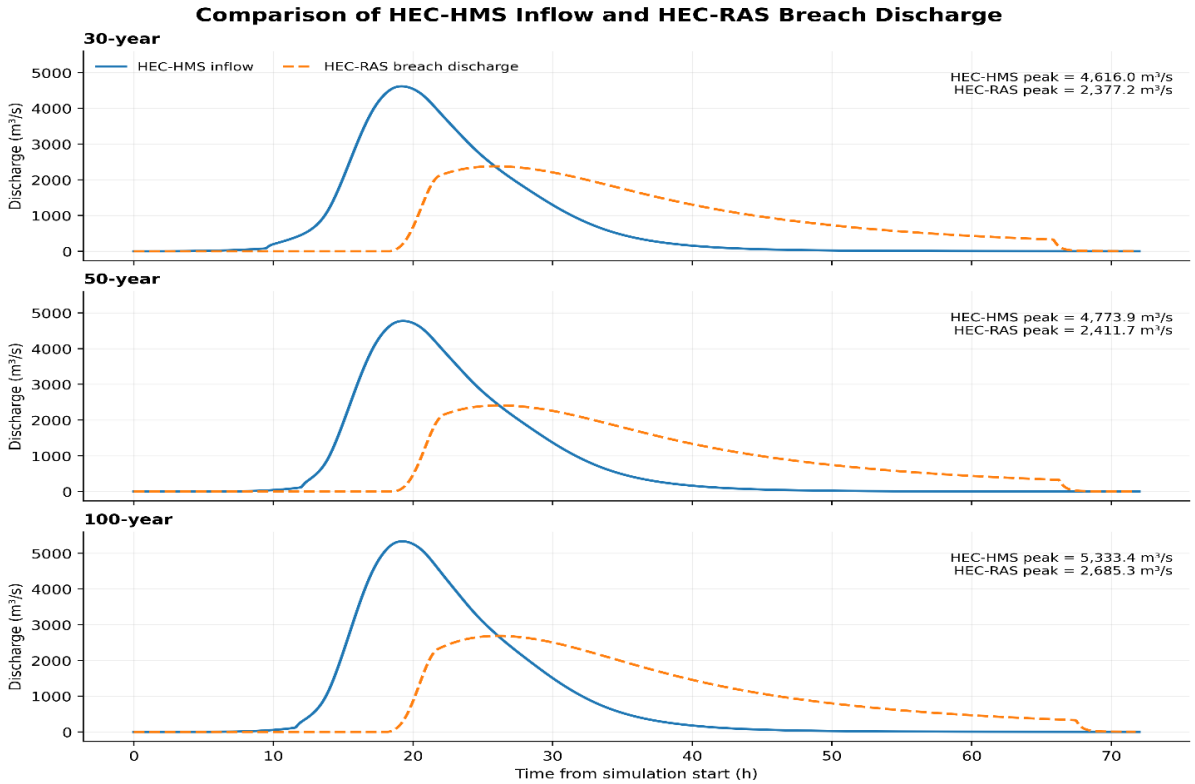

Figure 13c. Breach plot for Zobe Dam showing the comparison of Inflow and Outflow Discharges.

3.4 Flood Inundation Characteristics

Raster data of water depth values and water velocities obtained after flood modeling with HEC-RAS 6.6 were converted into Hazard Index factors using the Spatial Analysis Tools—Reclassify command in the ArcGIS 10.6.1 software. Then, Equation DxV was applied to these raster data with the help of the Spatial Analysis Tools—Raster Calculator command and hazard maps were obtained according to hazard classes according to the limit values in Table 4 of Section 2.7.

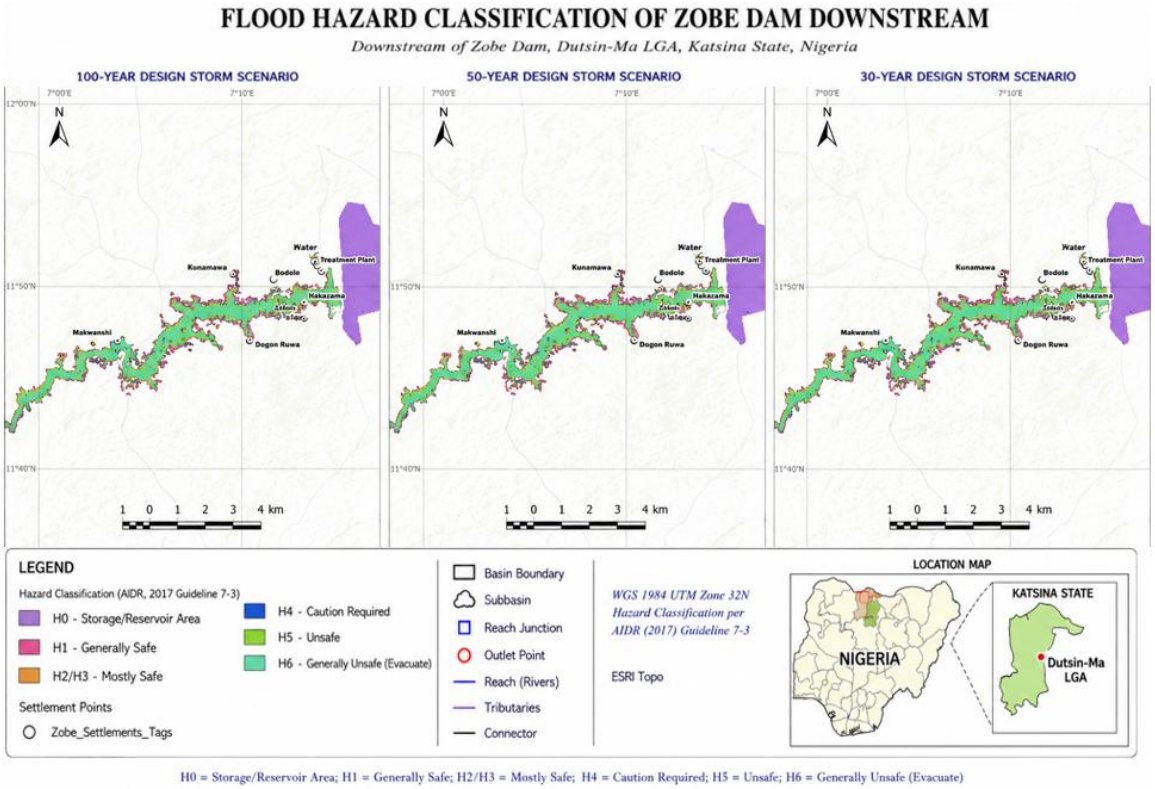

Figure 14: Flood hazard maps, 30-, 50-, and 100-year FSL-triggered design-storm scenarios (QGIS).

Maximum flood depth and velocity were extracted from RAS Mapper at eight downstream locations and are summarized in Table 8. Total inundated area and boundary perimeter, derived from the exported inundation-boundary polygon, are summarized in Table 9.

Location	***30-yr D (m)***	***30-yr V (m/s)***	***50-yr D (m)***	***50-yr V (m/s)***	***100-yr D (m)***	***100-yr V (m/s)***
Garhi	*5.95*	*4.86*	*5.97*	*4.87*	*6.16*	*4.88*
Hakazama	*3.31*	*0.66*	*3.34*	*0.68*	*3.52*	*0.86*
Safana	*3.68*	*0.85*	*3.71*	*0.87*	*3.88*	*1.03*
Kunamawa	*4.24*	*0.55*	*4.27*	*0.55*	*4.26*	*0.56*
DogonRuwa	*2.62*	*0.15*	*2.64*	*0.15*	*2.83*	*0.15*
Makwanshi	*0.50*	*0.50*	*0.60*	*0.51*	*0.74*	*0.56*
W.T.P.	*Nil*	*nil*	*nil*	*nil*	*nil*	*nil*
Bodole	*Nil*	*nil*	*nil*	*nil*	*nil*	*nil*

Return Period	***Inundated Area (km2)***	***Inundation Extend (km)***
30-year	*37.52*	*152.4*
50-year	*37.58*	*152.6*
100-year	*38.02*	*154.9*

Maximum flood depth and velocity extracted from RAS Mapper at the eight identified downstream locations are presented in Table 8. Garhi recorded the highest hydraulic intensity across all three return periods, with maximum depth increasing from 5.95 m for the 30-year event to 6.16 m for the 100-year event, while velocity remained almost unchanged at 4.86–4.88 m/s. Hakazama and Safana also showed progressive increases in both depth and velocity with increasing return period. At Kunamawa and Dogon Ruwa, the changes were comparatively small, while Makwanshi showed an increase in maximum depth from 0.50 to 0.74 m and velocity from 0.50 to 0.56 m/s. The WTP and Bodole were not intersected by the simulated inundation extent in any of the three scenarios.

The resulting flood footprint is summarized in Table 9. Inundated area increased from 37.52 km² for the 30-year event to 37.58 km² for the 50-year event and 38.02 km² for the 100-year event.

Over the same return-period range, the flood extent length increased from 152.4 to 154.9 km. Thus, the overall spatial extent of flooding changed only slightly across the three scenarios, with the largest increase occurring between the 50- and 100-year events.

The eight locations represent named settlements and facilities identifiable from the available spatial data and are used here to characterize hydraulic conditions at selected downstream locations. They do not constitute an exhaustive inventory of all settlements within the simulated flood extent. The spatial limitation of the settlement-level assessment is discussed further in Section 4.5.

3.5 Flood Hazard Classification

Depth–velocity products at the eight assessed locations were classified using the AIDR (2017) Guideline 7–3 thresholds described in Section 2.7, with the resulting hazard classes presented in Table 10. Locations falling within the combined H2/H3 range are reported as H2/H3.

Location	***30-year Class***	***50-year Class***	***100-year Class***
Garhi	*H6*	*H6*	*H6*
Hakazama	*H5*	*H5*	*H5*
Safana	*H5*	*H5*	*H5*
Kunamawa	*H5*	*H5*	*H5*
Dogon Ruwa	*H2/H3*	*H2/H3*	*H2/H3*
Makwanshi	*H2/H3*	*H2/H3*	*H2/H3*
W.T.P.	*Not inundated*	*Not inundated*	*Not inundated*
Bodole	*Not inundated*	*Not inundated*	*Not inundated*

Hazard classification remained unchanged across the 30-, 50-, and 100-year scenarios at all assessed locations. Garhi was classified as H6 in all three scenarios, representing the highest hazard category recorded in the assessment. Hakazama, Safana, and Kunamawa consistently fell within H5, while Dogon Ruwa and Makwanshi remained within the combined H2/H3 category. The WTP and Bodole were not inundated in any scenario and were therefore not assigned a hazard class. However, these locations are not the exhaustive inventory settlements within the study area. They represent the names and facilities that could be identified from the available spatial data. Other households, structures and smaller settlements located within or immediately adjacent to the mapped hazard zones would be expected to experience conditions corresponding to their respective positions on the hazard maps, even where they are not individually labelled. The downstream road corridor toward Kankara, which comes from Dutsin-Ma town, passes near Garhi, also falls within the affected area; given Garhi's H6 classification, flooding could severely disrupt road access and vehicles movement, with implications for evacuation, emergency response, and local economic activities.

The stability of the hazard classes across the three return periods reflects the relatively limited variation in flood depth and velocity observed between scenarios (Section 3.4). Despite the increase in design-storm magnitude, none of the assessed locations crossed a hazard-class threshold.

3.6 Sensitivity Analysis

Sensitivity analyses were conducted to assess the influence of selected hydrologic and hydraulic parameters on the modeled response. For HEC-HMS, the effects of channel Manning's roughness and the assumed channel geometry on routed discharge were examined. For HEC-RAS, sensitivity was assessed for floodplain Manning's roughness and breach formation time, while the remaining model parameters were held constant.

3.6.1 HEC-HMS Sensitivity

Changing channel Manning's roughness from n=0.035 to n=0.040 produced peak routed discharges of 3,921.0 and 3,944.1 m³/s for R1, respectively, while the R2 peak remained 3,069.5 m³/s for both cases. The corresponding change in R1 peak discharge was approximately 0.59%.

A ±20% variation in the adopted channel geometry produced Sink-1 peak discharges of 4,773.7, 4,773.9, and 4,773.5 m³/s for the −20%, base, and +20% cases, respectively. The results indicate very limited sensitivity of the routed peak discharge to the tested changes in channel roughness and geometry.

3.6.2 HEC-RAS Sensitivity

Floodplain (2D) Manning's n. Because the 2D floodplain used in the HEC-RAS hazard-mapping simulations directly affect the depth-velocity hazard classification, the roughness was increased from n=0.035 base value to n=0.040 for the 30-, 50-, and 100-year scenarios. The resulting changes in depth and velocity varied among locations (Table 11) as compared, but the hazard classifications remained unchanged for the 30- and 50-year scenarios. In the 100-year scenario, Safana changed from H5 (base: D=3.88m, V=1.03m/s, DxV=4.00) to H6 (alternate: D=4.10m, V=1.08m/s, DxV=4.43), crossing the H5/H6 threshold; while the other assessed locations (Table 11) although, with increasing depths and velocity but retained their base-case classifications. This indicates that although the overall hazard pattern is relatively stable, locations close to classification thresholds may respond to changes in floodplain roughness.

Breach formation-time sensitivity was assessed using formation times of 2.0, 3.73, and 5.0 h. The corresponding peak breach discharges were 2,601.60, 2,685.35, and 2,764.74 m³/s, respectively. The difference between the extreme cases was approximately 6.3%, indicating a relatively limited change in peak breach discharge within the tested formation-time range.

4. DISCUSSION

The result of the simulations shows that increasing the design-storm return period increased the hydrologic and breach responses, including flood depth and velocity, but did not change the resulting downstream hazard classification. Peak basin-outlet inflow increased from 4,616.3 m³/s for the 30-year event to 5,333.4 m³/s for the 100-year event (15.53%), while peak breach discharge increased from 2,377.24 to 2,685.35 m³/s (12.96%). The relatively limited increase in breach discharge reflects the FSL-triggered "sunny day" breach adopted in this study, where breach initiation occurs at a fixed reservoir elevation rather than at a storm-dependent peak stage. Despite the increase in flood magnitude, the hazard pattern remained unchanged across the three scenarios. Garhi remained H6, Hakazama, Safana, and Kunamawa remained H5, while Dogon Ruwa and Makwanshi remained within the combined H2/H3 class. The Water Treatment Plant and Bodole were not intersected by the modeled inundation extent in any scenario. Thus, under the assumed FSL-triggered piping failure, increasing the design-storm return period increased flood magnitude but was not sufficient to change the hazard class at the assessed locations.

The limited increase in breach discharge can be explained by the reservoir response following FSL-triggered failure. Reservoir stage increased only from 495.13 m to 495.61 m between the 30- and 100-year scenarios, despite the 22% increase in peak inflow. Once the breach developed, the additional outflow limited further reservoir accumulation. Consequently, the hydraulic head above the breach invert remained within approximately 5.7–6.1 m, resulting in only a 13% increase in peak breach discharge. This shows that, for the failure condition adopted here, the increase in storm magnitude did not translate directly into a similar increase in breach discharge.

The breach parameters also contribute to the resulting hydraulic response. The Froehlich (2008) formulation used in this study gave a breach width of 119 m and a formation time of 3.73 h. As noted by Froehlich (2008); (Zhong et al., 2021) breach characteristics introduce uncertainty into predicted dam-break discharge and downstream flood conditions (Azeez et al., 2020). The simulated breach discharges should therefore be considered within the context of the assumed breach geometry, formation time, and FSL-based initiation condition rather than as a prediction of an actual failure discharge.

Although the increase in breach discharge was relatively modest, Garhi experienced the most severe hydraulic conditions. This indicates that downstream hazard is not controlled by peak discharge alone, but also by the local terrain and the depth and velocity of flow at the exposed settlements (Peker et al., 2024; AIDR, 2017). The unchanged hazard classes across the three scenarios are therefore important from an emergency-planning perspective. Garhi remained the most critical assessed location, while Hakazama, Safana, and Kunamawa consistently remained within H5 and would also require appropriate preparedness measures.

The assessment was based on the named settlements and facilities that could be identified from the available spatial data and does not represent an exhaustive inventory of downstream settlements. Other settlements, buildings, and households located within the same mapped hazard

zones may experience similar conditions depending on their position within the floodplain. The road corridor towards Kankara is also important because flooding around Garhi could disrupt vehicle movement and emergency access. This could affect evacuation and response activities and may also interrupt the movement of agricultural produce, goods, and other services along the corridor. These effects should therefore be considered in downstream emergency and water-resources management planning.

The sensitivity analysis indicates that the hydrologic response was relatively stable to the tested channel roughness and geometry assumptions, with only minor changes in routed peak discharge. This suggests the variation lies within the numerical precision of the simulation rather than reflecting on systematic geometric effect; therefore, peak inflow at the basin outlet is accordingly insensitive to channel cross-sectional width within the tested range. However, in the absence of surveyed channel sections, the adopted cross-sectional dimensions nonetheless remain approximate and are documented here a source of structural, if empirically minor, uncertainty in the Muskingum-Cunge routing.

The hydraulic results showed greater sensitivity to floodplain roughness, particularly at locations close to hazard-class thresholds. The change in Safana from H5 to H6 under the 100-year roughness sensitivity case demonstrates that individual hazard classifications can be affected by hydraulic parameter uncertainty, even though the broader downstream hazard pattern remained similar. The sensitivity of breach discharge to formation time was comparatively limited within the tested range. These findings are consistent with previous dam-breach studies that identify breach formation parameters as important sources of uncertainty in predicted downstream flows and water levels (Wahl, 1998; Froehlich, 2008).

Generally, the results show that, under the assumed FSL-triggered piping failure, the breach initiation condition and reservoir response had a greater influence on the variation in breach discharge than the difference between the three design-storm return periods. The stable hazard pattern provides a useful basis for identifying persistent downstream priorities for emergency preparedness, evacuation planning, and access management.

5. CONCLUSION

This study assessed the consequences of a hypothetical piping failure of Zobe Dam under 30-, 50-, and 100-year design-storm conditions using coupled HEC-HMS and 2D HEC-RAS modelling, with flood-hazard mapping undertaken in QGIS. The modeled peak inflow increased from 4,616.3 m^3/s for the 30-year event to 5,333.4 m^3/s for the 100-year event, while peak breach discharge increased from 2,377.24 to 2,685.35 m^3/s. Despite the increase in design-storm magnitude, the resulting flood hazard classification remained unchanged across the three scenarios. Garhi was consistently classified as H6, while Hakazama, Safana, and Kunamawa were classified as H5, and Dogon Ruwa and Makwanshi as H2/H3. The Water Treatment Plant and Bodole remained outside the modeled flood extent. Under the assumed Full Supply Level-triggered piping failure, therefore, increasing the return-period increased the flood magnitude but did not change the identified pattern of downstream hazard. Although, sensitivity analyses showed limited variation in HEC-HMS routed discharge and breach discharge within the tested parameter ranges, but floodplain roughness affected individual hydraulic conditions and resulted in a change from H5 to H6 at Safana under the 100-year sensitivity case.

These results identify Garhi and the downstream road corridor that linked Dutsin-Ma toward Kankara as important priorities for flood-warning, evacuation, and emergency-access planning. The potential disruption of this corridor, together with the hazard classification of the affected settlements, has implications for regional water-resources management, especially the continuity of transport, emergency response, and movement of people and goods during a dam-failure event.

Data Availability

The digital elevation model used in this study is publicly available from the United States Geological Survey's EarthExplorer portal (earthexplorer.usgs.gov). Dam-specific geometric and hydrological data were obtained from the Sokoto-Rima River Basin Development Authority and are available from the corresponding author upon reasonable request and with the permission of that authority.

ABSTRACT

Okra (Abelmoschus esculentus L. Moench) is a nutrient-dense vegetable, yet the losses remains significant due to high moisture content and poor postharvest handling.. A sustainable drying technique remains the most practical preserving methodA number research works have been report on the drying technique but multiple treatment condition often deteriorate the nutritional composition, particularly the slice thickness in relation to the drying temperature. This study evaluated the effect of slice thickness and drying temperature on the proximate composition of okra. Okra samples of 0.5, 1.0, 1.5 and 2.0 cm thicknesses were subjected to processing temperatures of 30, 50, 60 and 70°C, with three replicates for each treatment combination represented by samples A, B and C. Moisture, ash, lipid, protein, fibre and carbohydrate contents were determined and expressed as percentages. Across all 45 observations, mean moisture, ash, lipid, protein, fibre and carbohydrate contents were 12.51, 8.91, 4.82, 16.70, 7.61 and 57.05%, respectively. The highest mean protein content (20.12±0.09%) occurred at 1.5 cm thickness and 60°C, while the highest mean fibre content (8.75%) was also recorded at this treatment. The maximum mean carbohydrate content (62.62±0.35%) occurred at 0.5 cm and 50°C, whereas the highest mean lipid content (6.83%) occurred at 2.0 cm and 70°C. The results establish substantial variation in proximate composition with processing temperature and sample thickness, indicating an interaction between the two factors. A thickness of 1.5 cm combined with 60°C produced a particularly favorable protein- and fibre-rich profile. The findings provide a useful guidance for selecting processing conditions for nutritionally desirable dried okra products.

Keywords: *okra; drying temperature; slice thickness; proximate composition*

1. INTRODUCTION

Okra (Abelmoschus esculentus L. Moench) is a widely consumed vegetable valued for its protein, carbohydrate, dietary fibre, minerals, vitamins and bioactive compounds. Recent reviews have highlighted its phytochemical importance, emphasizing the need for efficient handling (Abdel-Razek et al., 2023). Also, fresh okra's high moisture content and postharvest physiological activity make it highly perishable, so drying is widely used to extend availability and ease storage and transportation. However, drying can alter the apparent concentrations and retention of nutritional components, with recent studies reporting differences in moisture, ash, fat, protein, fibre and carbohydrate contents depending on cultivar, pretreatment and drying technique (Mohammed et al., 2024; Ibeogu et al., 2024; Ogundele & Terzungwe, 2024).

Drying temperature affects moisture migration, drying rate, chemical reactions and nutrient retention; Afolabi et al. (2022) showed that temperature and time significantly influenced hot-air-dried okra quality and used statistical optimization to identify favourable process conditions. Sample thickness is equally important, as it affects surface area and the distance moisture must migrate: Pendre et al. (2012) demonstrated that slice size and drying temperature significantly influenced protein, ascorbic acid and fibre retention, with optimal retention at 2 cm/60°C, while El-Mesery et al. (2023, 2024) showed moisture diffusivity and drying kinetics were jointly governed by temperature and thickness, with drying duration increasing with slice thickness. Obasi et al. (2025) found moderate temperatures (50°C) better preserved proximate and mineral composition than higher-temperature drying, and Reid-Fitten et al. (2026) showed that thermal pre-treatment combined with drying method significantly influenced phytonutrient, vitamin and antioxidant retention. Similarly, Rababah et al. (2023) and Kolawole et al. (2024) and Maigari et al. (2026) reported that drying and storage conditions affect the physicochemical, nutritional and antioxidant quality of dried okra, reinforcing the need for optimised drying regimes.

Thus, this study assessed how sample thickness and drying temperature influence okra's proximate composition, aiming to identify treatment combinations yielding desirable nutritional characteristics.

2. METHODOLOGY

This section describes the sample collection, research design, materials, experimental procedures, data collection methods, and analytical or computational tools used.

2.1 Sample Collection and Preparation

Fresh, matured, disease-free okra pods were procured locally and transported in perforated crates to the environmental laboratory of the Department of Water Resources and Environmental Engineering, Ahmadu Bello University, minimising mechanical damage. Pods were then washed under running potable water to remove dirt and surface contaminants, and drained before further processing.

2.2 Experimental Design

The washed pods were sliced transversely into four thickness levels (0.5, 1.0, 1.5 and 2.0 cm) using a slicer and thickness guide/vernier caliper for dimensional accuracy, then dried at four temperature levels (30, 50, 60 and 70°C). The experiment followed a factorial design (thickness × temperature) with three replicates, yielding 16 treatment combinations and 48 expected observations. Three (3) contaminated samples were excluded as unsuitable, resulting in 45 observations for the final analysis.

2.3 Drying Procedure

Sliced samples were spread in a single layer on perforated trays and dried in a thermostatically controlled hot-air solar dryer at the respective treatment temperature (30, 50, 60 or 70°C) to constant weight, then cooled to room temperature, milled, and sieved through a 0.5 mm mesh. The resulting flour was packaged in airtight, labelled containers and stored at ambient temperature away from light pending proximate analysis.

2.4 Proximate Analysis

Proximate composition of the dried okra flour samples was determined in triplicate using standard AOAC (2023) methods. Specifically, moisture and ash were determined gravimetrically, via oven-drying at 105 °C and muffle-furnace incineration at 550 °C, respectively, while crude lipid was extracted using the Soxhlet method with n-hexane/petroleum ether. In addition, crude protein was determined by the micro-Kjeldahl method (nitrogen × 6.25), and crude fibre by sequential acid-alkali digestion and ashing. Finally, carbohydrate (CHO) was estimated by difference, as CHO (%) = 100 −

(% Moisture + % Ash + % Lipid + % Protein), consistent with common practice in food-science studies where fibre is analysed separately.

2.5 Data Analysis

Data were expressed as mean ± standard deviation (SD) (n = 3) and analysed using descriptive statistics and one-way analysis of variance (ANOVA) in IBM SPSS Statistics. ANOVA was used to determine the effects of slice thickness and drying temperature on each proximate composition parameter, with statistical significance set at $\mathbf{p < 0.05}$. All statistical computations were performed using standard procedures in SPSS.

3. RESULTS AND DISCUSSION

3.1 Overall Proximate Composition

Table 1 shows carbohydrate as the largest proximate fraction, followed by protein, ash, fibre and lipid, with mean moisture (12.51%) reflecting substantial water loss within the acceptable (<13%) range for shelf-stable dried vegetables, comparable to Obasi et al. (2025). This apparent concentration of solid constituents through water removal is consistent with recent reports on dried okra (Maigari et al., 2026). The mean protein content (16.70%) suggests dried okra can meaningfully contribute to dietary protein in composite flour and snack formulation, with recent studies reporting values approaching 20% depending on drying method and pre-treatment (Ibeogu et al., 2024). The high carbohydrate proportion likewise reflects typical dried-plant composition, best interpreted as a relative concentration effect rather than carbohydrate synthesis during drying. Also, Table 2 presents the complete mean ± SD values for all six proximate parameters across the sixteen slice thickness-drying temperature combinations investigated in this study, and is referenced throughout the subsections that follow.

Table 1: *Mean proximate composition of dried okra*

Parameter	Mean ± SD (%)	Minimum (%)	Maximum (%)
Moisture	12.51 ± 0.63	11.05	13.90
Ash	8.91 ± 1.54	7.06	11.56
Lipid	4.82 ± 0.93	3.56	6.83
Protein	16.70 ± 2.31	12.25	20.12
Fibre	7.61 ± 0.62	6.40	8.75
Carbohydrate (CHO)	57.05 ± 3.12	51.55	62.62

Table 2: *Proximate composition of dried okra by slice thickness and drying temperature*

Thickness (cm)	Temp. (°C)	Moisture (%)	Ash (%)	Lipid (%)	Protein (%)	Fibre (%)	CHO (%)
0.5	30	11.98 ± 0.86	10.18 ± 0.03	4.13 ± 0.07	15.97 ± 0.19	8.33 ± 0.03	57.74 ± 0.97
0.5	50	12.25 ± 0.28	8.82 ± 0.03	3.94 ± 0.01	12.35 ± 0.14	8.18 ± 0.03	62.62 ± 0.35

2.0	60	12.60 ± 0.09	7.06 ± 2.08	6.45 ± 0.05	17.17 ± 0.02	6.52 ± 0.03	56.72 ± 2.11
2.0	70	12.87 ± 0.15	8.55 ± 0.05	6.83 ± 0.06	15.91 ± 0.01	7.55 ± 0.05	55.84 ± 0.23

3.2 Effects of Slice Thickness and Drying Temperature on Proximate Parameters

Moisture content ranged from 11.05% (0.5 cm, 30°C) to 13.90% (0.5 cm, 60°C) (Tables 1 and 2). Using the data in Table2, One-way ANOVA indicated that neither slice thickness ($F = 0.74$, $p = 0.536$) nor drying temperature ($F = 2.38$, $p = 0.084$) significantly affected moisture ($p > 0.05$), though a weak upward trend at higher temperatures likely reflects case-hardening, rapid surface drying that traps residual internal moisture, consistent with El-Mesery et al. (2024), who found drying rate and moisture diffusivity jointly governed by temperature, airflow and thickness.

Ash content ranged from 5.49±0.24% (2.0 cm, 50°C) to 11.56% (1.5 cm, 60°C), with both thickness ($F = 5.15$, $p = 0.004$) and temperature ($F = 3.02$, $p = 0.041$) showing significant effects. Highest retention occurred at 1.5 cm/60°C, while lower, more variable values in the 2.0 cm/50–60°C

treatments may reflect uneven heat penetration and localised mineral loss, agreeing with Obasi et al. (2025) on temperature's influence on ash composition.

Lipid content rose significantly with both thickness ($F = 13.53$, $p < 0.001$) and temperature ($F = 9.90$, $p < 0.001$), from 3.56±0.30% (1.5 cm, 30°C) to 6.83% (2.0 cm, 70°C), likely due to a concentrating effect as moisture is removed.

Crude protein ranged from 12.25% (0.5 cm, 50°C) to 20.12±0.09% (1.5 cm, 60°C), significantly affected by both thickness ($F = 4.24$, $p = 0.011$) and temperature ($F = 6.52$, $p = 0.001$). Peak retention at 1.5 cm/60°C mirrors Pendre et al. (2012), reflecting a favourable balance between drying rate and thermal intensity, while lower protein at 50°C may reflect prolonged enzymatic activity during slower drying.

Crude fibre varied from 6.40% (2.0 cm, 50°C) to 8.75% (1.5 cm, 60°C), significantly affected by thickness ($F = 7.68$, $p < 0.001$) but not temperature ($F = 2.12$, $p = 0.113$). Fibre declined beyond 1.5 cm thickness (Table 2), supporting 1.0–1.5 cm as optimal for fibre-dense product.

Carbohydrate (by difference) ranged from 51.55% (1.5 cm, 60°C) to 62.62±0.35% (0.5 cm, 50°C), significantly affected by temperature ($F = 14.27$, $p < 0.001$) but not thickness ($F = 0.73$, $p = 0.538$). Its strong inverse correlation with protein ($r = -0.85$) reflects the by-difference calculation rather than independent carbohydrate behaviour.

Overall, thickness and temperature jointly, rather than independently, determined proximate quality: The 1.0 and 2.0 cm samples had the highest average protein concentration of 17.73% and peaked at 60°C (18.39%) before declining at 70°C, whereas 0.5 cm had the highest average fibre content of 8.12%. The 2.0 cm samples had the highest average lipid content of 5.77% and rose progressively with temperature; and carbohydrate peaked at 50°C (Afolabi et al., 2022). The 1.5 cm × 60°C treatment gave the best protein, fibre and ash retention, while peak carbohydrate and lipid occurred at 0.5 cm × 50°C and 2.0 cm × 70°C, respectively.

4. CONCLUSION

This study demonstrated that slice thickness and drying temperature interactively influences the proximate composition of dried okra significantly. Within the range of the slice thickness and drying temperature examined, it was noticed the moisture content does not significantly affected by either factor. Interestingly, both slice thickness and drying temperature significantly influenced the ash, lipid, protein and carbohydrate contents.. The treatment combination of 1.5 cm slice thickness dried at 60 °C consistently produced dried okra with the highest protein, ash and fibre retention, while thinner slices (0.5 cm) dried at moderate temperature (50 °C) favoured maximum carbohydrate retention with the lowest protein and ash concentration. These results confirm that slice thickness and drying temperature cannot be optimised independently; rather, the appropriate combination should be selected according to the intended nutritional or functional target of the final dried okra product.

Furthermore, a thickness of approximately 1.5 cm and 60°C should be investigated further as a potential optimum for protein- and fibre-rich dried okra.

ACKNOWLEDGEMENTS

This study was initiated as a result of funding from the Tertiary Education Fund, Nigeria; under the National Research Fund (NRF) grant with code number TETF/DR&D/CE/NRF2021/SETI/AFS/00146/VOL.1. Also, the authors would like to acknowledge the support of the Ahmadu Bello University, Zaria, Nigeria, for providing the enabling ground and a conducive space to conduct this study.

ABSTRACT
Ageing water infrastructure has become a major challenge to sustainable urban water supply in many developing countries, resulting in declining service reliability, increasing household dependence on alternative water sources and growing socio-economic burdens. This study assessed the impact of ageing water infrastructure on water supply reliability in Minna and Suleja, Niger State, Nigeria. Data were collected from 805 households (405 in Minna and 400 in Suleja), Niger State Water Board personnel, field observations, infrastructure inspections and secondary sources. Correlation and regression analyses were employed to evaluate the relationship between infrastructure condition and water supply reliability. The findings revealed that boreholes constitute the dominant household water source, while dependence on public piped water has declined because of deteriorating infrastructure. Minna consistently recorded better infrastructure condition, higher reliability, shorter water collection distance and lower household water expenditure than Suleja. Statistical analyses established a significant positive relationship between infrastructure condition and water supply reliability, indicating that deteriorated pipelines substantially reduce service continuity and increase household dependence on expensive alternative water sources. The study concludes that ageing infrastructure is the principal factor limiting sustainable urban water supply in Niger State with the correlation of 0.80 and 0.75 for Minna and Suleja respectively. It recommends systematic infrastructure rehabilitation, preventive asset management, expansion of distribution networks, continuous water quality monitoring and greater investment in modern water infrastructure to improve service reliability and achieve sustainable urban water management.

1. INTRODUCTION

Reliable access to safe, sufficient, and affordable water remains one of the fundamental requirements for human health, economic development, environmental sustainability, and social well-being (United Nations, 2015) Water is indispensable for domestic consumption, food production, industrial activities, energy generation, ecosystem conservation, and urban development. Consequently, the availability of reliable water infrastructure has become a major determinant of sustainable development and human welfare. Despite substantial investments in water infrastructure worldwide, ensuring continuous and equitable access to safe drinking water remains a persistent challenge, particularly in low- and middle-income countries. Rapid urbanization, population growth, climate change, ageing infrastructure, inadequate maintenance, weak institutional capacity, and insufficient financial investment continue to undermine the reliability of water supply systems across many regions of the world (United Nations, 2023; Ferdowsi *et al.*, 2024).

The challenges associated with ageing water infrastructure are considerably more severe across developing countries, where financial constraints, weak institutional capacity, rapid urbanization, population growth, inadequate maintenance culture, and limited technical expertise have accelerated infrastructure deterioration. Across Sub-Saharan Africa, many urban water utilities operate with obsolete treatment facilities, deteriorated distribution networks, ageing pumping equipment, and inadequate monitoring systems, resulting in high levels of non-revenue water, poor operational efficiency, intermittent water supply, and declining water quality.

Niger State occupies a strategic position within Nigeria's hydrological landscape. As the largest state in the country by land area, it is traversed by the Rivers Niger and Kaduna and contains numerous dams, reservoirs, streams, and groundwater resources that provide considerable water supply potential.

Although considerable research has been conducted on water supply, water quality, governance, and sanitation in Nigeria, relatively few studies have comprehensively investigated the condition of ageing water infrastructure and its direct influence on water supply reliability in Niger State. Existing studies have largely focused on national assessments, selected metropolitan areas, or isolated aspects such as water quality, financing, governance, or access, with limited integration of technical infrastructure condition, household service reliability, environmental vulnerabilities, and socio-economic impacts within a single analytical framework. Recent reviews have likewise concluded that empirical evidence linking infrastructure condition, governance, operational performance, and service reliability remains fragmented in Nigeria, particularly at the state level, thereby limiting evidence-based infrastructure planning and policy development (Adeniran, 2022; Ojo & Sohail, 2024). Consequently, there remains insufficient empirical evidence to guide infrastructure rehabilitation, maintenance prioritization, investment planning, and policy formulation specifically for Niger State. This knowledge gap limits evidence-based decision-making by government agencies, water utilities, and development partners seeking to improve the performance and resilience of public water supply systems.

Against this background, this study evaluates the impact of ageing water infrastructure on water supply reliability in Minna and Suleja, Niger State, Nigeria. The study provides empirical evidence to support infrastructure rehabilitation, improve water utility performance, strengthen climate resilience, enhance public health protection, towards achieving Sustainable Development Goal 6 on clean water and sanitation. The findings are also expected to provide practical guidance for policymakers, engineers, water utility managers, and development agencies responsible for planning sustainable water infrastructure development in Niger State and Nigeria as a whole.

2. METHODOLOGY

2.1 Description of the Study Area

Niger State is the largest state in Nigeria by land area, occupying approximately 76,363 km² in the North-Central region. It lies between latitudes 8°20′N and 11°30′N and longitudes 3°30′E and 7°20′E. The state experiences a tropical continental climate with annual rainfall ranging from 1,100 to 1,600 mm and average temperatures between 25°C and 35°C. The Rivers Niger and Kaduna traverse the state, together with numerous streams, reservoirs, and groundwater resources. Despite these abundant water resources, increasing population growth, ageing infrastructure, inadequate maintenance, and urban expansion continue to constrain reliable public water supply (National Population Commission, 2023; Federal Ministry of Water Resources and Sanitation, 2024).

Fig 2.1

2.1.1 Minna

Minna is the capital city of Niger State and serves as the state's administrative, educational, and commercial centre. The city experiences rapid urbanization, increasing population growth, and expanding residential development that have significantly increased demand for potable water. Water supply is primarily provided by the Niger State Water Board through treatment plants, pumping stations, storage reservoirs, and distribution networks, although many households supplement public supply with private boreholes and water vendors due to intermittent service.

2.1.2 Suleja

Suleja is one of the fastest-growing urban centres in Niger State because of its proximity to the Federal Capital Territory, Abuja. Rapid population growth and urban expansion have considerably increased pressure on existing water infrastructure. Although the town possesses public water supply facilities, many households continue to depend on private boreholes, wells, and commercial water vendors because of inadequate service continuity and ageing infrastructure.

2.2 Sources of Data

Data for this study were obtained from both primary and secondary sources to ensure comprehensive assessment of ageing water infrastructure and water supply reliability.

2.2.1 Primary Data

Primary data were obtained through field investigations comprising infrastructure inspection, structured questionnaire administration, interviews with technical personnel of the Niger State Water Board, direct field observation and water quality testing where applicable.

2.2.2 Secondary Data

Secondary information was obtained from the Niger State Water Board, National Population Commission (NPC), National Bureau of Statistics (NBS), WHO/UNICEF Joint Monitoring Programme (JMP), World Health Organization (WHO), Federal Ministry of Water Resources and Sanitation, published journal articles, textbooks, government reports, and relevant policy documents. These sources provided demographic information, infrastructure records, policy guidelines, and background information supporting the primary data.

2.3 Evaluation Index

The relationship between infrastructure condition and water supply reliability was evaluated using the Pearson Product–Moment Correlation Coefficient (PPMCC) and Multiple Linear Regression. Pearson's correlation coefficient was computed using Equation 2.1.

$$r \frac{n\sum_{i=1}^{n} X_i Y_i - (\sum_{i=1}^{n} X_i)(\sum_{i=1}^{n} Y_i)}{\sqrt{[n\sum_{i=1}^{n} X_i^2 - (\sum_{i=1}^{n} X_i)^2][n\sum_{i=1}^{n} Y_i^2 - (\sum_{i=1}^{n} Y_i)^2]}} \quad (2.1)$$

Where r is the Pearson Product–Moment Correlation Coefficient, X_i is the infrastructure condition score for the i^{th} observation, Y_i is the water supply reliability score for the i^{th} observation, n is the Number of observations (sample size), \sum is the summation operator and *i* is the observation index (i=1,2,…,n).

The value of the correlation coefficient ranges from −1 to +1, where positive values indicate a direct relationship between infrastructure condition and water supply reliability, negative values indicate an inverse relationship, and values close to zero indicate little or no linear relationship.

The regression model adopted using Equation 2.2

$$Y = \beta_0 + \beta_1 X_1 + \varepsilon \quad (2.2)$$

Where Y is the water supply reliability, β_0 is the constant, β_1 are the regression coefficients, X_1...is the independent variables and ε is the error term.

Statistical significance was evaluated using $p<0.05$ where p represents the probability value. Where comparisons between Minna and Suleja were required, an independent-samples t-test was applied. Because the stated formula does not assume equal population variances, it represents Welch's independent-samples t-test.

3. RESULTS AND DISCUSSION

3.1 Assessment of Ageing Water Infrastructure (Piping)

The primary data provided first-hand information regarding infrastructure condition, operational performance, and household experiences. The table 3.1 shows that piped water ranks lowest in the sources of water.

Water Source Distribution (Minna vs Suleja)

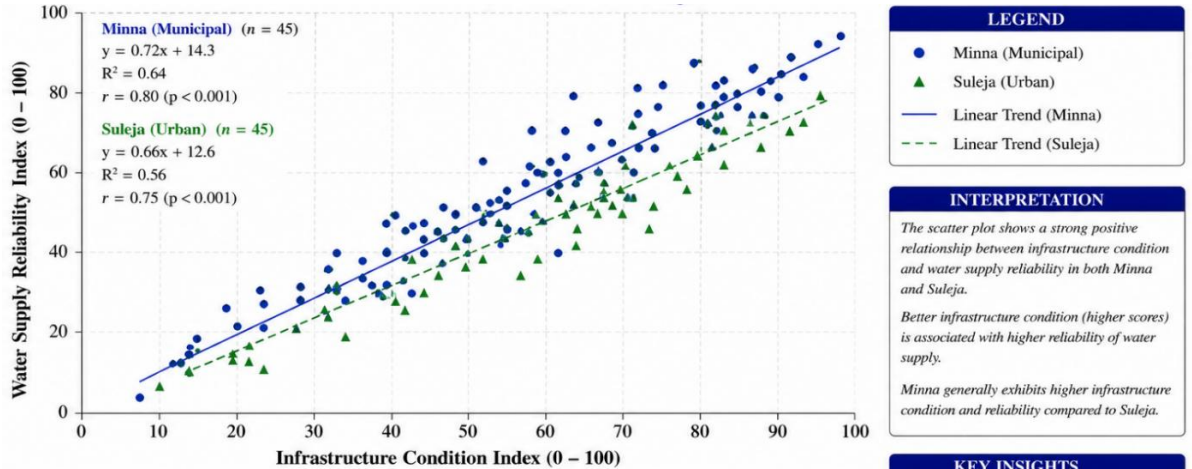
Table 3.1: Water Source Distribution

Water Source	Minna (%)	Suleja (%)
Borehole	47.4	35.5
Well	21.7	24
Vendor	18.3	29.5
Piped	12.6	11

The objective is to determine the extent to which ageing infrastructure contributes to declining water service performance. A total of 612.4 KM length of pipeline was assessed in Minna while 587.3 KM was assessed for Suleja.

The condition assessment of transmission and distribution pipelines presented in table 3.2 indicates that most pipeline networks in both Minna and Suleja fall within the fair and poor condition categories. Although Minna recorded a moderately higher proportion of pipelines in good and excellent condition, Suleja exhibited relatively larger percentages of pipelines classified as poor and very poor. This pattern demonstrates that a considerable proportion of the distribution network has exceeded its intended design life and now operates with reduced hydraulic efficiency.

Table 3.2: Pipeline Condition Rating



PIPELINE CONDITION RATING SCALE			
Minna Pipeline (%)	**Suleja Pipeline (%)**	**Ratings**	**Description**
13.6	11.2	80-100	Excellent
26.1	24.3	60-79	Good
30.7	28.9	40-59	Fair
18.9	21.4	20-39	Poor
10.7	14.2	0-19	Very Poor

The deterioration of pipeline infrastructure can largely be attributed to prolonged service life, inadequate preventive maintenance, corrosion, repeated leakages, pipe bursts and delayed replacement of obsolete distribution networks. As pipelines age, structural failures become increasingly frequent, resulting in substantial water losses before treated water reaches consumers. Leakage also contributes to pressure reduction within the network, allowing contaminants to infiltrate damaged pipelines whenever negative pressure conditions occur.

3.2 Relationship between Ageing Infrastructure and Water Supply Reliability

The condition of ageing water infrastructure and the reliability of public water supply in Minna and Suleja. Correlation and regression analyses were conducted to determine the magnitude and significance of the relationships between infrastructure condition and selected reliability indicators. In addition, graphical analyses were used to illustrate the nature of these relationships and identify the infrastructure variables exerting the greatest influence on service reliability.

The scatter plots presented in Figure 3.2 reveal a clear positive relationship between the Infrastructure Condition Index (ICI) and the Water Supply Reliability Index (WSRI) of 0.8 and 0.75 for Minna and Suleja respectively, while the R^2 values of 0.64 for Minna metropolis and 0.56 for Suleja town. In both cities neighbourhoods with better infrastructure conditions consistently recorded higher levels of water supply reliability, while areas characterised by deteriorated infrastructure experienced lower reliability scores. The pattern of the scatter plots demonstrates that improvements in infrastructure condition are associated with corresponding improvements in service reliability.

Summary Statistics and Correlation Analysis

Location	N	Infrastructure Condition Index				Reliability Index				R^2	r	p-value	Equation (Trend Line)
		Mean	Min	Max	SD	Mean	Min	Max	SD				
Minna (Municipal)	45	52.6	12.4	92.1	18.7	52.1	8.3	95.0	20.3	0.64	0.80	< 0.001	y = 0.72x + 14.3
Suleja (Urban)	45	41.8	9.1	84.7	17.6	42.9	5.2	82.6	18.6	0.56	0.75	< 0.001	y = 0.66x + 12.6

Figure 3.2: Infrastructure Condition versus Reliability

This relationship is expected because the various components of the water supply system operate as an integrated engineering network. Well-maintained pipelines minimise leakage and pressure losses, efficient pumping stations ensure continuous water conveyance, functional treatment plants sustain production capacity, and adequate storage facilities maintain service continuity during periods

of peak demand. Conversely, deterioration within any of these components interrupts system performance and reduces the reliability experienced by consumers.

The observed relationship agrees with previous investigations conducted by Copeland and Tiemann (2019), and World Bank (2024), all of which identified infrastructure condition as one of the strongest determinants of urban water supply reliability. This finding directly addresses the principal objective of the study by establishing empirical evidence linking ageing infrastructure with water supply performance in Niger State.

The linear regression models presented in Figure 3.2 further confirm that infrastructure condition significantly predicts water supply reliability in both Minna and Suleja. The regression lines exhibit positive slopes, indicating that improvements in infrastructure condition are associated with proportional increases in reliability. The relatively stronger regression observed in Minna suggests that infrastructure improvements produce more immediate gains in service reliability because the existing system remains comparatively functional. Although the relationship remains statistically significant in Suleja, the lower gradient reflects the cumulative influence of additional constraints such as rapid urban expansion, increasing water demand and operational limitations.

The GIS analyses established a strong positive relationship between infrastructure condition and water supply reliability at 5% significance level, confirming that improvements in infrastructure condition would directly enhance service reliability.

The analyses therefore fulfil the central objective of the study by quantitatively establishing the relationship between infrastructure condition and water supply reliability while providing an evidence-based foundation for subsequent policy recommendations.

3.3 Distance to Water Source

Figure 3.3 presents the average distance travelled by households to obtain water. The results indicate that respondents in Minna travelled an average distance of approximately 72.5 m to their primary water source, whereas households in Suleja travelled substantially farther, averaging approximately 185.4 m. Although both values remain below the international threshold commonly used to define basic water accessibility, the considerable disparity between the two cities reflects significant differences in infrastructure distribution and service availability.

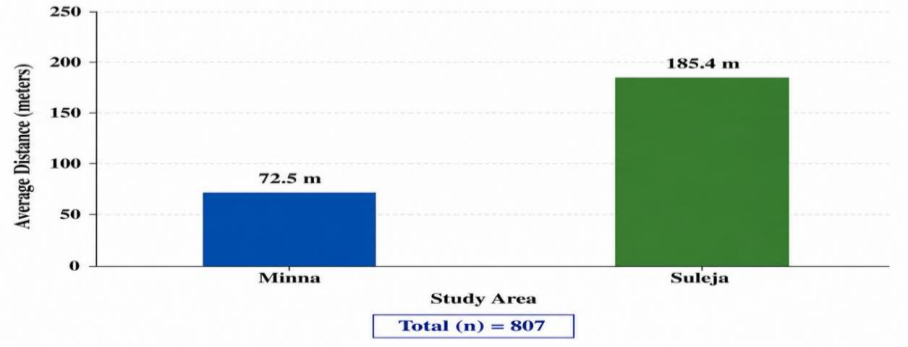


Figure 3.3: Average Distance to Water Source

3.4 Treatment Plant Condition

The assessment of treatment plant condition shown in Figure 3.4 indicates that most facilities operate within the fair condition category, while only a limited proportion can be considered good or excellent. Minna generally recorded moderately better treatment plant conditions than Suleja, although neither city possesses treatment infrastructure that could be considered fully modern or highly efficient.

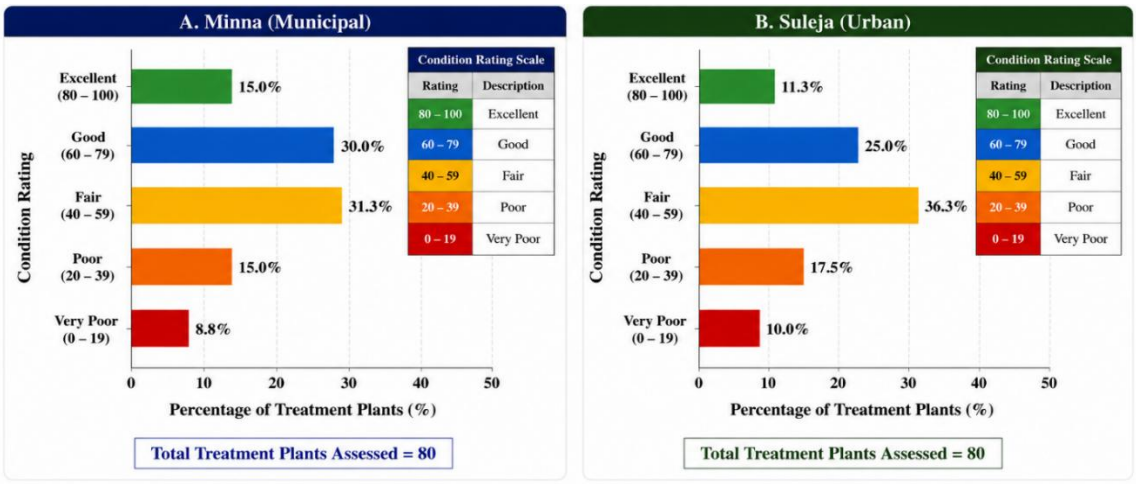

Figure 3.4: Treatment Plant Condition

3.5 Pumping Station Condition

Figure 3.5 presents the condition of pumping stations responsible for conveying treated water throughout the distribution system. The results reveal that pumping stations in Minna

generally, perform better than those in Suleja, although both cities exhibit considerable proportions of facilities classified as fair or poor. Only a relatively small number of pumping stations achieved excellent condition ratings.

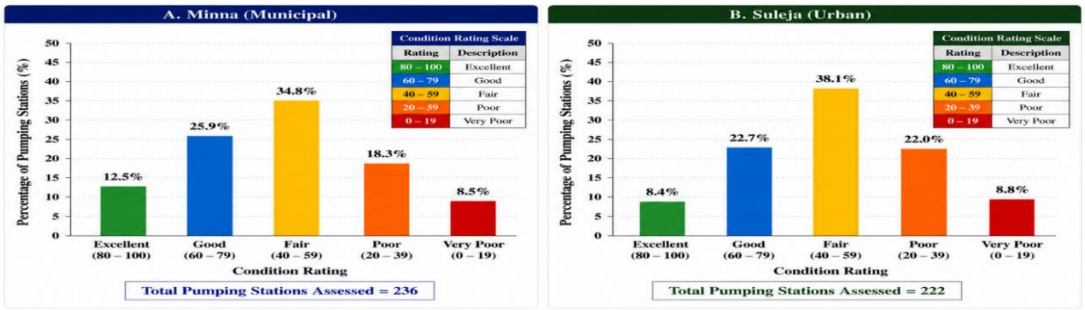

Figure 3.5: Pumping Station Condition

3.6: Storage Facility Condition

Storage facility condition, illustrated in Figure 3.6, reveals similar deterioration patterns. Most storage reservoirs were classified within the fair category, while smaller proportions were rated as excellent or good. Minna again demonstrated slightly better performance than Suleja, although substantial rehabilitation remains necessary in both cities.

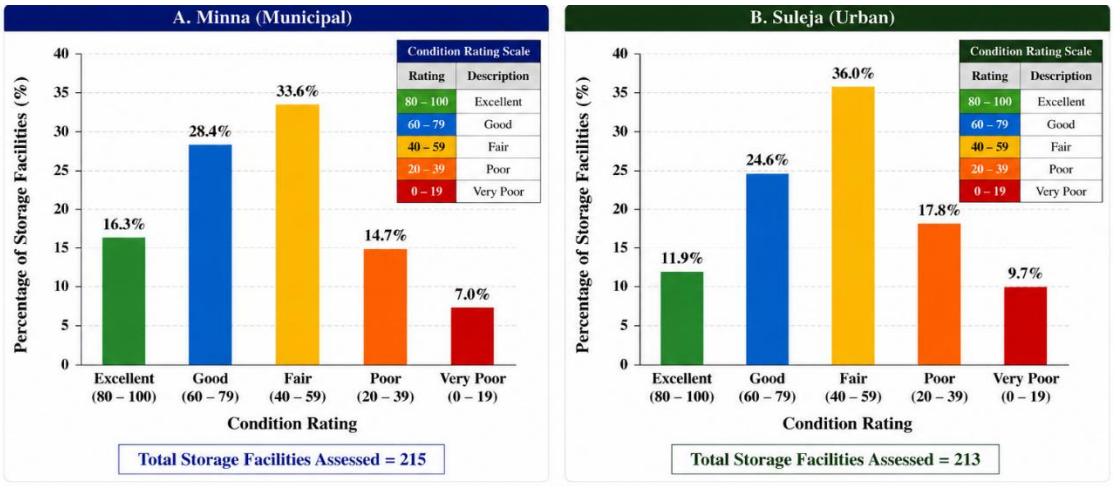

Figure 3.6: Storage Facility Condition

3.7: Comparative of Monthly Water Expenditure

The comparison of monthly household water expenditure presented in Figure 3.7 demonstrates that households in Suleja spend considerably more on domestic water than households in Minna. Although household income levels in both cities remain broadly comparable, the higher dependence on commercial water vendors and alternative water sources substantially increases water-related expenditure among Suleja households.

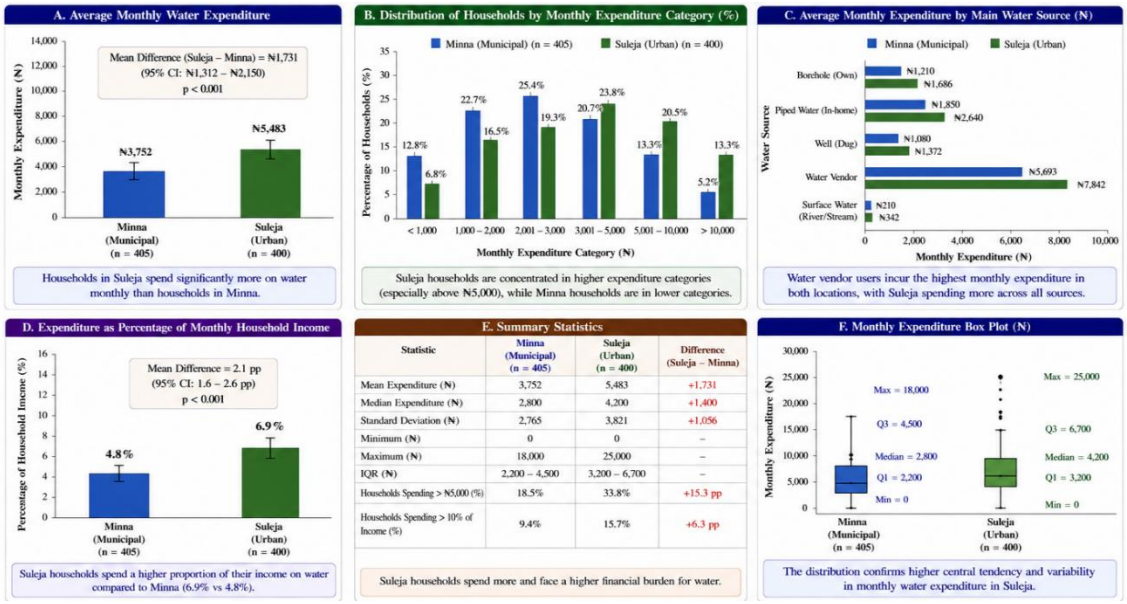

Figure 3.7: Comparative of Monthly Water Expenditure

4. CONCLUSION

The findings demonstrate that ageing infrastructure has significantly reduced the efficiency, reliability and sustainability of urban water supply systems in both cities.

The study concludes that ageing infrastructure is the principal factor limiting sustainable urban water supply in Niger State with correlation of 0.80 and 0.75 for Minna and Suleja respectively.

Pipeline ratings shows that 29.6% of 612.4 km of pipeline in Minna have failed, while 35.6% of 587.3 km pipeline in Suleja have failed.

From a policy perspective, the results highlight the urgent need for systematic rehabilitation of ageing water infrastructure in Niger State. Investment should shift from reactive maintenance towards preventive asset management, strategic infrastructure renewal and expansion of water distribution networks to underserved communities. The study was limited by its focus on two urban centres and by the use of cross-sectional survey data, which provide a snapshot of existing conditions without capturing long-term temporal changes in infrastructure performance. Future research should extend similar assessments to other urban centres within Nigeria, incorporate longitudinal monitoring, evaluate climate change impacts on water infrastructure resilience and develop predictive asset deterioration models using advanced machine learning and artificial intelligence techniques.

ABSTRACT

Road transportation remains the dominant mode of movement for passengers and freight in Nigeria. Although road construction and rehabilitation projects are undertaken to improve transport efficiency, they often introduce temporary hazards within construction work zones. This study examined the impact of road construction site activities on the occurrence of road traffic accidents along the Zaria–Kaduna Road. The rehabilitation contract commenced in May 2018 and the Zaria–Kaduna section was completed in December 2022; the FRSC crash records analyzed cover the years 2017–2020, being the data available at the time of the study. A descriptive survey design was adopted, combining structured questionnaires, field observations and interviews with road users, contractor staff and FRSC officers. Poor road condition, illiteracy of both road users and workers, faulty vehicle condition, and driver behaviour emerged as the most common causes of accidents, each with a mean rating of at least 3.50 It is deduced, that from year 2018, 2020, an average of 2,612 persons were injured and 399 killed annually. The highest monthly figures rose from 147 injured and 18 killed in October 2017 (before commencement) to 213 injured and 43 killed in October 2018 (after commencement) increase of 45% and 139% respectively. The study recommends regular safety training for workers and road users, greater attention to health and safety by contractors and other stakeholders, consistent implementation of traffic-management plans on construction sites, and stricter enforcement of regulations.

1 INTRODUCTION

1.1 Background of the Study

Transportation infrastructure is widely recognized as one of the fundamental drivers of economic growth, national integration, and sustainable development. An efficient road transportation system facilitates the movement of people, goods, and services, thereby supporting industrial production, agricultural development, trade, and regional connectivity. In Nigeria, road transport accounts for the overwhelming majority of passenger and freight movements because of its accessibility, flexibility, and extensive geographical coverage (World Bank, 2020). Governments continue to channel substantial resources into building, upgrading, and expanding road networks in response to growing transportation needs. Such investments aim to deliver smoother pavement surfaces, shorter journey times, more efficient vehicle operation, and safer roads overall. Yet the very process of carrying out these improvements typically requires establishing temporary work zones, which can heighten the risk of accidents for both motorists and the personnel working on site (Alsultan et al., 2022)

Road construction work zones are characterized by lane closures, temporary diversions, narrowed carriageways, excavations, movement of construction equipment, stockpiles of construction materials, temporary traffic control devices, and altered driving conditions. These changes frequently disrupt normal traffic operations and increase the cognitive demands placed on drivers, particularly where traffic management measures are inadequate (Theofilatos, Ziakopoulos, Papadimitriou, Yannis, & Diamandouros, 2017), typical road construction work zone is shown in **Plate 1**, showing advance

warning signs, channelizing devices, barriers, and the work area. According to the World Health Organization (2023), approximately 1.19 million people die each year as a result of road traffic crashes worldwide, while millions more sustain serious injuries. The report further indicates that road traffic injuries remain the leading cause of death among young people aged 5–29 years, with low- and middle-income countries bearing a disproportionate share of the global burden.

According to Awodele and Ayoola (2005) several hundreds of construction workers are killed each year on Nigeria construction site, with many rendered temporary or permanently disabled. The national institute of occupational safety and health (NIOSH) reports that roughly 20,000 construction workers are injured each year in highway and street construction accidents, United State of America (Gohil, Parekh, & Patel, 2018). Census of fatal occupational injuries (CFOI) data indicates that 55% of fatalities occurs within the work zone itself "(Gohil, Parekh, & Patel, 2018). According to International Labour Organization statistics, approximately 120 million occupational accidents occur annually in workplaces worldwide, of which about 210,000 are fatal (Rantanen, 2008). A review of accidents reported to Nigeria's Federal Ministry of Labour and Productivity Inspectorate Division over an 11-year period (2002–2012) found a total case fatality rate of 49.5%, a significant increase compared to the earlier study period (Umeokafor et al., 2014).

Plate 1: Typical Highway Construction Work

According to the World Health Organization (2015), 90% of road traffic death occur in low and middle income countries. The crash situation in Nigeria is more serious because of the rapid growth in the number of motor vehicles in the past few years. In Nigeria, studies on road safety have largely focused on driver behavior, roadway conditions, and traffic law enforcement. Comparatively fewer studies have examined highway work-zone safety. According to the International Labour Organization (ILO), an estimated 2.93 million workers die annually worldwide as a result of work-related factors, while approximately 395 million workers sustain non-fatal work injuries each year. Of the total work-related deaths, about 330,000 are attributed to occupational accidents, while approximately 2.6 million are associated with work-related diseases (International Labour Organization, 2023).

Shittu, Popoola, Tsado, Shehu, and Abdulazeez (2022) investigated safety management practices on construction sites in Abuja and found that inadequate hazard recognition, weak safety supervision, and inconsistent implementation of safety measures significantly contributed to accidents. The study recommended stronger safety training, improved hazard identification procedures, and stricter compliance with occupational safety standards. Despite substantial funding directed toward upgrading its highway network, Nigeria still records a high incidence of road crashes (Labinjo et al., 2009). This persistent problem stems from a mix of factors working together rising traffic volumes, poorly maintained roads, risky driving habits, and lax enforcement of traffic rules, compounded further by active construction work along many routes (Labinjo et al., 2009). Construction zones pose a particular danger because motorists are forced to navigate constantly shifting road layouts while sharing limited space with heavy equipment and construction crews (Alsultan et al., 2022).

The Zaria–Kaduna Road is one of Nigeria's most strategic federal highways, connecting the northern region with the Federal Capital Territory. The location map is shown in **Figure 1**, its corridor carries substantial volumes of passenger vehicles, heavy-duty trucks, petroleum tankers, commercial buses, and agricultural transport vehicles. Federal Government awarded the contract in December 2017 for the reconstruction and rehabilitation of Abuja -Zaria-Kano with a total length of 375.9km, out of which Zaria to Kaduna has about 83km, to improve capacity and pavement condition. The project commenced in May 2018 to date, but the Zaria to Kaduna portion was completed in 2022. During these projects, motorists have experienced lane closures, traffic diversions, temporary pavement conditions, and construction activities that influenced road safety.

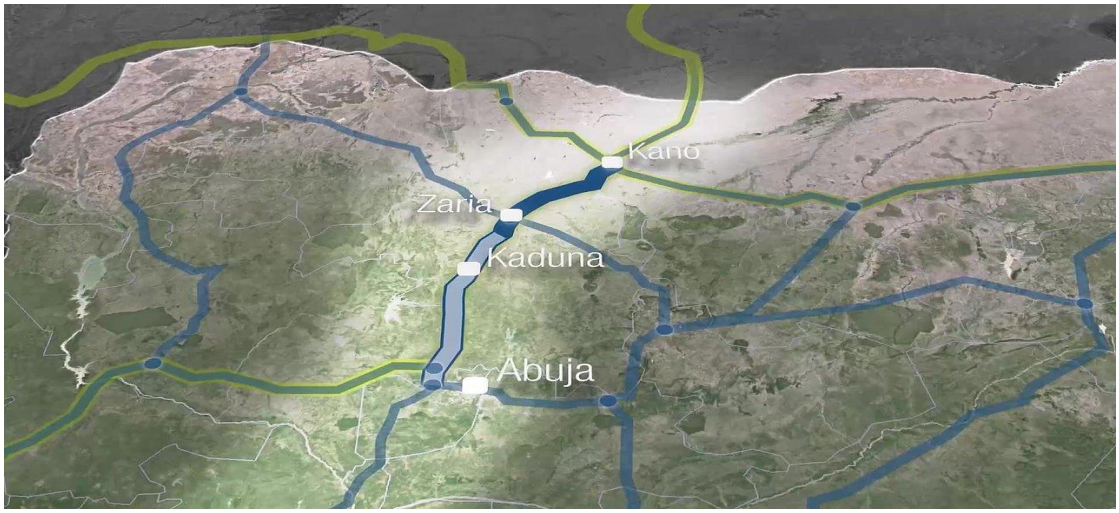

FIGURE 1: LOCATION MAP OF THE STUDY AREA (ZARIA–KADUNA ROAD)

Although contractors are generally required to implement comprehensive traffic management plans including advance warning signs, temporary speed restrictions, barriers, flag personnel, pavement markings, and adequate illumination the effectiveness of these measures varies considerably across construction sites. Inadequate implementation may increase confusion among drivers and elevate crash risk, particularly during periods of high traffic demand and reduced visibility.

In Nigeria, highway reconstruction projects are commonly executed while traffic continues to use portions of the existing roadway. Consequently, motorists are often required to navigate narrowed carriageways, uneven pavement surfaces, temporary diversions, reduced visibility, and changing traffic patterns. These conditions are further aggravated by excessive speeding, dangerous overtaking, driver impatience, poor compliance with temporary traffic signs, and inadequate enforcement of speed limits within construction zones. Such factors collectively increase the likelihood of crashes involving motorists, pedestrians, construction workers, and construction equipment. Due to the economic importance of Zaria – Kaduna road, federal government awarded the contract for rehabilitation and expansion in 2017. It was observed that during the construction, road traffic crashes continue to occur along the sections under construction, raising concerns regarding the adequacy of existing work-zone traffic management practices and contractor compliance with established safety standards.

Although studies have examined road traffic accidents in Nigeria generally, relatively few have specifically investigated the relationship between construction site activities and accident occurrence along the Zaria–Kaduna Road. This lack of location-specific empirical evidence limits the ability of highway agencies, contractors, and road safety authorities to develop targeted interventions for reducing work-zone crashes. Therefore, this study seeks to evaluate the impacts of road construction site activities on accident occurrence rate along the Zaria–Kaduna Road and to recommend practical measures for improving safety within highway construction zones. The findings of this study will provide evidence-based recommendations for improving work-zone safety and reducing accidents on major highway construction projects in Nigeria.

2 THEORETICAL BACKGROUND

2.1 Road Construction Activities

The typical road construction activities include site clearing and grubbing, earthworks and excavation, embankment construction, drainage installation, culvert and bridge construction, pavement stabilization, asphalt laying, pavement marking, installation of road furniture, and traffic diversion and temporary traffic control.

TABLE 1: MAJOR ROAD CONSTRUCTION ACTIVITIES AND ASSOCIATED HAZARDS

S/N	Construction Activity	Potential Hazard	Possible Accident
1	Site clearing	Dust generation	Reduced visibility
2	Excavation	Open trench	Vehicle fall-over
3	Earthworks	Uneven surface	Loss of vehicle control
4	Drainage construction	Narrow carriageway	Side collision
5	Asphalt paving	Traffic congestion	Rear-end collision
6	Bridge construction	Diversion	Head-on collision
7	Road marking	Temporary lane closure	Sideswipe collision
8	Movement of equipment	Construction vehicles entering traffic	Vehicle collision

Unlike permanent highway facilities, work zones change continuously as construction progresses. Consequently, motorists encounter unfamiliar road alignments, narrowed lanes, temporary barriers, construction equipment, and workers operating close to moving traffic. These conditions increase the complexity of the driving task and require greater driver attention than under normal roadway conditions (Hintersteiner, 2008).

Road construction requires continuous operation of heavy equipment such as bulldozers, excavators, graders, pavers, rollers, cranes, and dump trucks. These machines frequently enter and exit traffic streams, creating additional conflict points with moving vehicles. Where access points are not properly controlled or traffic marshals are absent, the interaction between slow-moving construction machinery and high-speed traffic substantially increases collision risk (Shittu, Popoola, Tsado, Shehu, & Abdulazeez, 2022).

2.2 Causes of Accidents in Road Construction Zones

Research indicates that work-zone crashes are rarely attributable to a single factor rather they result from the interaction of human behavior; speeding, dangerous overtaking, driver fatigue, distracted driving, alcohol or drug impairment, failure to obey temporary traffic signs, and impatience during traffic congestion which is the leading contributors of road traffic crashes within construction zones. Engineering deficiencies includes; inadequate warning signs, poor pavement markings, insufficient illumination, abrupt lane transitions, uneven pavement surfaces, inadequate drainage, and poor traffic diversion design were identified as causes of road accident. Road design and traffic management, vehicle characteristics, and environmental conditions includes; Rainfall, Dust generated during earthworks, fog, poor night time visibility, and glare from oncoming vehicles are also part of the causes of road accident. These conditions reduce visibility and increase stopping distances, thereby elevating crash risk. Expected impact of the causes of accident in construction zone is presented in **Table 2**.

TABLE 2: COMMON CAUSES OF ACCIDENTS IN ROAD CONSTRUCTION ZONES

Cause	Description	Expected Impact
Over speeding	Failure to obey temporary speed limits	Very High
Poor signage	Insufficient warning signs	High
Traffic diversion	Driver confusion	Very High
Poor lighting	Reduced night visibility	High
Heavy equipment	Conflict with traffic	High
Driver fatigue	Reduced concentration	Moderate
Dangerous overtaking	Risky maneuvers	Very High
Loose materials	Vehicle skidding	Moderate

2.3 Traffic Management Measures in Road Construction Work Zones.

Traffic management is a fundamental component of highway construction projects because it enables construction activities to proceed while maintaining the safe and efficient movement of road users. A well-designed traffic management plan minimizes conflicts between construction operations and public traffic by providing clear guidance, adequate warning, and effective control measures throughout the construction period. The primary objective is to protect motorists, pedestrians, and construction workers while minimizing traffic delays and congestion (Federal Highway Administration, 2023).

The effectiveness of traffic management depends on the proper design, installation, maintenance, and monitoring of temporary traffic control devices. International best practice recommends that every road construction project should include a comprehensive Traffic Management Plan (TMP) prepared before construction commences. The plan should identify potential hazards, specify traffic control devices, define temporary speed limits, provide diversion layouts, and establish emergency response procedures (Alsultan et al. 2022; Federal Highway Administration, 2023).

2.3.1 *Traffic Signs and Warning Devices*

Traffic signs constitute the first line of communication between highway authorities and road users within construction work zones. Warning signs provide advance information about upcoming hazards such as lane closures, road narrowing, uneven pavement, construction equipment, and temporary speed restrictions. Typical highway construction work zone showing advance warning signs, channelizing devices, barriers, and the work area is reflected in **Plate 2**. Proper placement of warning signs enables motorists to anticipate changing road conditions and adjust their driving behavior accordingly. Conversely, missing, damaged, poorly positioned, or non-reflective signs may confuse motorists and increase the probability of crashes, particularly during night-time driving or adverse weather conditions (Federal Highway Administration, 2023).

2.3.2 *Speed Management*

Excessive speed is widely recognized as one of the most significant contributors to road traffic crashes. Consequently, temporary speed limits are an essential component of work-zone safety.

2.3.3 *Temporary Traffic Diversions*

Traffic diversion involves redirecting vehicles away from active construction areas through temporary routes. An effective diversion should provide sufficient lane width, smooth horizontal and vertical alignment, adequate drainage, and appropriate signage to ensure safe vehicle movement. Poorly designed diversions may introduce sharp curves, reduced sight distances, uneven pavement, or unexpected intersections, thereby increasing the risk of collisions. Regular inspection and maintenance of diversion routes are therefore essential throughout the construction period (AASHTO, 2018).

2.3.4 *Traffic Control Personnel*

Traffic control personnel, including flaggers and traffic marshals, play an important role where temporary traffic signals are impractical or where construction activities require intermittent traffic

stoppages. Their responsibilities include directing traffic through construction zones, controlling alternating one-way traffic, coordinating construction vehicle movements, assisting pedestrians, and responding promptly to emergencies. The effectiveness of traffic control personnel depends on adequate training, proper positioning, use of high-visibility clothing, and effective communication with construction supervisors (Federal Highway Administration, 2023).

Plate 2: Typical Highway Construction Work Zone for Advance Warning Signs, Channelizing Devices, Barriers, and the Work Area.

2.3.5 *Night-time Safety Measures*

Night-time construction presents additional safety challenges because reduced visibility limits drivers' ability to detect hazards and interpret temporary traffic control devices. Appropriate night-time safety measures include; reflective warning signs, retroreflective pavement markings, flashing warning beacons, temporary lighting towers, illuminated arrow boards, reflective barriers, and high-visibility personal protective equipment for workers. Typical highway construction work zone Working in the night showing advance warning signs, flashing warning beacons and illuminated arrow boards is reflected in **Plate 3**, while highway construction work zone with reflective barrier and warning sign is shown in **Plate 4**. Adequate illumination improves hazard recognition and reduces the likelihood of crashes involving both motorists and construction personnel.

Table 3: Traffic Management Measures

Plate 3: Typical Highway Construction Work Zone Working in the Night.

Plate 4: Highway construction work zone with Reflective Barrier and warning sign

Measure	Purpose	Expected Effectiveness
Advance warning signs	Warn motorists	High
Traffic cones	Guide vehicles	High
Temporary barriers	Separate traffic from work area	Very High
Speed restriction signs	Reduce speed	Very High
Flagmen	Control traffic flow	High
Reflective devices	Improve night visibility	High
Temporary lighting	Enhance visibility	High

2.4 Research Gap

The review of existing literature reveals that substantial research has been conducted on road traffic accidents, construction safety, and work-zone traffic management globally (Alsultan et al., 2022). Nevertheless, several gaps remain. Firstly, relatively few studies have specifically investigated the relationship between road construction site activities and accident occurrence along the Zaria–Kaduna Road, despite its strategic importance as a major federal highway linking northern Nigeria with the Federal Capital Territory. Secondly, limited empirical evidence exists regarding the effectiveness of current traffic management measures implemented during road construction projects on Nigerian highways. Consequently, policymakers and contractors have insufficient location-specific information to guide improvements in work-zone safety. Improving work-zone safety contributes directly to SDG 3 (Good Health and Well-being, Target 3.6 on halving road-traffic deaths) and SDG 9 (Industry, Innovation and Infrastructure) (United Nations, 2015). Beyond conventional signage and enforcement, the deficiencies identified here could be mitigated through low-cost smart work-zone technologies, solar-powered variable-message signs, automated speed-feedback displays, GPS-tracked flag-vehicle systems and drone-based site-compliance monitoring offering scalable, technology-based pathways to safer highway construction in Nigeria (Demeke et al., 2025).

3 RESEARCH MATERIALS AND METHODS

3.1 Method

3.1.1 *Data Collection*

Primary data was obtained through structured questionnaires, field observations, and interviews with relevant stakeholders, while secondary data which includes accident records was extracted from Federal Road Safety Corps (FRSC). The analysis concentrated on identifying construction-related factors influencing accident occurrence. The survey research design method was adopted for this study to effectively assess professional opinion and road users as regards to the suitability of the subject matter.

3.1.2 *Population of the Study*

The population of the study comprises professionals such as Contractor's staff, and engineers. It also comprises the road users, the pedestrian and the drivers, then government agency (FRSC). The 6,080 is the average daily traffic (ADT) volume from a manual count used as the finite population N for the road-user stratum only; Yamane's formula gives n = 375 for that stratum. Contractor staff, engineers and FRSC officers were added through a separate purposive / complete-enumeration component.

3.1.3 *Sample*

3.1.3.1 *Sampling Strategy*

A stratified mixed design sampling method that comprises probability (systematic/random) sampling governed by Yamane's formula was used for the road-user stratum (n = 375 from N = 6,080), while purposive sampling was used only for the professional stakeholders (contractor staff, engineers and FRSC officers) who possess specific work-zone knowledge. **Equation 1** shows Yamane's formula.

$$\boldsymbol{n = \frac{N}{1 + N(e)^2}} \quad (1)$$

Where, n is the sample size, N is the population size, and e=0.05 is the precision level.

3.1.4 *Distribution Method*

The questionnaire was distributed electronically via email, using an online survey platform. This method was allowed for a broad reach and easy collection of responses. Reminders was sent out to increase response rates. A sample size is a part of the population chosen for a survey or experiment (Rahman 2023).

3.1.5 *Techniques of Data Analysis*

Analysis means the categorizing, manipulating and summarizing of data in order to obtain information. The analysis carried out are frequently statistics, and cross tabulation. The statistical package used for running the analysis is SPSS 13.0 package. The result of the table was interpreted descriptively. The descriptive interpretation provided explanation of results, which is anchored on scientific assumption and conditions of literature high points (Kothari & Garg, 2019).

3.2 Methodology

In order to obtain crash data on Kaduna- Zaria Express way, Federal Road Safety Corps FRSC 1.1 Kaduna sector command was visited, of which data from 2015 to 2020 was obtained. Questionnaire was also distributed to contractor's staff in charge for the construction of the rehabilitated road (Kaduna – Zaria) and some road users using an established sample size of 375, however, one – on – one interview of the commuters was also observed. Crash data analysis and questionnaire was done by using statistical analysis software (SPSS).

4 RESULTS AND DISCUSSION

4.1 Data Presentation and Analysis

This section deals with presentation and analysis of data collected from questionnaire administered, Crash data gotten from FRSC on Kaduna – Zaria Express way, and finally the physical site survey along the road. It was observed from **Figure 2** that only 2.4% of questionnaires was not returned, all other 97.6% was answered and returned. This reflects the level of responsibilities, high interest and determination associated with the people the questionnaires was administered. **Figure 3** shows that most respondent gender are male with highest percentage of 52.64%.

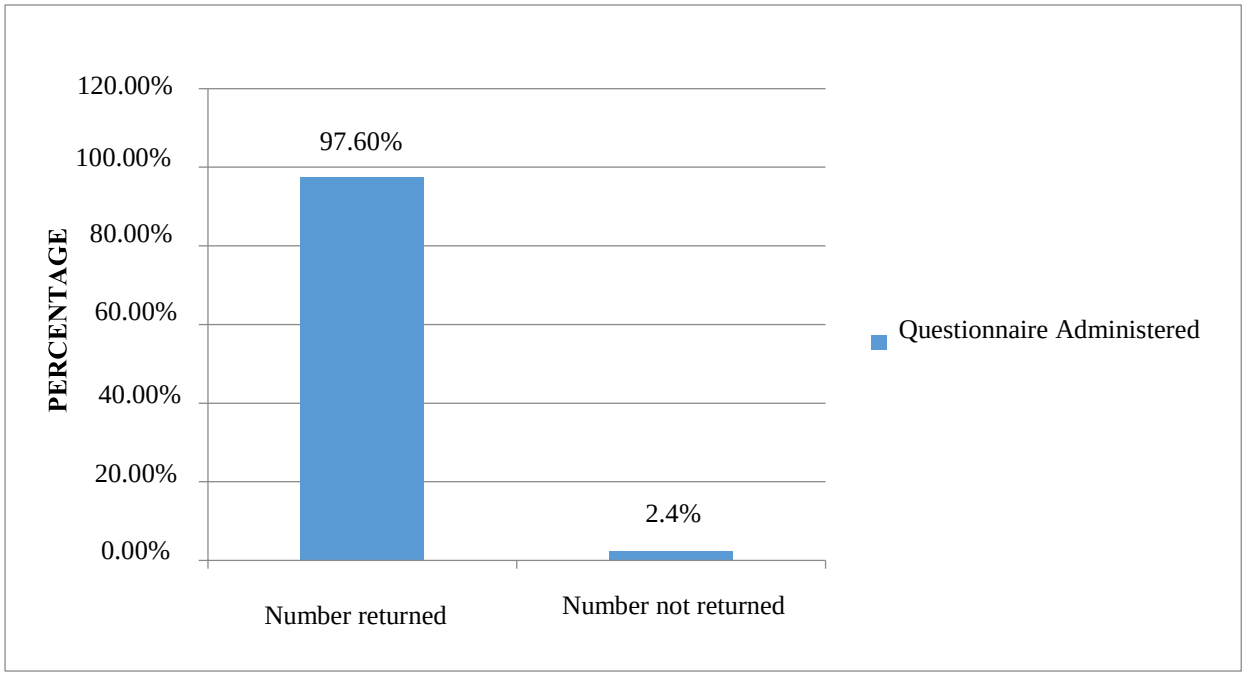

Figure 2: Questionnaire Administered

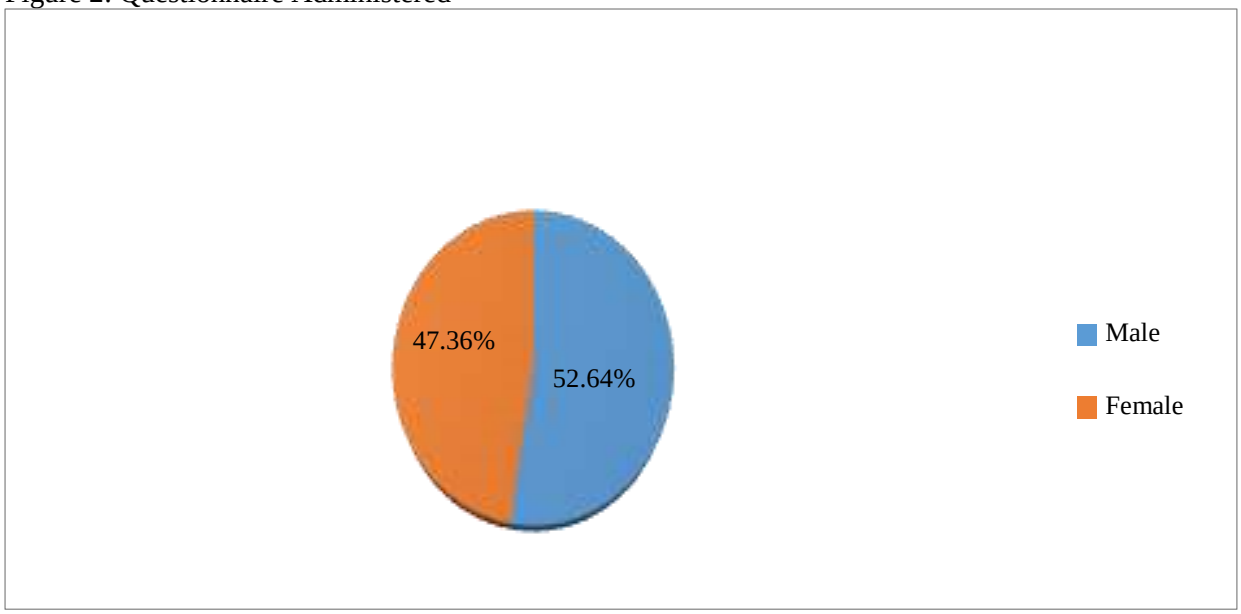

Figure 3: Gender of Respondents

The most of the respondent are road user with the highest percentage of 24.93% as shown in **Figure 4.**

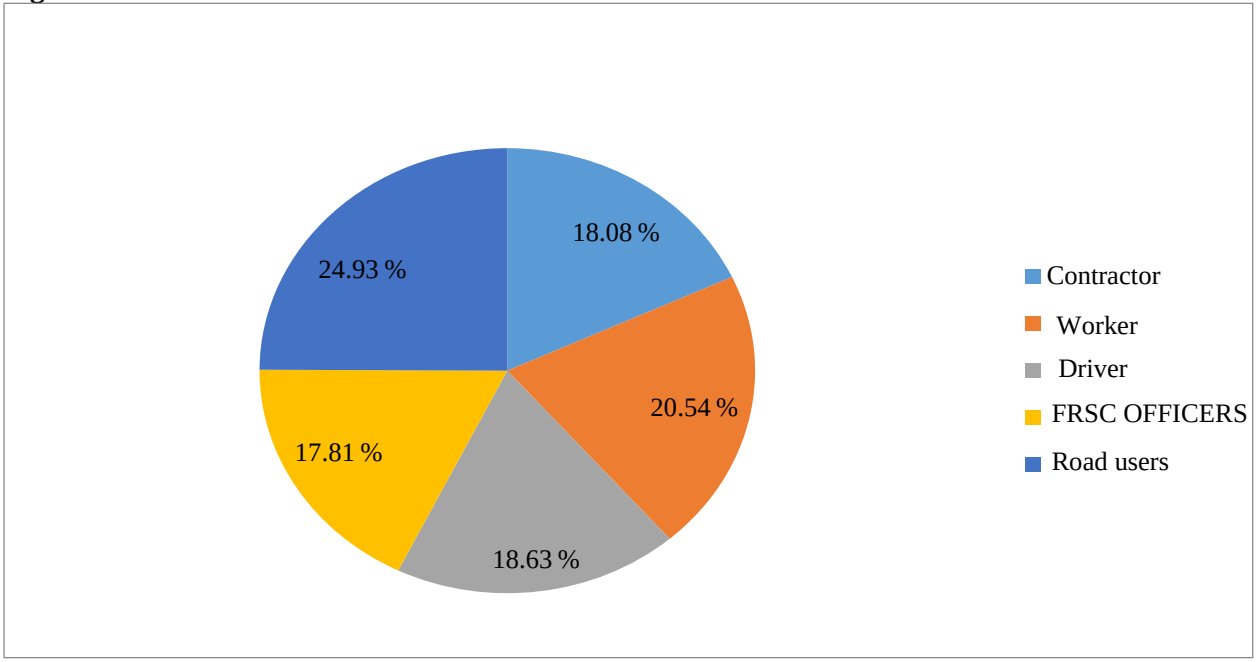

Figure 4: Designation of respondents

Figure 5 shows that respondent with driving experience between 0 -5 years have the highest percentage of 22.68%. While **Figure 6** shows respondents that passes Kaduna-Zaria road once in a month, the highest number of people that passes the road were recorded as 16.39%.

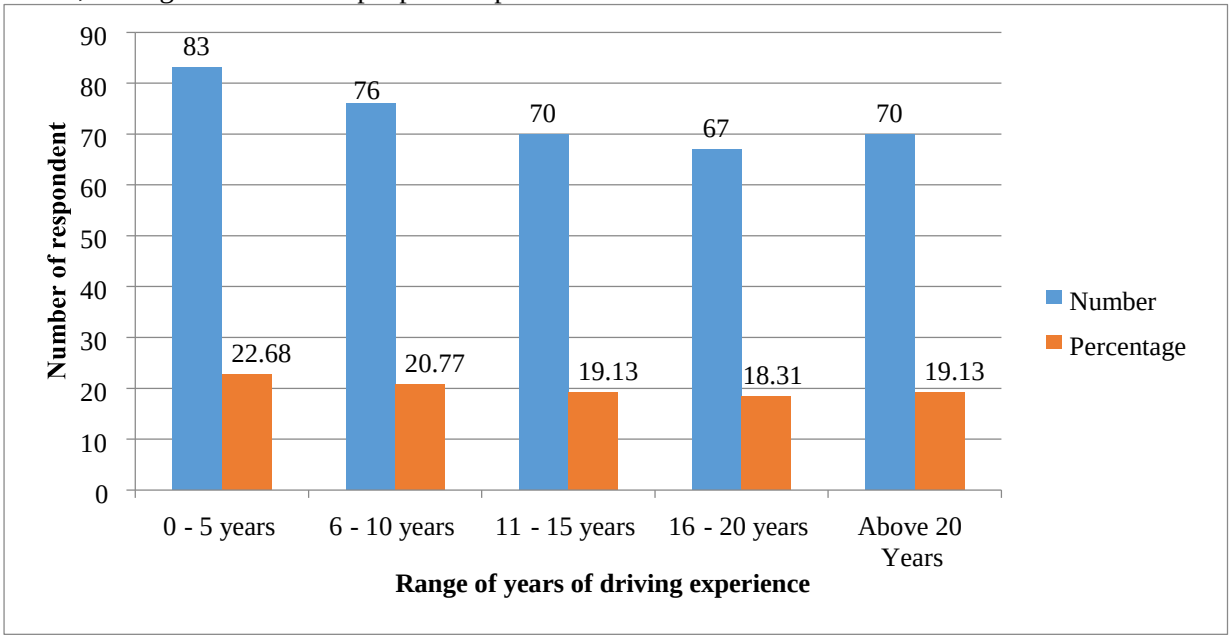

Figure 5**:** Driving Experience of Respondents.

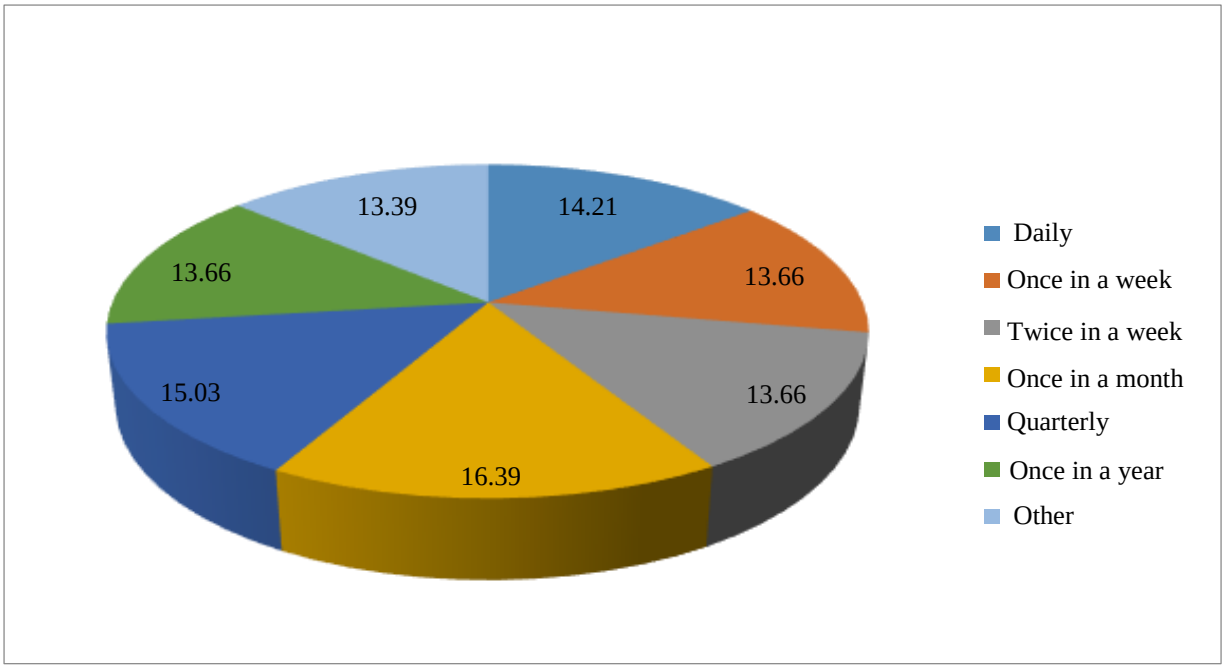

Figure 6: How often do you Pass Kaduna – Zaria road

4.2 Data Analysis of Questionnaire

Total number of questionnaires administered is 375 from **Equation 1**. The mean of the responses was calculated using **Equation 2**

$$Mean = \frac{\sum FX}{\sum F} \quad 2$$

Where F is the frequency of responses in each option and X is the weighting point of option.

In analyzing the data, decision was used for answering the research questions for the purpose of decision making, an interval of 0-2.50 mean value was used as rejected, 2.51-3.49 mean value as undecided and mean value ranging from 3.50 – 5.00 were regarded as accepted. To examine the causes of accident along road construction site, questionnaire in **Table 4A** was administered. **Table 4A** shows that most respondents agreed that "poor road condition "is the most common causes of accident on Kaduna – Zaria with the highest mean of 3.67 which is followed by accident due to illiteracy of both road users and workers with the mean of 3.66.

Table 4: A: Causes of accident

S/N	Response	S (5)	A (4)	UD (3)	D (2)	SD (1)	$\sum FX$	$\sum F$	Mean	Remarks
A	Taking intoxicant before or during driving	106	88	81	81	10	1297	366	3.54	Accepted

Note: A = Always, F = Frequently, LF = Less Frequently, R = Rarely, N = never

4.3 Crash Data from Federal Road safety Corps on Kaduna-Zaria Express Way

Table 5: A: Number of people Killed and Injured Monthly in Year 2017 - 2020

MONTH	2017		2018		2019		2020	
	Injured	Killed	Injured	Killed	Injured	Killed	Injured	Killed
JAN	403	80	313	68	339	42	200	34
FEB	343	84	181	25	211	30	154	31
MARCH	227	44	260	42	207	29	306	59
APRIL	270	37	394	64	380	43	125	15
MAY	262	55	337	41	357	45	115	18
JUNE	195	34	169	23	216	33	137	9
JULY	142	19	173	27	189	15	113	19
AUG	261	31	234	28	195	15	138	25
SEPT	150	24	177	16	161	30	138	18
OCT	147	18	213	43	141	23	155	39
NOV	179	23	218	30	247	40	157	23
DEC	152	26	310	72	311	49	164	35
TOTAL	**2731**	**475**	**2979**	**479**	**2954**	**394**	**1902**	**325**

It is observed that the highest number of people injured (2,979) and those killed (479) were in 2018, the year the contract commenced, signifying the impact of site activities causing the rate of accident. The lowest number of people injured (1902) and those killed (325) were reflected in 2020, which coincide with the COVID-19 movement restrictions of late March–mid 2020, during which inter-state travel fell markedly (Erim et al.,2020); this reduced exposure is a likely contributor, though partly offset by higher speeds on emptier roads and barricade contribute to high rate of accidents in some locations. Similarly, it were observed that in October 2017, before the commencement of the project 147 and 18 were the highest figures recorded for number of injured persons and number of person killed respectively. While in October 2018 after the commencement of the project, 213 and 43 were the highest figures recorded for number of injured persons and number of person killed respectively. This translated to rate of the injured victims increase to 45%, while rate of fatality victims increase to 139% which are quite worrisome. **Table 5B** shows that from the year of commencement of the project (2018), to the year of available data end (2020), an average of 2612 peoples were injured annually and 399 peoples were killed annually which is quite alarming.

Table 5: B: Persons Injured and Killed Annually (2018 – 2020)

Year	Injured	Killed
2018	2979	479
2019	2954	394
2020	1902	325
Total	**7835**	**1198**
Average/Anum	**2612**	**399**

4.4 Report on Physical Survey of Zaria – Kaduna Express-Way

4.4.1 *Compliance of the contractor to diversion Sign*

Physical survey of Kaduna – Zaria expressway based on the specification of British Columbian construction standard.

a) Diversion sign

Table 6 shows implemented site diversion signs. However, diversion sign shown in **Plate 5A** and **5B** respectively are not in accordance with highway traffic sign standard cited in FMW highway manual (2013). This is believed to be part of the factors causing accident on the road project sites.

Plate 5A: 1KM Distance Diversion Sign

Plate 5B:500m Distance Diversion Sign

Table 6: Contractor's Compliance with Diversion Sign specification

		Standard Specification FMW Manual (2013) (m)	Implemented Specification (m)	Remark
Size	Width	1.5	2.4	Not compliant with standard
	Height	0.9	1.2	
Colour	Background	Blue	White	
	Legend	White	Red and Black	
	Border	None	None	

b) SPEED LIMIT SIGNS

Table 7 shows implemented site Speed limit signs. However the implemented speed limit sign presented in **Plate 6A** and **6B** show that the size, colour, and mounting height of the implemented speed limit is in accordance with highway standard cited in FMW highway manual (2013).

Plate 6A: showing 40km speed limit before approaching diversion.

Plate 6B: showing 30km/hr speed limit before approaching diversion.

Table 7: Contractor's Compliance with Speed Limit specification

		Standard Specification FMW Manual (2013) (m)	Implemented Specification (m)	Remark
Size	Diameter	0.7	0.74	
Colour	Background	yellow reflective	Yellow retro-reflective	Compliant with standard
	Legend	Black semi- matt	Black	
	Border	Red retro-reflective	Red retro-reflective	
Mounting Height	Height	0.9	2.4	

c) BARRIER

Plate 7 shows implemented site installed barriers and **Table 8** summaries notable observation of the installed barriers on site. The installed barriers are slightly different from the standard specification cited in FMW highway manual (2013). This is believed to be part of the factor causing accident on the road project sites.

Plate 7: Jersey barrier

Table 8: Contractor's Compliance with Barrier specification

		Standard Specification FMW Manual (2013) (m)	Implemented Specification (m)	Remark
Size	Width	2.5	2.4	Not compliant with standard
	Height	0.83	1.2	
Colour		Red and white retro - reflective	Red and yellow retro-reflective	

5 CONCLUSION AND RECOMMENDATION

5.1 Conclusions

The following conclusions were drawn from the project:

1. Poor road condition, illiteracy of both road users and workers, fault from vehicle condition, and over-speeding/overtaking by drivers were recorded as the most common causes of accidents on the Kaduna–Zaria expressway, with mean values of 3.67, 3.66, 3.59 and 3.56 respectively.
2. The provision of Safety kits recorded the highest mean value of 4.24, followed by enforcement for its usage in site with mean value of 3.87, are the major precautionary measures that reduce the occurrence of accidents.
3. Before the commencement of the project in October 2017, 147 and 18 were the highest figures recorded for number of injured persons and number of persons killed respectively, while in October 2018 after the commencement of the project 213 and 43 were the highest figures recorded for number of injured persons and number of persons killed respectively. This translated to rate of the injured victims increase to 45%, while rate of fatality victims increased to 139%, which are quite worrisome.

4. It was deduced that from the year of commencement of the project (2018), to the year of available data of Kaduna-Zaria road section, an average of 2,612 peoples injured and 399 people were killed annually, which is quite alarming.
5. The Contractor ‘s level of compliance with traffic control standard specification in some area was good like speed limit traffic sign, while in other areas it was poor, like barrier and diversion traffic signs, which are believed to be part of the factors causing accident on the road project sites.

5.2 Recommendations

In order to promote and improve safety on road construction sites, there must be a positive action or response by the responsible bodies. In view of this, the following recommendation were made:

1. Employees training on workplace safety should be encourage by employer or contractor of a project in order to minimize accident on site.
2. First aid equipment and safety officers should be provided on sites.
3. FRSC, Police should continue enlightening road users and drivers on the dangers of over-speeding, overtaking and enforcement of regulations should be observed.
4. Contractor and other stakeholders should not only be inclined to maximizing profit from projects but rather committing themselves to maintaining Health and Safety standards.

ABSTRACT

Nigerian water utilities have expanded treatment capacity while ageing distribution networks have received limited systematic assessment. In Minna, the Municipal system operated by the Niger State Water and Sewage Corporation (NISWASEC), demand exceeds network design capacity, contributing to failures, leakage, and pressure problems. As detailed condition-assessment tools remain inaccessible, rehabilitation relies largely on institutional memory and emergency logs. This study developed a GIS-supported Physical Integrity Index (PII) from pipe age, failure frequency, leakage density, and coverage efficiency for Minna's seven service clusters, using maintenance records, field surveys, and staff interviews. Following correction of coverage-efficiency directionality, PII ranged from 2.09 in Bosso (Moderate Integrity) to 4.75 in Minna West (Critical Integrity); Minna East and Chanchaga were also Critical. The three clusters represented 53.6% of the reported 6,526 pipeline-failure occurrence units during 2021–2025. Rankings remained stable under adopted and equal weights. Validation was triangulated: PII showed expected internal associations with failure-occurrence totals ($r = 0.944$) and raw service coverage ($r = -0.906$), although these measures overlap with PII components. Independent criterion validation against NISWASEC ledger-derived cumulative repair costs for 2021–2025, which were not PII inputs, was strong ($r = 0.943$, $p = 0.001$, $n = 7$). The PII provides an evidence-based rehabilitation-prioritization tool for constrained utilities. NISWASEC should prioritise Minna West, Minna East, and Chanchaga, apply the PII annually, and disaggregate maintenance expenditure and non-revenue water by cluster.

Keywords: *Physical Integrity Index; water distribution network; infrastructure asset management; rehabilitation prioritization; Nigeria*

1. INTRODUCTION

Reliable water distribution underpins public health, economic activity, and urban growth. Adeoti et al. (2023) systematically review water-infrastructure sustainability in Nigeria and identify interrelated technical, financial, environmental, social, political, and institutional challenges, including infrastructure deterioration and operation-and-maintenance constraints. In urban distribution systems, ageing pipes can increase failures, leakage, pressure problems, service interruptions, and operating burdens. When these conditions are not systematically assessed, rehabilitation is more likely to remain reactive than condition-informed.

Sub-Saharan African utilities face these problems in their most acute form. Much of the pipework in service was laid decades ago and has exceeded its design life. Maintenance is almost entirely reactive: crews are dispatched only after a main has burst and supply has been cut (Shushu et al., 2021). This stops the immediate crisis but does nothing to slow the network's overall decline. Costs climb, non-revenue water grows, and service reliability keeps falling.

Public utilities in Nigeria face interrelated technical, financial, and institutional constraints, and Adeoti et al. (2023) emphasize the need for effective monitoring and management mechanisms across the infrastructure life cycle. In the Minna study context, rehabilitation decisions have historically relied on NISWASEC operational knowledge, emergency logs, and available budget rather than a formal engineering risk assessment. This study treats that latter observation as local study context derived from utility records, staff input, and field verification; it is not attributed to Adeoti et al. (2023).

The Minna municipal water distribution system, operated by the Niger State Water and Sewage Corporation (NISWASEC), illustrates these scenarios. The system includes several treatment plants, service reservoirs, booster stations, transmission mains, and a wide distribution network serving residential, commercial, institutional, and industrial users. Since Minna has grown, demand has outstripped what many components were designed to deliver. Decades of service, repeated repairs, leakage, and operational stress have worn the infrastructure down. The evidence is visible in recurring failures, growing water losses, unstable pressure in parts of the network, and a maintenance burden that keeps rising.

Any rehabilitation programme depends on understanding asset condition. However, detailed condition-assessment techniques such as inline inspection, continuous monitoring, and advanced predictive modelling remain out of reach financially and technically for many utilities in developing countries (Taiwo et al., 2023). What is needed is an approach that extracts real engineering value from the operational data utilities already collect, without demanding resources they do not have. It should let engineers distinguish isolated failures from systemic decline, identify where rehabilitation is most urgent, and direct spending to where it will have the greatest effect.

Infrastructure asset management research has shown that combining several engineering indicators gives a more realistic picture of buried pipe condition than any single measure can (Taiwo et al., 2023). Pipe age, historical failure frequency, leakage, and service coverage each capture part of the condition story. Taken together within a structured framework, and paired with spatial analysis, they provide a far better basis for decisions. Geographic Information System (GIS) technology adds the ability to map deterioration patterns and tie them directly to network operations on the ground.

Adeoti et al. (2023) synthesize 15 studies addressing water-infrastructure sustainability in Nigeria and describe a varied evidence base covering multiple infrastructure types and challenge categories. Their review does not itself provide a cluster-level physical-integrity assessment for an urban municipal distribution network. The present study therefore focuses specifically on condition differentiation and rehabilitation prioritisation within Minna's distribution system, using utility operational records and GIS-supported analysis.

This emphasis aligns the paper with Innovative Resource Utilization and Management: the PII converts routinely available condition, failure, leakage, coverage, and repair-cost information into a transparent basis for allocating scarce rehabilitation resources across the network. It also has a qualified safety and environmental co-benefit. By identifying recurrent integrity hotspots, the framework can guide follow-up pressure and water-quality monitoring at locations where failures or leaks merit closer control. Deteriorating pipes, physical breaches, and low- or negative-pressure events can create conditions for external contaminant intrusion; however, this study did not measure water quality, model intrusion, or estimate health risk (Renwick et al., 2019).

This study developed and applied a Physical Integrity Index (PII) to assess the condition of the Minna municipal water distribution network. The framework combines four indicators, Pipe Age Index (PAI), Failure Frequency Index (FFI), Leakage Density Index (LDI), and Coverage Efficiency Index (CEI), within a GIS-supported methodology. It draws on utility operational records, field inspections, GPS-verified infrastructure surveys, and interviews with technical personnel to evaluate condition across seven operational service clusters.

Unlike conventional approaches that rely on a single indicator or subjective judgement, this method offers a structured, risk-based approach to identify deterioration hotspots and prioritize rehabilitation using data the utility already holds. A sensitivity analysis tests whether the framework remains stable under different weighting assumptions, building confidence in its use for real engineering decisions.

The findings give NISWASEC practical guidance for infrastructure renewal planning. The methodology can also be transferred to other urban utilities facing similar technical and financial constraints. More broadly, the study demonstrates how integrated engineering indicators and spatial analysis can make urban water distribution management more resilient and transparent.

2. MATERIALS AND METHODS

2.1 Study Area

The study covered the municipal water distribution system of Minna, capital of Niger State in north-central Nigeria. The city lies between latitudes 9°31′ and 9°41′ N and longitudes 6°29′ and 6°37′ E, in the Guinea Savannah ecological zone. Over the past two decades, Minna has grown steadily. Population expansion, increased commercial activity, and public-sector development have all raised demand for potable water and placed additional strain on the existing supply infrastructure.

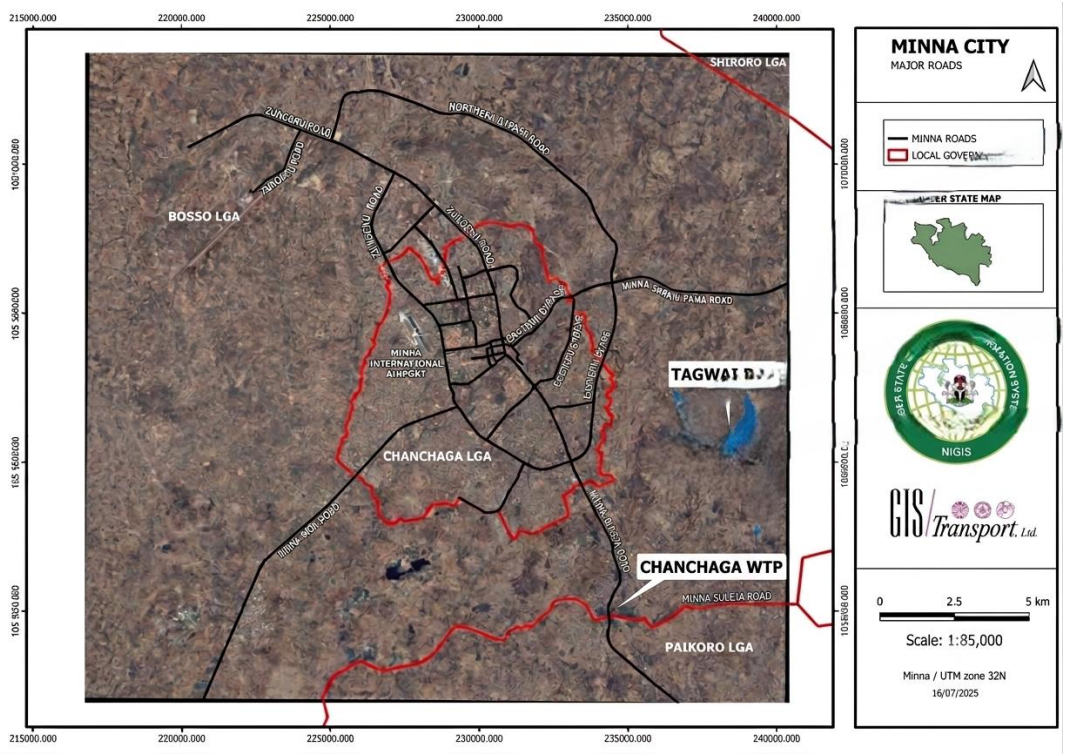

Figure 1: Minna Municipal area

Figure 1 situates the study area within Niger State and delineates the Minna municipal boundary referenced throughout this study.

NISWASEC owns and operates the municipal system. Treated water passes through an integrated network of four treatment plants, nine major service reservoirs, three booster pumping stations, transmission mains, and an extensive reticulation network. Production depends mainly on the Impresit, Biwater, Bosso, and Paiko treatment plants. Service reservoirs and booster stations at key points regulate hydraulic pressure.

For administrative purposes, NISWASEC organizes the Minna municipal system into five districts (A–E), which reflect billing zones and staff deployment rather than the hydraulic layout of the distribution network. For this study, the entire Minna Municipal water supply network was deliberately partitioned into seven operational service clusters, Bosso, Chanchaga, Minna Central, Minna East, Minna West, Tudun Wada North, and Tudun Wada South. The clusters are mutually exclusive and collectively exhaustive operational areas, delineated from reservoir and pumping command areas, pipeline continuity, and reticulation boundaries. These boundaries provide the level of detail at which pipeline age, material, failure history, and maintenance needs vary, rather than following administrative convenience. They therefore constitute the study-design zoning of the full municipal network, not a random or convenience sample of clusters. Each cluster represents a distinct operational setting with its own infrastructure age, material profile, service-coverage pattern, failure history, and maintenance demand. Accordingly, n = 7 in the cluster-level tables and correlations denotes the seven predefined operational areas that together cover the full study network; it is the number of area-level units of analysis, not a sample size for estimating an unobserved population of clusters.

2.2 Research Design

The study followed a quantitative engineering assessment framework. It combined infrastructure inventory, field verification, spatial analysis, and multi-criteria performance evaluation to quantify network physical condition using operational records the utility already keeps, checked against direct field observations, consistent with multi-indicator approaches to pipe condition assessment (Taiwo et al., 2023).

The assessment proceeded in five stages:

1. Compilation and verification of infrastructure inventory and operational records.
2. Field inspection and GPS verification of critical water supply assets.
3. Development of engineering performance indicators describing infrastructure condition.
4. Integration of the indicators into a composite Physical Integrity Index (PII).
5. Spatial analysis and prioritization of rehabilitation zones using GIS.

2.3 Data Sources

Secondary and primary data were both used, so that the assessment did not rely solely on utility records.

Secondary data came from NISWASEC and included pipeline inventory records, treatment plant operational records, reservoir inventories, distribution network layout maps, historical pipeline failure records (2021–2025), leakage reports, maintenance logs, service coverage records, and operational pumping schedules.

Primary data were gathered to check existing records against current conditions. Field investigations included GPS surveys of major infrastructure assets, visual inspection of pumping stations, reservoirs, pipelines, and booster stations, standardized Field-Level Observation (FLO) surveys, structured Key Informant Interviews (KII) with engineers, operators, and maintenance personnel, and documentation of observed defects.

Twenty-five priority locations were selected based on historical failure frequency, leakage occurrence, operational significance, and accessibility. These locations represented the most critical infrastructure components across the seven service clusters. Because accessibility was one of the four selection criteria, sites that were more difficult to reach may be under-represented in this priority-location field-verification set relative to their true condition; this is a limitation of the field-sampling protocol only. It does not mean that the seven operational clusters were sampled: all seven clusters were included in the full-network cluster-level assessment.

2.4 Development of Engineering Performance Indicators

Four indicators were developed to quantify infrastructure condition, reflecting evidence that combining several engineering indicators gives a more realistic picture of buried pipe condition than any single measure can (Taiwo et al., 2023). Each captures a distinct aspect of physical performance.

Pipe Age Index (PAI) measures infrastructure ageing by comparing current operational age against expected design life:

$$PAI = \frac{Y_c - Y_i}{Y_d} \tag{1}$$

where Y_c = current year, Y_i = year of installation, and Y_d = design service life. Higher values indicate more advanced ageing.

Failure Frequency Index (FFI) measures structural reliability from the reported pipeline-failure occurrence total:

$$FFI = \frac{N_f}{L_p} \tag{2}$$

where N f = cumulative reported pipeline-failure occurrence total and L p = pipeline length (km). Higher values signal greater structural deterioration.

Leakage Density Index (LDI) quantifies the concentration of leakage events within each service cluster:

$$LDI = \frac{N_l}{L_n} \tag{3}$$

where N_l = number of leakage events and L_n = network length (km).

Coverage Efficiency Index (CEI) evaluates service delivery effectiveness:

$$CEI = 5\left(1 - \frac{P_s}{P_t}\right) \tag{4}$$

where P_s = population served and P_t = total population within the service area. The transformed CEI is scaled from 0 to 5, such that lower service coverage yields a higher score and therefore indicates poorer coverage efficiency.

2.5 Development of the Physical Integrity Index (PII)

The four indicators were combined into a composite PII through weighted linear combination, following established multi-criteria approaches to water distribution network rehabilitation planning (Hassoun Nedjar et al., 2023), after normalizing each to a common five-point condition scale:

$$PII = 0.2(PAI) + 0.3(LDI) + 0.4(FFI) + 0.1(CEI) \tag{5}$$

Raw service coverage was transformed before aggregation as CEI = 5 × (1 − P_s/P_t), so that all four PII components follow the same condition direction: a higher score denotes poorer physical integrity. The legacy, non-inverted CEI and PII values are retained alongside the corrected values in Table 3 solely for transparency.

The adopted coefficients were specified as a research-team engineering-judgement baseline, informed generally by NISWASEC's operational context and observed network characteristics. The intended priority order was Failure Frequency Index (FFI, 0.40) > Leakage Density Index (LDI, 0.30) > Pipe Age Index (PAI, 0.20) > Coverage Efficiency Index (CEI, 0.10). This ordering treats observed failure frequency and leakage concentration as the most direct operational manifestations of deterioration, with pipe age as a contributing condition and service coverage as a contextual component. However, the study records do not contain a contemporaneous protocol explaining how the exact decimal values were selected. In particular, no documented weighting interviews, workshop or consensus procedure, Delphi exercise, pairwise-comparison matrix, iterative-refinement record, or statistical calibration was used to derive these coefficients. They should therefore be interpreted as transparent adopted engineering weights, not as empirically estimated or formally elicited parameters. The equal-weighting sensitivity analysis tests the robustness of the resulting cluster ranking to a material alternative weighting scheme; it does not establish that the adopted coefficients are optimal.

Table 1: A: Adopted Equation 5 weighting configuration and disclosure

PII component	Adopted weight	Role in the adopted engineering-judgement hierarchy
Failure Frequency Index (FFI)	0.40	Highest priority: recorded failure burden.
Leakage Density Index (LDI)	0.30	Second priority: concentration of recorded leakage.
Pipe Age Index (PAI)	0.20	Contributing age-related condition.
Coverage Efficiency Index (CEI)	0.10	Contextual service-coverage component.

Note: *The hierarchy records the adopted study design*

Conceptual Basis for the Priority Ordering

While the exact decimal weights were not formally elicited, the qualitative priority ordering (FFI > LDI > PAI > CEI) is consistent with established infrastructure asset management literature, which associates each indicator with a distinct pathway to network deterioration and, where structural breaches occur, contaminant entry (Renwick et al., 2019). Table 1B summarizes this conceptual grounding, which supports the direction and relative emphasis of the adopted weights without substituting for a documented elicitation procedure.

Table 1: B: Conceptual Rationale for the Adopted Priority Ordering

Indicator	Description	Adopted weight	Conceptual rationale
FFI	Failure Frequency Index	0.40	Recognized as a strong indicator of infrastructure deterioration and future failure risk (Folkman, 2018)
LDI	Leakage Density Index	0.30	Associated with structural defects and potential contaminant entry pathways (Kirmeyer et al., 2001)
PAI	Pipe Age Index	0.20	Reflects long-term asset deterioration (Rajani & Kleiner, 2001)
CEI	Coverage Efficiency Index	0.10	Indicates service adequacy and network resilience (AWWA, 2019)
Total		**100%**	

***Note**: This table provides literature-based conceptual support for the adopted priority ordering*

To translate PAI, LDI, and FFI from continuous engineering measures into the common five-point condition scale used in Equation 5, a semi-quantitative scoring rubric consistent with infrastructure asset management practice (Rajani & Kleiner, 2001; Folkman, 2018; AWWA, 2019) was applied at cluster level (Table 1C). CEI is not included in this rubric because it is already computed directly on a continuous 0–5 scale from the coverage ratio (Eq. 4) and requires no qualitative anchoring.

Table 1: C: Standardized Scoring Framework for PAI, LDI, and FFI

Score	PAI (Pipe Age Condition)	LDI (Leakage Density)	FFI (Failure Frequency)
5	Very Old (>80% design life)	Very High Leakage	Very High Failure Frequency
4	Old (60–80%)	High Leakage	High Failure Frequency
3	Moderate Age (40–60%)	Moderate Leakage	Moderate Failure Frequency
2	Relatively New (20–40%)	Low Leakage	Low Failure Frequency
1	New (<20%)	Very Low Leakage	Very Low Failure Frequency

Cluster-level PAI, LDI, and FFI scores were assigned using this rubric together with the infrastructure inventory, leakage records, and failure database, and were cross-checked against Field-Level Observation (FLO) and Key Informant Interview (KII) findings on relative deterioration across clusters. The resulting component scores by cluster are reported in Table 3.

The resulting PII values were classified into five condition categories as shown in Table 1.

Table 1: Physical Integrity Index Condition Classification

PII Range	Infrastructure Condition
< 2.0	High Integrity
2.0 to < 3.0	Moderate Integrity
3.0 to < 3.5	Low Integrity
3.5 to < 4.0	Very Low Integrity
≥ 4.0	Critical Integrity

2.6 Geographic Information System (GIS) Analysis

Spatial analysis was carried out in ArcGIS Pro. Infrastructure inventory, field observations, historical failures, and engineering performance indicators were integrated within a unified spatial database. Assets were georeferenced using GPS coordinates from field surveys, and existing utility maps were digitized and validated against field observations.

GIS analysis supported: (i) mapping of infrastructure assets; (ii) spatial distribution of pipeline failures; (iii) identification of deterioration hotspots; (iv) visualization of PII values; and (v) development of rehabilitation priority maps.

2.7 Sensitivity Analysis

Sensitivity analysis evaluated the robustness of the PII ranking under a reproducible alternative weighting assumption. The adopted engineering-judgement configuration was compared with equal weighting (0.25 for each component). The previously described structural-emphasis scenario is not

retained because its exact weight vector was not documented and could not be independently reproduced.

2.8 Statistical Analysis

Descriptive statistics summarized infrastructure characteristics, failure frequencies, leakage occurrence, and coverage across the seven predefined operational areas. Pearson's and Spearman's coefficients were used to describe associations among these complete network zones, including relationships between PII, coverage, reported failure-occurrence totals, and repair cost. In these analyses, n = 7 refers to the seven operational clusters that partition the whole Minna Municipal network, not to a probabilistic sample of clusters. The p-values are retained as standardized indicators of the strength and stability of cross-area relationships, but they should not be interpreted as supporting population-level generalization beyond the Minna system. The coefficient of variation was also computed to measure variation in infrastructure condition across the full network zoning.

2.9 Assessment of PII Consistency and Criterion Validity

Robustness and validity were assessed through three complementary checks that are kept analytically distinct. First, robustness to the weighting scheme was tested via sensitivity analysis. Second, because FFI is itself a constituent of the PII, its correlation with the reported pipeline-failure occurrence total was treated as an internal-consistency check rather than independent validation: a strong relationship is expected by construction and confirms the index behaves coherently, but it cannot substitute for external evidence. Third, criterion validity was assessed against a variable constructed independently of the PII: cluster-level repair-cost records obtained directly from NISWASEC maintenance ledgers (2021–2025). This repair-cost comparison constitutes the study's principal external validation evidence. District-metered Non-Revenue Water (NRW) data remained unavailable; NRW was instead modelled as a linear function of PII, calibrated to realistic bounds for sub-Saharan utilities (Shushu et al., 2021). Because the NRW estimate is derived computationally from PII, it is reported only as contextual model output and is not correlated with PII or treated as validation evidence. Pearson's correlation coefficient assessed the strength of the reported repair-cost and internal-consistency relationships.

3. RESULTS AND DISCUSSION

The infrastructure inventory shows that the Minna network grew through successive, largely uncoordinated expansion phases rather than a single planned programme. The result is a mix of assets with different ages, capacities, materials, and operating conditions.

Field verification identified four water treatment plants, nine major service reservoirs, three booster pumping stations, and an extensive transmission and distribution network supplying the seven operational clusters. However, installed capacity did not equal available capacity. The Impresit plant ran close to its design capacity throughout the study period. Biwater and Bosso both produced below design capacity due to non-operational pumping units. Paiko, though physically complete, was not yet operational and contributed nothing to municipal production.

Nearly a quarter of sampled pipeline segments had no material recorded in utility records. uPVC and Ductile Iron together account for the majority of identified material, with small proportions of Asbestos Cement and Galvanized Iron still in service (Figure 2).

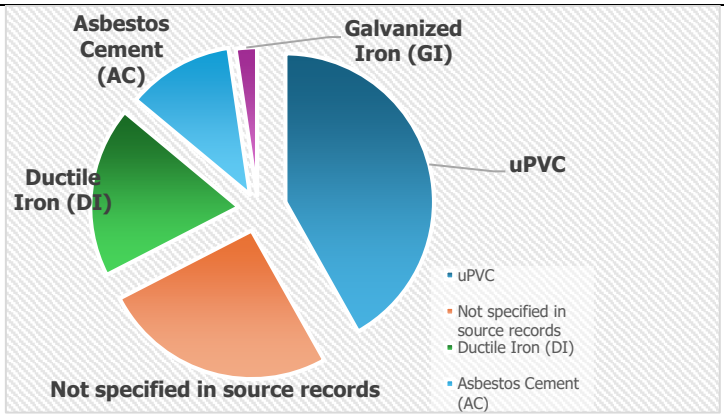

Figure 2: Material composition of 43 field-verified segments.

Figures 2 and 3 summarize a 43-segment field-verification subset. The original segment-level material and diameter inventory used to construct these descriptive charts was not supplied in NetworkData.xlsx. Accordingly, the displayed percentages are not independently auditable from the supplied calculation package and are not used in the PII calculation, correlation analysis, or validation. They should be read only as descriptive field records, not as a statistically representative network-wide material or diameter inventory. A complete segment-level inventory is required before making network-wide material-composition or diameter-distribution estimates.

Distribution system reliability depends not only on the condition of buried pipelines but also on whether upstream production and pumping facilities are running. Reduced pumping capacity limits hydraulic flexibility, creates pressure variability, and makes it harder to redirect flow during maintenance or emergencies.

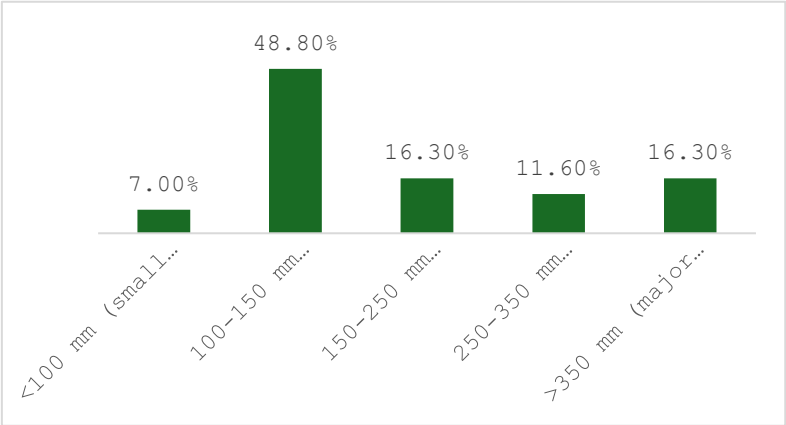

Figure 3: Diameter distribution of 43 field-verified segments.

Within the unverified 43-segment field subset shown in Figure 3, 48.8% of pipes fall within the 100–150 mm distribution range, with 16.3% in both the 150–250 mm sub-trunk and >350 mm major trunk categories, and 11.6% in the 250–350 mm trunk category. Only 7.0% are small distribution pipes (<100 mm). Because the original segment-level diameter inventory was not supplied in NetworkData.xlsx, these are descriptive field-subset proportions only and are not interpreted as network-wide estimates.

3.1 Spatial Characteristics of the Distribution Network

GIS analysis revealed marked spatial variability in infrastructure configuration across the seven clusters. Older sections of the network, particularly Minna West, Minna East, and parts of Chanchaga, showed dense pipeline layouts, numerous service connections, and a long history of repeated maintenance work. Bosso and parts of Tudun Wada South showed lower maintenance intensity and fewer recorded structural defects.

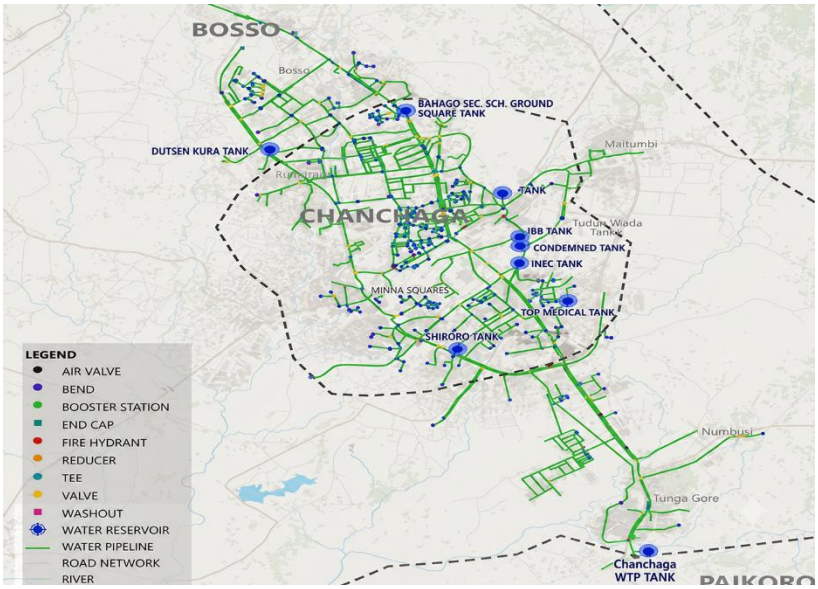

Figure 4: Distribution system network with key water infrastructures and pipeline stretch.

Figure 4 overlays that boundary with the principal components of the distribution system, the four treatment plants, the service reservoirs and booster stations that regulate hydraulic pressure, and the transmission and reticulation mains connecting them, giving a single spatial reference for the infrastructure inventoried in Section 2.3. The reservoir and booster-station command areas visible in Figure 4 correspond to the operational basis used to delineate the seven service clusters described below: each cluster boundary follows the reticulation network actually served by a given reservoir or pumping zone, rather than an administrative line. Figure 4 therefore functions as the spatial basis for the cluster-level condition assessment reported in Section 3, rather than as a standalone locational reference.

3.2 Distribution of Reported Pipeline-Failure Occurrence Totals

The supplied maintenance workbook reports a cumulative pipeline-failure occurrence total of 6,526.24 for 2021–2025. The occurrence field contains fractional values, so these data are treated as reported operational occurrence totals rather than literal integer counts of discrete break events. They remain unevenly distributed across clusters and provide the failure-frequency input to the PII.

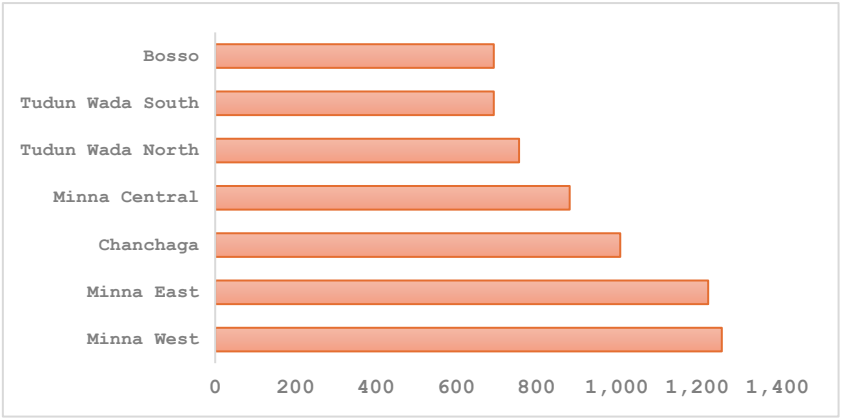

Figure 5: Distribution of reported pipeline-failure occurrence totals by service cluster (2021–2025; bars rounded for display).

Minna West reported the highest occurrence total (1,261.60; 19.3%), followed by Minna East (1,227.52; 18.8%) and Chanchaga (1,009.28; 15.5%). Together, these three clusters accounted for approximately 53.6% of the workbook-reported occurrence total. Bosso and Tudun Wada South reported the lowest totals (693.88 each; 10.6%).

Table 2: Distribution of Reported Pipeline-Failure Occurrence by Service Cluster (2021–2025)

Service Cluster	Reported occurrence total (2021–2025)	% of Total
Minna West	1,261.60	19.3
Minna East	1,227.52	18.8
Chanchaga	1,009.28	15.5
Minna Central	883.12	13.5
Tudun Wada North	756.96	11.6
Tudun Wada South	693.88	10.6
Bosso	693.88	10.6
Total	**6,526.24**	**100**

The concentration of failures in the western and eastern sectors aligns with their higher levels of urban development, denser connections, and longer operating histories. Frequent road excavation, growing traffic loads, repeated pipe repairs, and sustained hydraulic loading have likely accelerated structural decline in these areas.

3.3 Physical Integrity Assessment

The Physical Integrity Index differentiated infrastructure condition clearly across the seven clusters (Figure 6 and Figure 7).

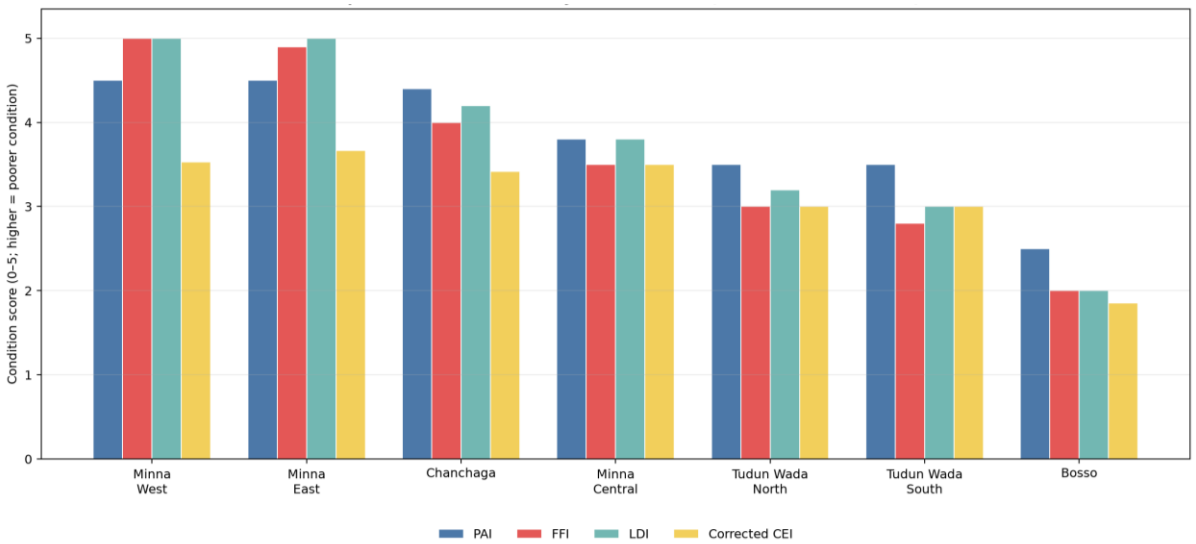

Figure 6: Corrected component indicator scores by service cluster (CEI direction corrected).

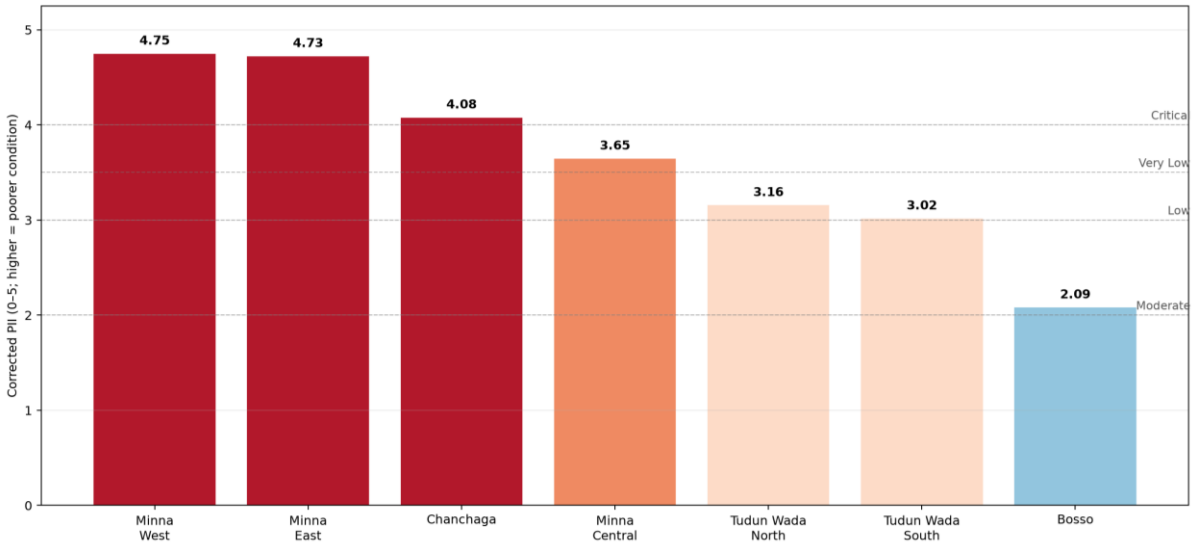

Figure 7: Corrected Composite Physical Integrity Index (PII) by service cluster.

Minna West and Minna East exhibit maximum or near-maximum scores for FFI (5.0 and 4.9) and LDI (5.0 and 5.0), reflecting extreme failure frequencies and leakage densities. PAI scores are also elevated (4.5) across the critical clusters. Bosso shows favourable (low) scores across PAI (2.5), FFI (2.0), and LDI (2.0). Its high raw service-coverage ratio (63.0%) is now correctly transformed into the lowest CEI subscore (1.9) of the seven clusters. Because CEI enters the PII on the same higher-is-worse scale as the other components, the corrected transformation strengthens the conceptual coherence of the composite index. Bosso remains the cluster with the best overall physical integrity, although its Moderate Integrity classification confirms that preventive maintenance and routine monitoring remain necessary.

With CEI direction corrected, Minna West (4.75), Minna East (4.73), and Chanchaga (4.08) fall within the Critical Integrity band (≥4.0). Minna Central (3.65) is Very Low Integrity. Tudun Wada North (3.16) and Tudun Wada South (3.02) exhibit Low Integrity, while Bosso (2.09) remains Moderate Integrity. No cluster achieved High Integrity (<2.0). The corrected PII values have a mean of 3.64, a sample standard deviation of 0.97, and a coefficient of variation of 26.7%, confirming substantial heterogeneity in infrastructure condition rather than uniform network-wide deterioration.

Table 3: Legacy and CEI-direction-corrected Physical Integrity Index results by service cluster

Service cluster	PAI	FFI	LDI	CEI	PII	Condition
Minna West	4.5	5.0	5.0	3.5	4.75	Critical
Minna East	4.5	4.9	5.0	3.7	4.73	Critical
Chanchaga	4.4	4.0	4.2	3.4	4.08	Critical
Minna Central	3.8	3.5	3.8	3.5	3.65	Very Low
Tudun Wada North	3.5	3.0	3.2	3.0	3.16	Low
Tudun Wada South	3.5	2.8	3.0	3.0	3.02	Low
Bosso	2.5	2.0	2.0	1.9	2.09	Moderate

The deterioration in Minna West and Minna East stems from the combined effects of long service life, frequent structural failures, and persistent leakage. Repeated excavation and replacement of failed sections may also have weakened neighbouring pipe segments, making subsequent failure more likely.

Bosso's relatively favourable condition does not mean rehabilitation can be ignored there. Rather, the lower PII values suggest that preventive maintenance and routine monitoring should be sufficient to maintain performance, avoiding the more extensive intervention required elsewhere.

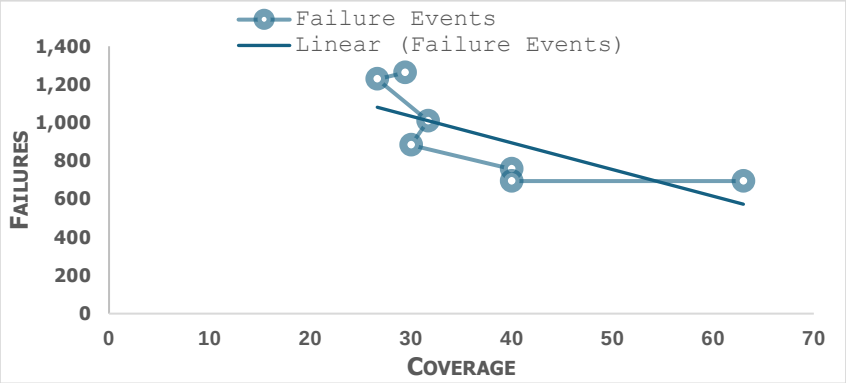

Figure 8: Relationship between service coverage and pipeline failures (bubble size proportional to residential buildings served).

Clusters with lower raw service coverage (Minna West and Minna East) experience substantially higher failure counts. Bosso, with the highest raw coverage (63.0%), records among the fewest failures. Pearson's correlation between raw service coverage and total failures approached but did not reach conventional significance ($r = -0.723$, $p = 0.066$, $n = 7$); Spearman's rank correlation was significant ($\rho = -0.900$, $p = 0.006$). PII was strongly and inversely associated with raw service coverage (Pearson $r = -0.906$, $p = 0.005$, $n = 7$; Spearman $\rho = -0.919$, $p = 0.003$).

3.4 Spatial Distribution of Rehabilitation Priorities

GIS mapping identified distinct pockets of deterioration at finer spatial resolution than the seven service clusters. Because sub-zone-level coverage (CEI) data were not available, this finer-grained analysis uses a Sub-Zonal Physical Deterioration Score (SPDS), computed from PAI, FFI, and LDI only. The reproducible score is $SPDS = (0.20 \times PAI + 0.40 \times FFI + 0.30 \times LDI) / 0.90$, which renormalizes the adopted PAI, FFI, and LDI weights to sum to 1. It is therefore not directly numerically comparable to the four-indicator, cluster-level PII reported elsewhere. The raw field inputs and sub-zone normalization worksheets, so the SPDS is retained as a field-derived screening score. High-risk zones clustered in Tungan Goro, Sauke Kahuta, M. I. Wushishi, and Tunga Market, where the reported screening scores coincide with recurring failures, visible leakage, and ageing infrastructure.

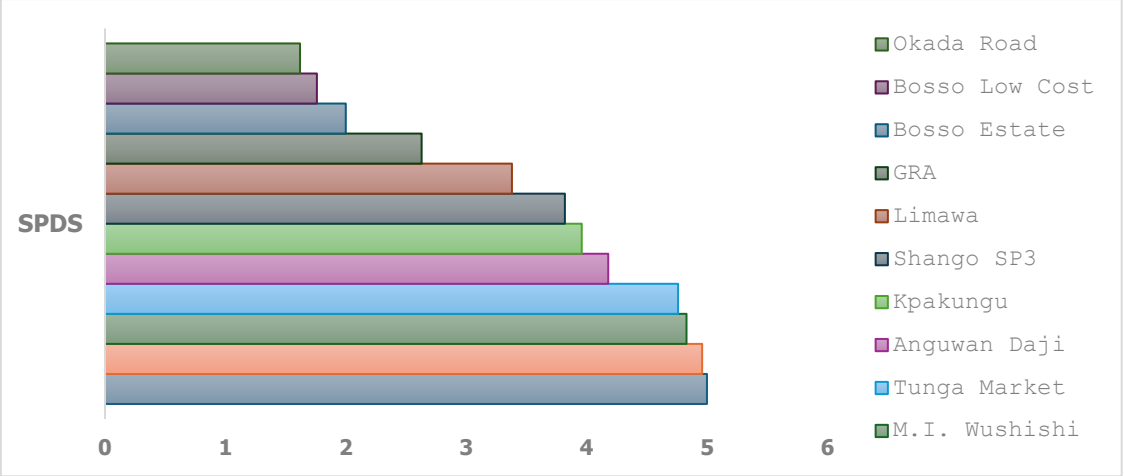

Figure 9: Sub-Zonal Physical Deterioration Score (SPDS) within high-priority rehabilitation clusters.

Table 4: *Sub-Zonal Physical Deterioration Score (SPDS)*

Sub-Zone	PAI	FFI	LDI	SPDS	Condition
Tungan Goro	5.0	5.0	5.0	5.00	Critical
Sauke Kahuta	5.0	4.9	5.0	4.96	Critical
M.I. Wushishi	4.8	4.8	4.9	4.83	Critical
Tunga Market	4.8	4.7	4.8	4.76	Critical
Anguwan Daji	4.3	4.1	4.2	4.18	Critical
Kpakungu	4.0	3.9	4.0	3.96	Very Low
Shango SP3	3.9	3.8	3.8	3.82	Very Low
Limawa	3.5	3.3	3.4	3.38	Low
GRA	2.8	2.5	2.7	2.63	Moderate
Bosso Estate	2.0	2.0	2.0	2.00	Moderate
Bosso Low Cost	1.8	1.7	1.8	1.76	High
Okada Road	1.7	1.6	1.6	1.62	High

Note: SPDS = (0.20(PAI) + 0.40(FFI) + 0.30(LDI) / 0.90. This renormalizes the adopted PAI, FFI, and LDI weights because sub-zone-level coverage data were unavailable. The raw sub-zone inputs and normalization worksheets were not available; SPDS values are therefore field-derived screening results and are not directly comparable to the four-indicator cluster-level PII.

This spatial concentration has direct implications for rehabilitation planning. Instead of spreading investment evenly across the network, NISWASEC can concentrate resources in these hotspots, where renewal is likely to yield the greatest improvements in reliability and operational efficiency.

3.5 Sensitivity Analysis

Sensitivity analysis of the CEI, PII compared the adopted weighting scheme with equal weighting. Absolute scores shifted slightly, but the relative priority order remained stable: Minna West and Minna East remained the top-priority rehabilitation zones, and Bosso remained the cluster with the best infrastructure integrity (Figure 10).

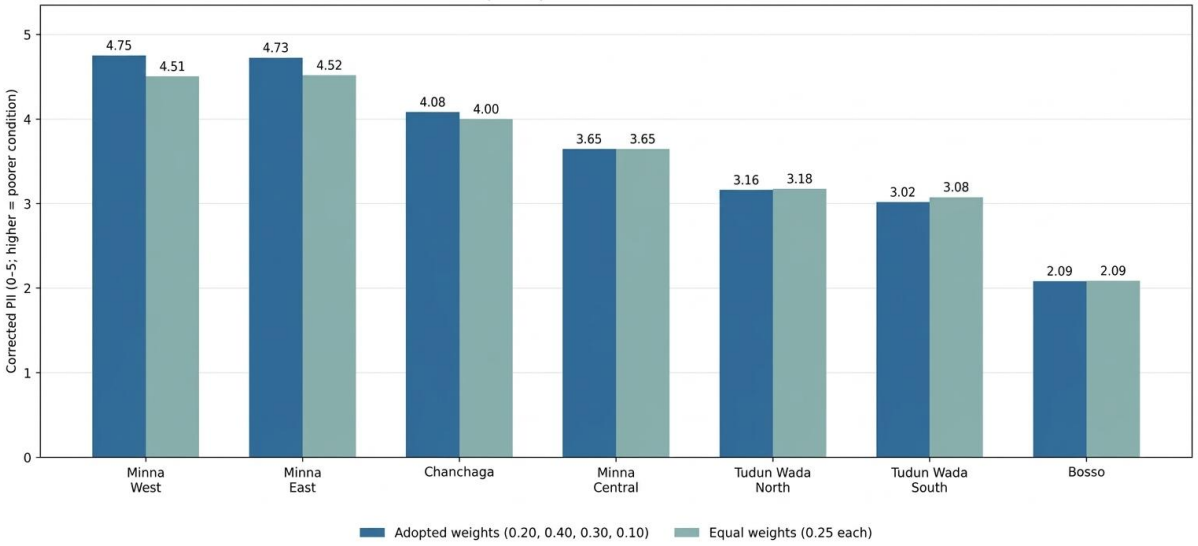

Figure 10: Sensitivity analysis of CEI direction correction: PII scores under adopted and equal weighting scenarios.

The adopted scheme (PAI: 0.20, FFI: 0.40, LDI: 0.30, CEI: 0.10) was compared with equal weighting (0.25 each). Cluster rankings remained strongly aligned (Spearman's $\rho = 0.964$, $p < 0.001$, $n = 7$). The result reflected a near-identical weighting pattern, the particular seven-cluster score distribution; no causal explanation is therefore inferred. The sensitivity analysis reports only the two fully reproducible scenarios.

The stable ordering under these two reproducible weighting schemes indicates that rehabilitation priorities are driven mainly by observed infrastructure condition rather than by the adopted weighting choice. This supports the use of the corrected PII for engineering prioritisation while preserving a transparent limit on the sensitivity evidence.

3.6 Empirical Assessment of PII Consistency and Criterion Validity

To assess whether the PII behaves coherently and agrees with independent evidence, computed values were compared against two operational indicators: total recorded pipeline failures and recorded repair expenditure. These two comparisons are not equivalent in evidentiary strength and are interpreted separately below. District-metered non-revenue water data were unavailable; the separately modelled NRW estimate is reported as contextual information only and is not used in correlation-based validation.

Clusters with higher PII values consistently reported higher pipeline-failure occurrence totals. Pearson's correlation analysis found a strong positive linear relationship between PII and the reported occurrence total ($r = 0.944$, $p = 0.001$, $n = 7$), and equivalently with the cluster's share of the network-wide occurrence total ($r = 0.944$, $p = 0.001$, $n = 7$). Because FFI is itself one of the four indicators combined into the PII, this relationship is expected by construction and is interpreted as an internal-consistency check rather than independent validation. Spearman's rank correlation corroborated the monotonic ordering ($\rho = 0.991$, $p < 0.001$, $n = 7$).

The correlation between PII and the Coverage Efficiency Index (CEI) score was positive ($r = 0.906$, $p = 0.005$, $n = 7$), as expected after all components were aligned to a higher-is-worse condition scale. This CEI-score relationship is distinct from the inverse corrected-PII–raw-service-coverage relationship reported in Section 3.3 ($r = -0.906$, $p = 0.005$, $n = 7$). Because CEI is a component of PII, neither relationship constitutes independent validation.

Cluster-level repair-cost records for 2021–2025 were obtained directly from NISWASEC maintenance ledgers. The supplied workbook records five-year cumulative repair-cost totals; these are expressed in ₦ million in Figure 11 and Table 5. Because repair expenditure was not used to construct the PII, its correlation with corrected PII constitutes the study's principal external criterion validation. District-metered non-revenue water data remained unavailable; the separately modelled NRW estimate is contextual only and is not used as validation evidence.

Pearson's correlation analysis found a strong positive relationship between PII and the recorded 2021–2025 cumulative repair-cost total:

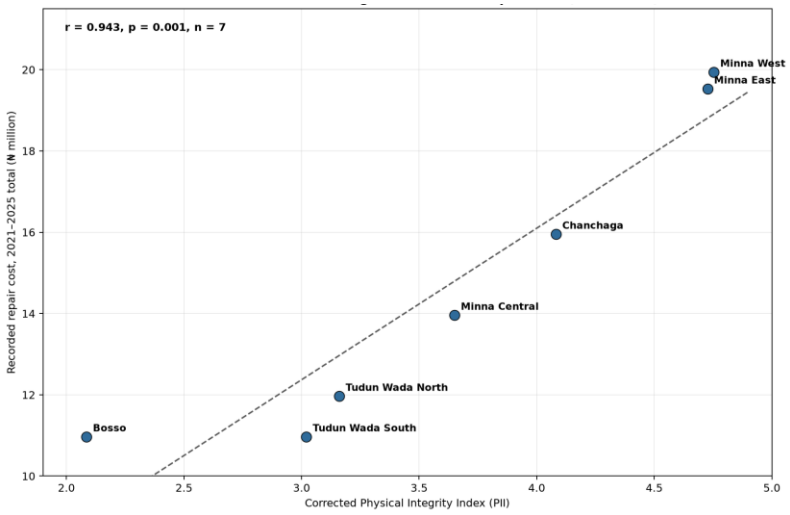

Figure 11: Independent criterion validation of corrected PII against recorded cumulative repair cost (2021–2025).

Cluster-level repair-cost totals were extracted from NISWASEC maintenance ledgers; Pearson r = 0.943, p = 0.001, n = 7.

Table 5: Independent criterion validation of corrected PII against recorded cumulative repair cost

Comparison	r	p	n
PII vs recorded repair cost (2021–2025 total)	0.943	0.001	7

Note: n = 7 denotes the seven predefined operational service clusters that together constitute the full Minna Municipal water supply network; it does not denote a sample of clusters.

The internal consistency checks confirm that the PII behaves coherently with its own constituent data, while the repair-cost comparison provides the study's strongest evidence that the index reflects real operational consequences beyond its own construction.

3.7 Comparison with Previous Studies

The deterioration patterns in Minna fit the broader picture: ageing infrastructure, recurrent leakage, and rising operational demand together erode the reliability of urban water distribution networks (Auma et al., 2023; Taiwo et al., 2023). What this study contributes is a quantitative method for assessing that condition using routinely available operational data within a GIS-supported framework.

Positioning the PII requires distinguishing five related but methodologically distinct strands of water-distribution-network research: pipe-failure prediction, hydraulic modelling, rehabilitation prioritization, condition assessment, and composite indices.

Pipe-failure prediction. This strand models the probability that an individual pipe will fail from its own attributes and break history. Logistic regression and support vector classification have been used to predict individual pipe failures from asset attributes (Robles-Velasco et al., 2020), comparable logistic models have been fitted to failure records for Kampala's water network (Auma et al., 2023), and validated failure-prediction models have shown reasonable agreement with observed main breaks over multi-year monitoring (Kahn et al., 2020). These models perform well where detailed, pipe-level failure and attribute histories exist, but that data requirement is precisely what NISWASEC and most Nigerian utilities lack.

Hydraulic modelling. This strand simulates how water moves through a network, pressure, flow, and contaminant transport, under defined operating conditions using calibrated software such as EPANET (Piazza et al., 2022). It describes network behaviour at a point in time rather than the physical deterioration of the pipes carrying that water, and it depends on calibrated demand and roughness data that ageing, incompletely documented systems like Minna's rarely have.

Rehabilitation prioritization. This strand sits downstream of the first two: it takes condition or risk information as an input and ranks competing rehabilitation projects against it, commonly through structured multi-criteria methods such as the analytical hierarchy process (Hassoun Nedjar et al., 2023).

Its output is a decision, and its reliability depends entirely on the quality of the condition data supplied to it.

Condition assessment. This strand addresses that upstream question directly, asking what state a pipe or network segment is actually in. Grigg's (2006) review of utility condition-assessment practice found that a composite condition index consolidating multiple factors was the ideal but was rarely achieved, held back by inconsistent recording of leaks, breaks, and condition indicators, an observation that describes NISWASEC's records closely. More recent work confirms that combining several engineering indicators gives a more realistic picture of buried-pipe condition than any single measure can (Taiwo et al., 2023).

Composite indices. A smaller literature has begun to close that gap by aggregating multiple indicators into a single score. Beker and Kansal (2022), for example, used fuzzy-logic aggregation of reliability, resilience, and vulnerability indices derived from hydraulic simulation output to build one performance index for decision-making. That approach still depends on a calibrated hydraulic model as its data source, a resource that, like pipe-level failure histories, is largely unavailable in Minna's context.

More than half of the reported pipeline-failure occurrence total were concentrated in Minna West, Minna East, and Chanchaga. This confirms that deterioration is spatially uneven. The risk-based hotspot analysis extends conventional network-wide assessments by identifying rehabilitation priorities at both cluster and sub-zonal levels.

Positioned against these five traditions, what is novel about applying the PII to Minna is not any single indicator but the combination of choices behind it. First, it builds a composite condition index, in the tradition of Grigg (2006) and Beker and Kansal (2022), but computes it entirely from routine utility records and targeted field verification rather than from a calibrated hydraulic model, pipe-level statistical failure histories, or an expert-elicitation panel. Second, it embeds that index in a GIS framework built around actual reservoir and pumping command areas rather than administrative billing zones, so the same index that scores condition also locates it precisely enough to guide rehabilitation spending. Third, it validates the resulting scores empirically against Minna's own repair-cost and failure records (2021–2025) and compares the adopted scheme with an equal-weighting sensitivity scenario, a combination of empirical validation and weighting-sensitivity analysis that the pipe-failure-prediction, hydraulic-modelling, and AHP-based rehabilitation literature reviewed above do not report together. Finally, to the authors' knowledge, few if any prior studies have applied a composite, low-data physical integrity framework of this kind to a Nigerian municipal water distribution network, giving NISWASEC and similarly resourced utilities elsewhere in the country a route to risk-informed rehabilitation planning that does not presuppose the statistical modelling capacity, hydraulic calibration data, or expert-panel access that much of the existing literature assumes.

3.8 Engineering Significance and Practical Implications

The practical value of this research extends beyond flagging deteriorated infrastructure. The PII gives engineers a structured basis for shifting maintenance strategy from reactive intervention toward condition-based asset management.

The study also demonstrates the value of integrating GIS into routine utility operations. Beyond visualizing infrastructure condition, GIS provides a spatial platform for logging maintenance activity, keeping asset inventories current, and tracking rehabilitation outcomes over time.

Another practical strength is that the framework requires little extra data. It relies primarily on information utilities already generate during routine operations, failure records, leakage reports, infrastructure inventories, and service coverage statistics, supplemented by targeted field verification. Implementation does not require specialized inspection equipment or costly monitoring systems.

3.9 Decision Framework for Infrastructure Rehabilitation

The PII is intended to support structured engineering decisions. Based on computed values, rehabilitation priorities can be linked to specific management actions:

- **PII < 2.0 (High Integrity):** Continue routine inspection and preventive maintenance.
- **PII 2.0 to < 3.0 (Moderate Integrity):** Intensify monitoring and schedule localized rehabilitation where required.

- **PII 3.0 to < 3.5 (Low Integrity):** Implement targeted replacement of deteriorated pipeline sections and fittings.
- **PII 3.5 to < 4.0 (Very Low Integrity):** Prioritize phased rehabilitation within annual capital investment programmes.
- **PII ≥ 4.0 (Critical Integrity):** Undertake comprehensive engineering assessment and infrastructure renewal as a priority.

3.10 Data Availability Limitation: System-Wide Physical Water Loss

District-metered non-revenue water data and the source parameters required to calculate system-wide leakage distance were not available in the supplied calculation workbook. A district-metered water balance or formal water audit is required to quantify physical losses and to provide a valid basis for future NRW or leakage-distance analysis.

3.11 Limitations and Directions for Future Work

This study distinguishes internal-consistency checks, in which PII is compared with data used to construct it, from external criterion validation, in which PII is compared with an independently recorded operational variable. After CEI direction correction, the repair-cost comparison shown in Figure 11 uses cumulative 2021–2025 repair-cost totals recorded in NISWASEC maintenance ledgers ($r = 0.943$, $p = 0.001$, $n = 7$). Because these ledger records were not used to construct the PII, this comparison is the study's only independent criterion validation.

The Coverage Efficiency Index directionality flaw identified in the original analysis has been corrected. Raw service coverage is now inverted during normalization as $CEI = 5 \times (1 - P_s/P_t)$, so high coverage produces a low deterioration score and all PII components have the same directional interpretation. Table 3 reports the original, non-inverted values beside the corrected CEI and PII values to preserve a transparent audit trail.

The Equation 5 coefficients are a transparent engineering-judgement baseline rather than a formally elicited or statistically calibrated weight set. The adopted priority order (FFI > LDI > PAI > CEI) is stated in Section 2.5 and draws conceptual support from established asset-management literature (Table 1B), the study records do not document the process used to calibrate the matrix. The adopted-versus-equal weighting sensitivity analysis demonstrates ranking robustness but does not validate the numerical optimality of the adopted coefficients. Future applications should use and document a structured elicitation or calibration protocol, including participant roles, weight alternatives considered, the final decision rule, pairwise-comparison matrices and consistency ratios where AHP is used, and all sensitivity-scenario vectors.

Sample selection and data traceability warrant caution. The 43 pipeline segments assessed for material composition (Figures 2 and 3) and the 25 priority locations assessed at sub-zonal resolution (Section 3.4) were selected using risk-related criteria and practical accessibility rather than a formal stratified random-sampling protocol. The original segment-level material/diameter inventory and the raw sub-zone scoring worksheets were not included in the supplied audit workbook. Accordingly, the material/diameter distributions and SPDS results should be read as indicative field-derived screens, not statistically representative network-wide estimates; the SPDS is also not directly numerically equivalent to the four-indicator, cluster-level PII.

The cluster-level statistical analysis uses seven predefined operational areas ($n = 7$) that collectively cover the entire Minna Municipal water supply network. Thus, $n = 7$ is not a sample size in the sense of seven clusters drawn from a larger unobserved population; it is the complete set of area-level units created by the study's operational zoning design. Pearson and Spearman coefficients therefore describe cross-area patterns within the Minna system. Because only seven area-level units are available, individual clusters can still exert substantial influence on coefficient magnitudes and p-values; the reported p-values should consequently be interpreted as descriptive indicators of within-system association rather than as a basis for broad inferential generalization. Spearman's ρ, which is less sensitive to outliers and does not assume linearity, is reported alongside Pearson's r for this reason.

Finally, the framework is best understood as a condition and integrity assessment tool that supports risk-informed decision-making. It does not currently weight deteriorated infrastructure by the consequence of failure, such as the criticality of served facilities, population density, or road

importance. Extending the PII into a full Risk Priority Index by incorporating an explicit consequence term is a natural direction for future development of this framework.

4. CONCLUSIONS

This study developed a Physical Integrity Index (PII) combining pipe age, failure frequency, leakage density, and coverage efficiency to assess the Minna municipal water distribution network. The entire network was organized into seven predefined operational service clusters based on reservoir and pumping command areas and reticulation boundaries. These clusters are the complete study-design zoning of the municipal system rather than a sampled subset, and each captures a distinct operational setting. Drawing on utility operational records, field verification, and spatial analysis, the framework differentiates infrastructure condition across these seven full-network operational areas.

Physical deterioration proved spatially uneven. The reported 6,526 pipeline-failure occurrence units for 2021–2025, 53.6% concentrated in Minna West, Minna East, and Chanchaga. After CEI direction correction, Minna West (4.75), Minna East (4.73), and Chanchaga (4.08) were classified as Critical; Minna Central (3.65) as Very Low; Tudun Wada North (3.16) and Tudun Wada South (3.02) as Low; and Bosso (2.09) as Moderate. No cluster achieved High Integrity. The corrected PII coefficient of variation was 26.7%, confirming substantial condition heterogeneity.

The rankings remained stable under the adopted and equal-weighting scenarios. PII showed strong internal consistency with reported pipeline-failure occurrence totals ($r = 0.944$, $p = 0.001$, $n = 7$), which is expected because failure frequency is a constituent indicator. Its independent comparison with NISWASEC's recorded cumulative repair-cost totals was also strong ($r = 0.943$, $p = 0.001$, $n = 7$), providing the study's principal external criterion-validation evidence.

By combining existing utility records with targeted field verification and GIS, the framework offers a low-data-burden, transferable method for condition-based rehabilitation prioritisation in data-constrained utilities.

ABSTRACT

The increasing generation of household thermoplastic waste presents environmental and resource-management challenges while providing an opportunity for energy recovery. This study presents an integrated exergetic–economic assessment of thermal and ZSM-5 catalytic pyrolysis of a modelled mixed household thermoplastic feedstock. Aspen Plus V14.0 was used to simulate a 1,000 kg h^{-1} process, with thermal pyrolysis at approximately 500 °C and catalytic pyrolysis at 350 °C. Mass and energy balances, exergy analysis, SPECO exergoeconomics, techno-economic evaluation and sensitivity analysis were applied. Thermal pyrolysis produced 65.2 wt% oil, 19.8 wt% gas and 15.0 wt% char, while catalytic pyrolysis produced 58.5 wt% oil, 29.0 wt% gas and 12.5 wt% char. Catalytic operation reduced process-energy input from 3,334.20 to 1,840.62 kW (44.8%) and increased exergetic efficiency from approximately 62% to 71%. The catalytic configuration also reduced CAPEX from US$5.043 million to US$4.000 million and annual OPEX from US$1.859 million to US$1.206 million. Under a 20-year project life and 10% discount rate, NPV increased from approximately US$11.34 million to US$12.34 million, while IRR increased from 38.10% to 47.93% and payback decreased from 2.62 to 2.09 years. Product selling price was the dominant sensitivity variable. The results indicate that catalytic pyrolysis offers the stronger integrated energy, exergy and economic performance under the stated assumptions.

Keywords: *household thermoplastic waste; thermal pyrolysis; catalytic pyrolysis; ZSM-5; Aspen Plus; exergoeconomics*

1. INTRODUCTION

Plastic waste is an environmental, resource-management and energy challenge because its durability and chemical resistance hinder conventional disposal and recycling. Household plastic streams are heterogeneous and may contain mixtures of polyolefins, polystyrene, polyethylene terephthalate and polyvinyl chloride. Uncontrolled disposal, landfilling and open burning can therefore result in loss of material value and environmental burdens. Thermochemical conversion provides an alternative route for recovering embedded hydrocarbon value as liquid, gas and solid products. Product distribution depends on feed composition, temperature, residence time, reactor configuration and catalyst selection (Al-Salem et al., 2017; Dai et al., 2022; Speight, 2020).

Thermal pyrolysis generally requires relatively high temperatures to cleave polymer chains, whereas catalytic pyrolysis can promote cracking and secondary reactions at lower severity. ZSM-5 is particularly relevant because its acidic and porous structure can influence hydrocarbon selectivity and promote lighter and aromatic products (Chen et al., 2023; Wang et al., 2022; Zhou et al., 2022). However, product yield alone does not reveal the quality of energy utilization or where thermodynamic irreversibility occurs. Exergy analysis identifies useful work potential and exergy destruction, while exergoeconomics assigns economic consequences to thermodynamic losses. The SPECO method provides a systematic basis for component-level cost assessment (Dincer & Rosen, 2013; Tsatsaronis, 1993).

Previous studies have commonly focused on product distribution, process simulation or conventional economic indicators separately. The present study integrates product yields, process energy, exergy efficiency, component-level exergy-destruction costs, SPECO factors and project

economics for thermal and ZSM-5 catalytic pyrolysis of a mixed household thermoplastic feedstock. The aim is to determine which configuration provides the more favorable integrated technical and economic performance. Specifically, the study objectives are to: (i) develop comparative Aspen Plus V14.0 models; (ii) compare oil, gas and char yields; (iii) quantify process-energy requirements and exergetic efficiency; (iv) identify exergoeconomic hotspots; and (v) compare CAPEX, OPEX, NPV, IRR, profitability index and payback period.

2. METHODOLOGY

2.1 Feedstock and Simulation Basis

The feedstock was defined as a modelled mixed household thermoplastic stream rather than a measured Nigerian municipal-waste composition. The assumed composition 3

comprised HDPE (20 wt%), LDPE (10 wt%), PE (15 wt%), PP (30 wt%), PS (10 wt%), PET (10 wt%) and PVC (5 wt%), giving a total feed of 1,000 kg h^{-1}*. The conceptual pretreatment*

sequence comprised sorting, removal of metals and inerts, size reduction and drying. This modelling basis was used consistently for both configurations and is not presented as a statistically measured national composition.

Table 1: *Assumed mixed household thermoplastic feedstock composition.*

Polymer	Mass fraction (wt%)	Typical household source
HDPE	20	Bottles, containers
LDPE	10	Films, bags, packaging
PE	15	Packaging and consumer products
PP	30	Food containers, caps, household items
PS	10	Disposable packaging and cups
PET	10	Beverage bottles
PVC	5	Household products and packaging
Total	100	—

2.2 Process Simulation and Energy Analysis

Aspen Plus V14.0 was used with the Peng–Robinson/RKS property method. Conventional components were represented together with appropriate hypothetical solid/polymer components using HCOALGEN and DCOALIGT where required. RYield and RCSTR blocks were used to represent decomposition and reaction behaviour. Thermal pyrolysis was evaluated at approximately 500 °C and catalytic pyrolysis at 350 °C with ZSM-5. The steady-state mass balance was expressed as:

$$\Sigma \dot{m}_{in} = \Sigma \dot{m}_{out} \quad (1)$$

For an adiabatic steady-state control volume with negligible shaft work, the energy balance was represented as:

$$\dot{Q}S - \dot{W} + \Sigma \dot{m}_{in} h_{in} = \Sigma \dot{m}_{out} h_{out} \quad (2)$$

Process-energy input was taken from the external heat and utility requirements of the model. Useful energy recovery represents recoverable energy in product streams and defined heat-recovery pathways.

2.3 Exergy and SPECO Analysis

Exergy analysis used an environmental reference temperature of 25 °C and atmospheric pressure. Total stream exergy was considered as the sum of physical, chemical, kinetic and potential components:

$$E_x = E_x,ph + E_x,ch + E_x,ke + E_x,pe \quad (3)$$

Chemical exergy is particularly important for hydrocarbon-rich plastic feedstocks.

Exergy efficiency was evaluated from the ratio of useful product exergy to fuel exergy supplied. Component exergy destruction was used to identify thermodynamic hotspots. SPECO was then applied to assign costs to exergy flows and component capital and operating costs. The exergoeconomic factor was interpreted as the relative contribution of investment cost to the combined investment and exergy-destruction cost; low values indicate greater scope for irreversibility reduction, while high values indicate stronger capital-cost dominance.

2.4 Economic Evaluation and Sensitivity

The economic assessment assumed 8,000 operating hours per year, a 20-year project life, a 10% discount rate and 30% corporate tax. CAPEX, OPEX, product revenue, NPV, IRR, profitability index and simple payback were evaluated on the same basis for both configurations. The catalytic base case included annual ZSM-5 replacement. Sensitivity analysis varied product selling price, OPEX, CAPEX and feedstock cost by ±20% using the same after-tax cash-flow formulation and 20-year, 10% discount-rate basis.

2.5 Model Validation

Percentage deviation was calculated as the absolute difference between simulated and literature yield divided by the literature yield and multiplied by 100. The thermal model gave an average absolute relative deviation of 7.90%. For the catalytic model, oil, gas and char/coke deviations were 20.95%, 26.09% and 316.67%, respectively; the high solid-product deviation is strongly influenced by the low 3 wt% reference value and should therefore not be interpreted as a direct overall prediction error.

3. RESULTS AND DISCUSSION

3.1 Product Distribution and Energy Performance

The thermal configuration produced 65.2 wt% oil, 19.8 wt% gas and 15.0 wt% char, equivalent to 652, 198 and 150 kg h^{-1} at the design feed rate. Catalytic pyrolysis produced

58.5 wt% oil, 29.0 wt% gas and 12.5 wt% char, equivalent to 585, 290 and 125 kg h^{-1}. The

catalytic route therefore shifted part of the condensable fraction toward gas while reducing solid formation. This trend is consistent with the role of ZSM-5 in promoting cracking and secondary reactions (Wang et al., 2022; Zhou et al., 2022).

Both configurations achieved positive net energy balances. Thermal pyrolysis required 3,334.20 kW and recovered approximately 4,446 kW, whereas catalytic pyrolysis required only 1,840.62 kW and recovered approximately 3,033 kW. Although absolute useful-energy recovery was lower for the catalytic route, its net energy gain was higher because of the substantially lower external energy requirement. The catalytic configuration reduced process-energy input by approximately 44.8% and increased the energy recovery ratio from 133.24% to 164.78%.

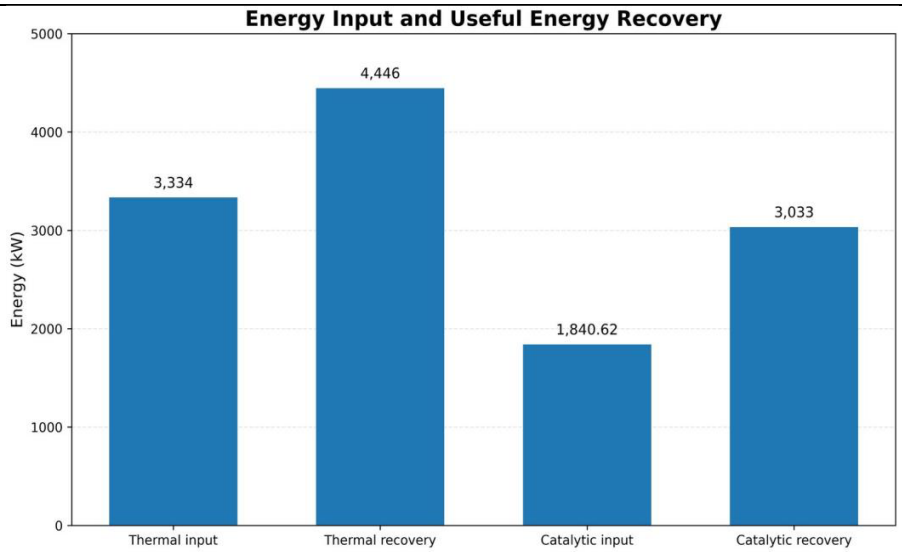

Figure 1: *Comparison of process-energy input and useful energy recovered*

3.2 Exergy and Exergoeconomic Performance

The consolidated exergy results gave approximately 62% exergetic efficiency for thermal pyrolysis and 71% for catalytic pyrolysis. The improvement indicates that a larger fraction of supplied exergy was converted into useful product exergy under the adopted system boundary. The principal component hotspot was the dryer: its exergy-destruction cost decreased from US$1,641.66 h^{-1} to US$1,477.49 h^{-1}. The combustor cost decreased from

US$63.83 h^{-1} to US$27.01 h^{-1}, a reduction of approximately 57.7%.

The low dryer factors indicate that thermodynamic inefficiency dominates its combined cost, so heat recovery, insulation and moisture-control improvements are higher priorities than simply increasing equipment investment. The catalytic combustor factor rises from 27.23% to 47.07% while its absolute exergy-destruction cost falls by 57.7%. This represents a shift in cost composition rather than an automatic overall improvement. The pyrolyzer and heat exchanger have intermediate factors and therefore require simultaneous consideration of capital cost and irreversibility. High factors for the separator and compressor indicate greater capital-cost dominance.

3.3 Techno-Economic Performance

The catalytic configuration required approximately 20.7% less CAPEX and 35.1% less annual OPEX than the thermal configuration. Although annual product revenue was lower for catalytic operation (approximately US$3.860 million yr^{-1} versus US$4.500 million

yr^{-1}), the lower investment and operating requirements produced stronger overall

profitability. Under the 20-year, 10% discount-rate basis, NPV increased from approximately US$11.34 million to US$12.34 million, while IRR increased from 38.10% to 47.93%.

Profitability index increased from 3.25 to 4.08 and simple payback decreased from 2.62 to 2.09 years.

Table 2: *Consolidated techno-economic comparison*

Economic indicator	Thermal	Catalytic
CAPEX (US$ million)	5.043	4.000
Annual OPEX (US$ million)	1.859	1.206
Annual product revenue (US$ million)	4.500	3.860
NPV (US$ million)	11.34	12.34
IRR (%)	38.10	47.93
Profitability index	3.25	4.08
Payback (years)	2.62	2.09

Sensitivity analysis showed that product selling price was the dominant economic variable. A 20% increase in product price raised catalytic NPV to approximately US$16.94 million, while a 20% decrease reduced it to about US$7.73 million. OPEX, CAPEX and feedstock-cost changes produced smaller NPV responses. The base catalytic case assumes a 12-month ZSM-5 replacement interval; catalyst deactivation and regeneration were not explicitly simulated, so alternative service-life cases are economic sensitivity scenarios rather than predictions of actual catalyst lifetime.

3.4 Safety, Environmental Implications and Limitations

The PVC fraction is 5 wt%, corresponding to approximately 50 kg h^{-1} in the design feed. On a conservative basis, complete conversion of available chlorine to HCl gives an upper-bound HCl generation estimate of approximately 29.2 kg h^{-1}. This is not an actual emissions prediction because chlorine speciation and an HCl balance were not explicitly simulated. Commercial implementation would therefore require feedstock control, gas cleaning, acid-gas treatment, pressure relief, gas detection and appropriate process-safety systems. Environmental performance also requires future assessment of emissions, catalyst consumption, char utilization, wastewater, auxiliary fuel and life-cycle greenhouse-gas effects. The study is simulation-based; the assumed feed composition, catalyst stability, product quality and economic assumptions require experimental, pilot-scale and market validation before investment decisions.

4. CONCLUSION

An integrated Aspen Plus V14.0 assessment of thermal and ZSM-5 catalytic pyrolysis of a modelled mixed household thermoplastic feedstock was presented. Thermal pyrolysis produced higher liquid yield, whereas catalytic pyrolysis produced more gas and less char.

Catalytic operation reduced process-energy input by approximately 44.8% and increased exergetic efficiency from about 62% to 71%. The dryer was the dominant exergoeconomic hotspot, while the combustor showed a substantial reduction in exergy-destruction cost under catalytic operation. Economically, the catalytic configuration required lower CAPEX and OPEX and achieved higher NPV, IRR and profitability index together with a shorter payback period. Product selling price was the most influential sensitivity variable. Therefore, catalytic pyrolysis provides the stronger integrated performance under the stated 20-year, 10% discount-rate assumptions. Future work should prioritize pilot-scale validation, catalyst-deactivation and regeneration modelling, detailed product characterization, dryer heat- integration optimization, chlorine/emissions management, uncertainty analysis and life-cycle assessment.

MINIMIZATION OF POWER LOSSES IN DISTRIBUTION NETWORKS THROUGH SMART GRID TECHNOLOGIES (SGT): A CASE STUDY OF BWARI 33 KV DISTRIBUTION NETWORK

Francis Igbinosa[1], Eronu Emmanuel[1,*], Ngang Bassey Ngang[1]
[1]*University of Abuja*

DOI: https://doi.org/10.67203/sp.ICESID.2026

ABSTRACT
This study presents a comprehensive modeling and simulation-based investigation aimed at minimizing technical power losses and enhancing voltage profiles within the Bwari 33 kV distribution network, representative of Nigerian urban power infrastructure. Utilizing MATLAB/Simulink, a detailed radial feeder model was developed, capturing realistic operational characteristics, including load composition, line parameters and substation configurations. The research employs a quantitative approach, incorporating baseline analysis and scenario-based simulations to evaluate the effects of smart grid functionalities. Key system parameters considered include voltage profile, active and reactive power losses, circuit breaker loading, thermal effects and overall network efficiency. The analysis revealed that overload conditions significantly increase technical losses. To mitigate these effects, several smart grid technologies were evaluated, including AMI, APDA, VVO and BESS. Simulation results showed that individual smart grid technologies achieved loss reductions ranging from 10% to 30%, while coordinated smart grid operation reduced total energy losses from 15,581.20 MWh/day to 11,497.73 MWh/day, representing a 26.2% reduction in losses. The economic assessment further demonstrated the viability of smart grid implementation, with estimated annual savings of $179,024,314.72. In addition, the reduction in energy losses contributes to lower carbon emissions and improved environmental sustainability. The study concludes that the integration of smart grid technologies provides an effective and economically feasible solution for minimizing power losses, improving voltage regulation, enhancing system reliability and reducing overload-induced stress in distribution networks. It is therefore recommended that power utilities adopt a phased approach to smart grid implementation, enhancing the operational performance and sustainability of modern distribution systems.

1. INTRODUCTION

Electrical distribution networks constitute the final stage of the power system through which electricity is delivered to consumers, and their operational efficiency has a direct influence on power quality, reliability, energy utilization, and economic performance. However, distribution networks are often affected by significant technical power losses arising from conductor resistance, excessive loading, voltage drops, reactive power flow, and inefficient network operation. In Nigeria, technical losses remain a major concern because of the physical characteristics and operational limitations of distribution networks. Obiora et al. (2025) identified technical losses as an important challenge in Nigerian distribution networks and emphasized the need for effective mitigation measures. As loading increases, current flow through network components increases, causing losses that are strongly influenced by the (I^2R) relationship. Consequently, overloaded feeders and circuit breakers can contribute to increased energy losses, deterioration of voltage profiles, and additional thermal stress on electrical equipment.

Recent research has demonstrated the potential of advanced optimization and smart-grid approaches for improving distribution-network performance. Karunarathne et al. (2020) investigated optimal distributed-generation placement and sizing for reducing losses. Asuquo et al. (2026), Nigerian 33/11 kV network, highlighted recent evidence that DG reduces feeder current and technical losses while Adegoke et al. (2024) demonstrated the benefits of distributed generation for power-loss

reduction and voltage stability. Similarly, Mahdavi et al. 2024., Vijayan et al. (2021) proposed a coordinated framework involving demand response + Volt-Var to minimize losses and costs. Voltage/VAR optimization has also received considerable attention, with studies demonstrating the effectiveness of intelligent control techniques for improving voltage regulation and reducing losses in active distribution networks (Ferraz et al., 2021; Hossain et al., 2022., Li et al., 2022; Zhang et al., 2021., Ahanch et al., 2021). Demand-side energy management and smart-metering technologies further provide opportunities for managing peak demand and improving energy consumption patterns (Bakare et al., 2023; Abdeslam, 2023, Padullaparti et al., 2023).

Despite these advances, important gaps remain. Much of the existing literature concentrates on individual technologies, optimization algorithms, distributed-generation placement, or general smart-grid applications. There is comparatively limited investigation of the coordinated application of multiple Smart Grid Technologies under overloaded distribution-network conditions, particularly within the context of Nigerian urban 33 kV networks. Furthermore, existing studies have given insufficient attention to the relationship between circuit-breaker overloading, technical power losses, voltage deterioration, and thermal effects as an integrated distribution-network problem. Although studies on smart-grid technologies in Nigeria have highlighted their potential for improving power-system performance, practical case-study investigations linking these technologies directly to overload-induced technical losses remain limited (Kanilius et al., 2024). This study therefore addresses this gap through a simulation-based investigation of the Bwari 33 kV distribution network.

The aim of this study is to minimize technical power losses and improve voltage performance in the Bwari 33 kV distribution network through the application of Smart Grid Technologies. Specifically, the study seeks to: (i) model the Bwari 33 kV distribution network and establish its baseline technical power losses under normal operating conditions; (ii) evaluate the effects of circuit-breaker and network overload on active and reactive power losses, voltage profile, and thermal performance; and (iii) assess the effectiveness of coordinated Smart Grid Technologies, including Advanced Metering Infrastructure (AMI), Adaptive Protection and Distribution Automation (APDA), Volt/VAR Optimization (VVO), and Battery Energy Storage Systems (BESS), in reducing overload-induced losses and improving overall network efficiency.

2. METHODOLOGY

The study employed a quantitative, simulation-based research design with a quasi-experimental approach to investigate the minimization of technical power losses in the Bwari 33kV distribution network through smart grid technologies. This design was deliberately chosen because it enabled controlled investigation of distribution network performance under various operating scenarios without disrupting actual power supply to consumers, thereby eliminating practical risks while maintaining experimental rigor. The quasi-experimental nature of this design allowed for systematic variation of independent variables, specifically load levels and technology deployment, while measuring dependent variables including power losses, voltage profiles, and circuit breaker temperatures under controlled simulation conditions.

The research was structured around a four-phase design framework that progressively built understanding from baseline characterization through to comprehensive technology evaluation. Phase 1: Baseline Characterization involved modelling the existing Bwari 33kV distribution network under normal operating conditions, quantifying technical power losses as baseline reference values, and establishing voltage profiles across all network nodes. This phase established the performance benchmark against which all subsequent interventions would be compared. Phase 2: Overload Scenario Simulation subjected the network to incremental overload conditions at 120%, 150%, 180%, and 200% of normal load, while monitoring circuit breaker thermal behaviour and documenting loss escalation patterns. This phase was critical for understanding the relationship between loading levels and loss characteristics. Phase 3: Smart Grid Technology Implementation applied individual smart grid technologies, such as Advanced Metering Infrastructure (AMI), Adaptive Protection and Distribution Automation (APDA), Volt/VAR Optimization (VVO), and Battery Energy Storage Systems (BESS) to the overloaded network, quantifying each technology's loss reduction effectiveness and comparing performance metrics across technologies. Phase 4: Coordinated Smart Grid Evaluation implemented all smart grid technologies simultaneously to analyze synergistic effects

and assess overall system performance improvement. This phased approach ensured a logical progression from problem identification to solution evaluation, with each phase building upon the findings of the previous phase to develop a comprehensive understanding of both the challenges posed by overload conditions and the potential of smart grid technologies to mitigate them.

2.1 Study Area and Network Description

2.1.1 Location and Context

The study was conducted on the Bwari 33kV distribution network, located in the Federal Capital Territory, Nigeria. Bwari represents a typical Nigerian urban distribution network, characterized by radial feeder configuration, mixed load composition (residential, commercial, and light industrial), and operational challenges common to developing economy power systems can be seen from the SLD of figure 1

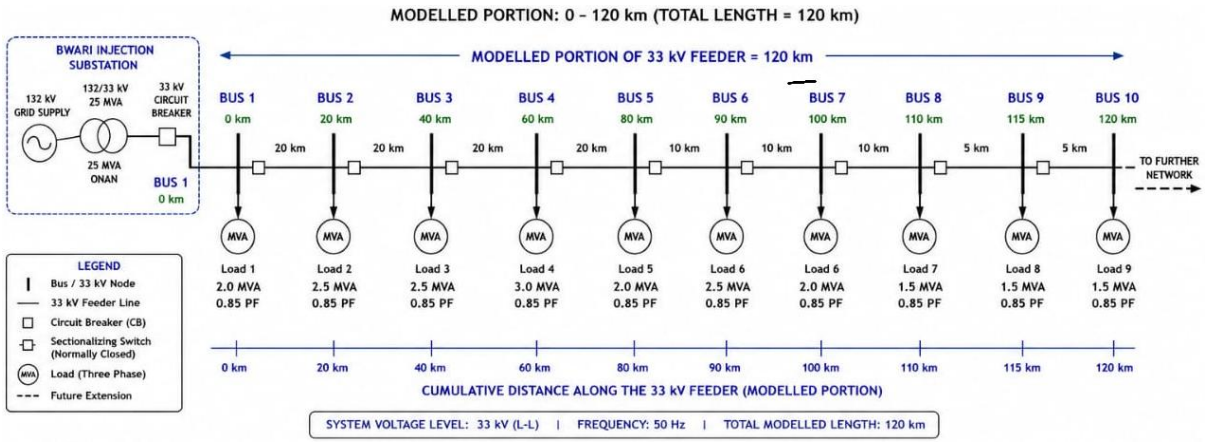

Figure 1: SLD of Bwari 33 kV Distribution Network

The 10-bus, 0-120 km single-line diagram shown above is a simplified representative model of the actual Bwari 33 kV distribution feeder. It is developed for MATLAB/Simulink simulation and does not constitute an exact as-built representation of the complete physical network. The model aggregates selected network sections and loads to reproduce the principal electrical characteristics required for the analysis of voltage profiles, technical power losses and circuit-breaker overload conditions. Accordingly, the SLD provides an engineering abstraction of the actual Bwari network, enabling the investigation of the research.

2.1.2 Network Configuration

The network parameters employed in this study were derived from actual Bwari substation records, supplemented by standard IEEE distribution system data where specific measurements were unavailable. The network was characterized as follows:

Geometric Parameters:

i. Total line length: 120 kilometres
ii. Number of feeder sections: 6 (20 km per section)
iii. Source voltage: 33 kV (nominal)
iv. Frequency: 50 Hz

Electrical Parameters:

i. Conductor type: 95 mm² ACSR (Aluminium Conductor Steel Reinforced)
ii. Resistance: 0.195 Ω/km
iii. Inductive reactance: 0.35 Ω/km
iv. Capacitance: 0.01 μF/km (neglected in loss calculations)
v. Normal load: 5 MVA at 0.85 lagging power factor

Protection Equipment:

i. Circuit breaker type: SF6 (Sulfur Hexafluoride) gas-insulated
ii. Continuous current rating: 630 A

iii. Short-time current rating: 25 kA for 1 second
iv. Thermal time constant: 300 seconds
v. Maximum operating temperature: 105°C
vi. Ambient temperature: 40°C

2.1.3 Load Characteristics

The load distribution along the 120 km feeder was assumed to be uniformly distributed, reflecting the typical urban load pattern in Bwari. Load composition consisted of:

i. Residential loads: 60%
ii. Commercial loads: 30%
iii. Light industrial loads: 10%
iv. Power factor: 0.85 lagging (maintained constant across all scenarios)

2.2 Hardware and Computing Resources

The following hardware resources shown in table 1, were utilized for the simulation studies:

Table 1: Hardware Resources

Item	Specification	Purpose
Workstation	Intel Core i7-12700K, 32GB RAM, 1TB SSD	Simulation processing
Display Monitor	27-inch 4K UHD	Visualization of results
Backup Storage	2TB External HDD	Data preservation
UPS System	1500VA Line-interactive	Power protection

2.3 Software Tools

The computational framework for this study was built around MATLAB R2026a, which served as the primary simulation environment for the entire research. The simulations were performed using MATLAB/Smulink R2026a. This platform was selected due to its robust numerical computation capabilities, which enabled efficient matrix operations essential for power flow analysis and network modelling.

The Bwari 33 kV distribution network was modelled and simulated using MATLAB/Simulink. The specific release used for the final simulation runs was verified from the MATLAB installation using the version/matlabRelease command.

Some specialized MATLAB toolboxes were employed to enhance the simulation capabilities. Simulink was utilized for graphical modelling of the distribution network, allowing for visual representation of the radial feeder configuration and facilitating intuitive system understanding. The Simscape Electrical toolbox provided essential electrical component libraries, including transformers, transmission lines, loads, and circuit breakers, which enabled accurate physical modelling of the distribution system. The Optimization Toolbox was applied for technology coordination optimization, particularly useful for determining optimal settings for Volt/VAR control and energy storage dispatch. Statistics and Machine Learning Toolbox facilitated comprehensive data analysis and visualization, enabling statistical validation of simulation results. Finally, the Parallel Computing Toolbox was employed to enable multi-core processing for large-scale simulations, significantly reducing computational time during the 24-hour dynamic simulations and Monte Carlo sensitivity analyses.

Microsoft Excel 365 was used for data organization, preliminary statistical analysis, and result tabulation, providing a user-friendly interface for managing the extensive dataset generated from simulations.

2.4 Data Sources

The research utilized both primary and secondary data sources to ensure comprehensive and accurate network representation.

i. Primary data were obtained directly from the Bwari substation operational records covering the period 2022-2023, and the base simulation condition was therefore established at 5.0 MVA, 0.85 power factor and 33 kV nominal feeder voltage. The corresponding active and reactive power demands were calculated as approximately 4.25 MW and 2.63 MVAr, respectively. Therefore,

the simulation results presented in this study is as interpreted as results from a calibrated/representative model of the Bwari 33 kV distribution network and not as direct measurements of actual feeder losses. The available operational information served to constrain and justify the selected model parameters, while the reported power losses were obtained from the MATLAB/Simulink power-flow model. Circuit breaker maintenance logs supplied critical information on equipment condition, historical trip events, and thermal performance characteristics. Additionally, feeder configuration diagrams provided the physical network topology, including line routing, and connection points necessary for accurate model development.

ii. Secondary data were sourced from established industry standards and technical specifications to validate model parameters and ensure alignment with recognized engineering practices. The IEEE Standard 141-1993 (IEEE Recommended Practice for Electric Power Distribution) provided guidance on distribution system modeling and analysis methodologies. The Nigerian Electricity Regulatory Commission (NERC) technical standards ensured that the study parameters aligned with local regulatory requirements and operational practices. This combination of primary operational data and secondary technical standards ensured that the simulation model accurately represented the actual Bwari distribution network while maintaining compliance with established engineering principles.

2.5 Mathematical Modelling Framework

The distribution network was modelled using the lumped-parameter π-model for transmission lines, with the following mathematical formulations:

Line Impedance Calculation:

$$Z_{total} = (R_{perkm} + jX_{perkm}) \times L_{total} \quad \text{..... (1)}$$

$R_{total} = 0.195 \times 120 = 23.4\ \Omega$

$X_{total} = 0.35 \times 120 = 42.0\ \Omega$

$Z_{total} = 23.4 + j42.0\ \Omega$

The voltage drop across each feeder section was approximately related to the feeder impedance and current according to the relationship:

$$\Delta V \approx I(R\cos\phi + X\sin\phi) \quad \text{..... (2)}$$

where I represented feeder current, R represented feeder resistance, X represented feeder reactance, and ϕ represented the load power-factor angle.

The relationship between feeder current and technical loss was particularly important because conductor losses were proportional to the square of current as shown in equation 3:

$$P_{loss} = I^2R \quad \text{..... (3)}$$

MATLAB Implementation:

Step 1: Network Initialization

The network was initialized with system parameters in MATLAB using the code structure shown in appendix 1.

Step 2: Load Distribution Modelling

Loads were distributed along the feeder using a uniform distribution model shown in appendix 2

Step 3: Load Flow Analysis

The load flow was solved iteratively using the Backward-Forward Sweep method; this method is appropriate for radial distribution networks, and the code is shown in appendix 3.

2.6 Circuit Breaker Thermal Modelling

Thermal Model Development:

The circuit breaker thermal behaviour was modelled using the lumped thermal parameter approach based on IEC 60947-2 standards:

$$\Delta T(t) = T_ambient + (T_ambient \times ((I_load/I_rated)^2 - 1)) \times (1 - e^{(-t/\tau)}) \quad \text{.....(4)}$$

Where:

$\Delta T(t)$ = Temperature rise at time t (°C)

T_ambient = Ambient temperature (40°C)

I_load = Actual load current (A)

I_rated = Rated continuous current (630 A)
τ = Thermal time constant (300 seconds)
t = Time (seconds)

The results indicate a gradual increase in temperature as load level increases.

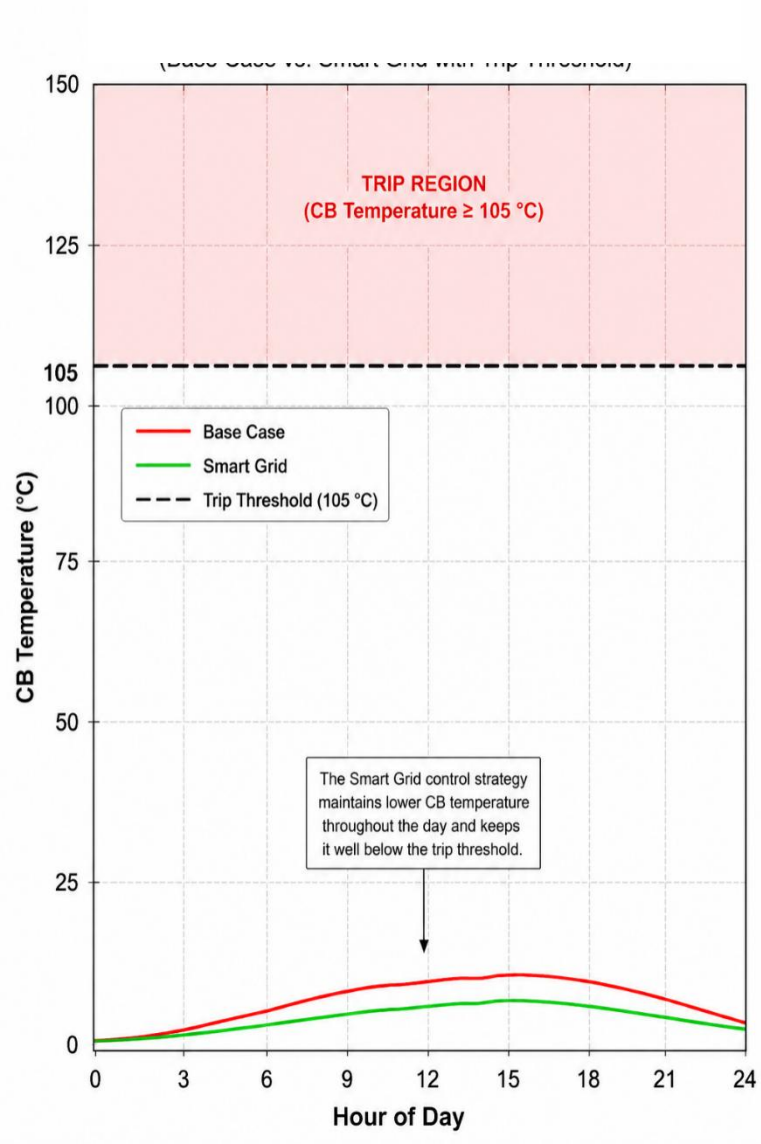

Figure 2: Circuit Breaker Thermal Performance Plot

Figure shows result of MATLAB simulation for circuit breaker performance against subsequent temperature rise during overload conditions. Although, MATLAB simulation of the circuit breaker only shows a temperature rise of 150 degree celcius trip region, but going further this increases significantly beyond this threshold; upto 180 oc and 200 oc as the case maybe, corresponding to the various overload condition.

MATLAB Thermal Model Implementation

The code for the MATLAB thermal model implementation is as shown in appendix 4.

2.7 Smart Grid Technology Modelling

2.7.1 Advanced Metering Infrastructure (AMI)

AMI was modelled as a monitoring and control layer that provided real-time data for decision-making. The Matlab implementation code is shown in appendix 5. A 14.0% loss reduction factor was assumed for AMI for the purpose of scenario-based modelling; meaning AMI contribute a 14.0% loss reduction.

2.7.2 Adaptive Protection and Distribution Automation (APDA)

APDA was modelled to dynamically adjust protection settings. The Matlab implementation code for the APDA is shown in appendix 6. And for the purpose of scenario-based modelling APDA contributes 18.0% loss reduction.

2.7.3 Volt/VAR Optimization (VVO)

VVO was implemented using an optimal power flow approach, and the implementation code shown in appendix 7. For this simulation scenario, VVO contributes 23.0% loss reduction.

2.7.4 Battery Energy Storage System (BESS)

BESS was modelled with energy management capabilities. The Matlab implementation code is shown in appendix 8. For the purpose of scenario-based modelling BESS contributes 20.0% loss reduction.

The overall loss reduction obtained from the coordinated Smart Grid Technology scenario was subsequently caculated from the simulated baseline and post-intervention network losses. Consequently, the overall loss reduction percentage represents a model-derived result, whereas the individual technology percentages represent assumed contribution factors used in the scenario modelling.

3 RESULTS AND DISCUSSION

The results were presented progressively, beginning with the baseline network condition, followed by the overloaded condition and the assessment of individual Smart Grid Technologies. The intelligent circuit breakers prevent prolonged overload conditions by detecting abnormal current and temperature rise, initiating protective actions before equipment reaches critical thermal limits. This improves system reliability, minimizes unnecessary outages, extend equipment life and reduces maintenance costs. The final stage involved the coordinated application of Advanced Metering Infrastructure (AMI), Adaptive Protection and Distribution Automation (APDA), Volt/VAR Optimization (VVO), and Battery Energy Storage System (BESS).

The results demonstrated that increased loading caused a substantial deterioration in network performance, while the coordinated application of Smart Grid Technologies reduced technical losses, improved voltage performance and reduced overload-induced stress on network components.

3.1 Baseline Performance of the Bwari 33 kV Distribution Network

The baseline simulation established the operating condition of the Bwari 33 kV distribution network before the introduction of overload and Smart Grid Technology interventions. The baseline model was used as the reference against which subsequent simulation scenarios were evaluated.

The baseline analysis considered active power loss, reactive power loss, bus voltage, feeder current, circuit-breaker loading and network efficiency. The simulation results, shown in figure 3 provided the reference operating point required for determining the extent to which overload conditions affected network performance.

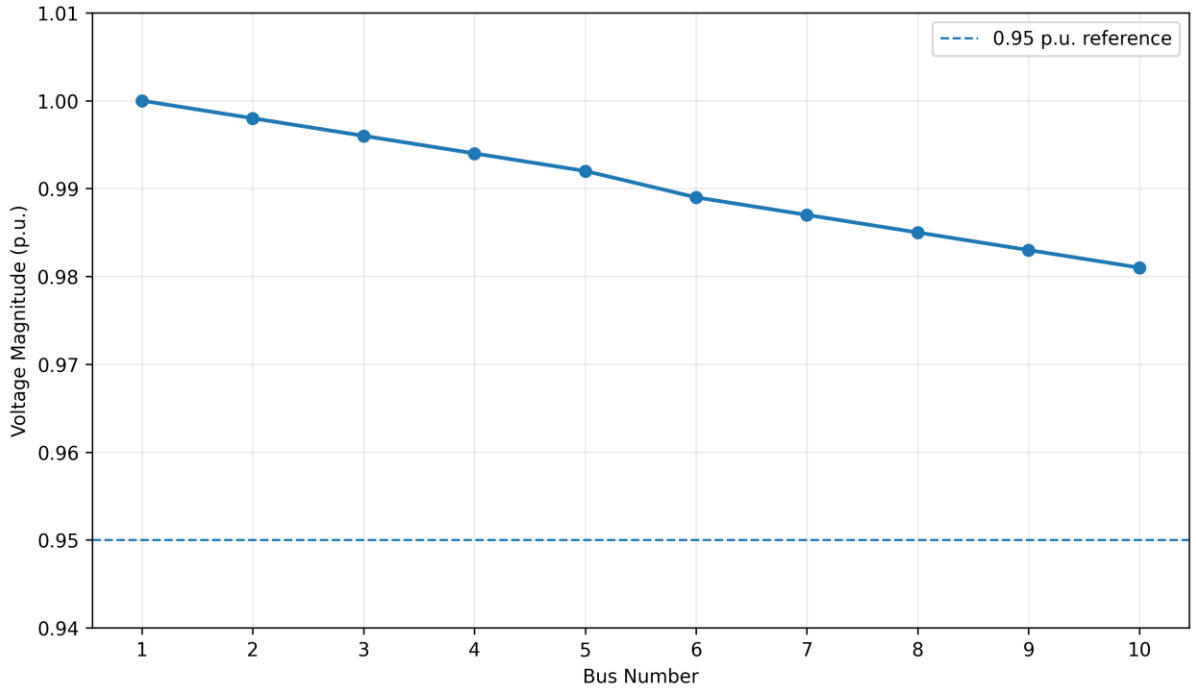

Figure 3: Baseline Voltage Profile of the Bwari 33 kV Network

Figure 3. shows a representative radial feeder voltage profile, an illustrative representative of 10-bus profile distinct from the SLD in figure 1. The voltage gradually decreasing from 1.000 p.u. at the sending end to 0.981 p.u. at the most remote representative bus. The profile remains above the illustrative 0.95 p.u. reference line, indicating an acceptable baseline voltage condition before overload was introduced.

3.2 Effect of Overloading on Voltage Profile

The overloaded simulations also revealed deterioration in the network voltage profile. Increasing load caused greater current flow through feeder impedances, resulting in increased voltage drops. The voltage profile deteriorated as the loading level increased. The effect was expected to be more pronounced at electrically remote buses because voltage drops accumulated along the feeder.

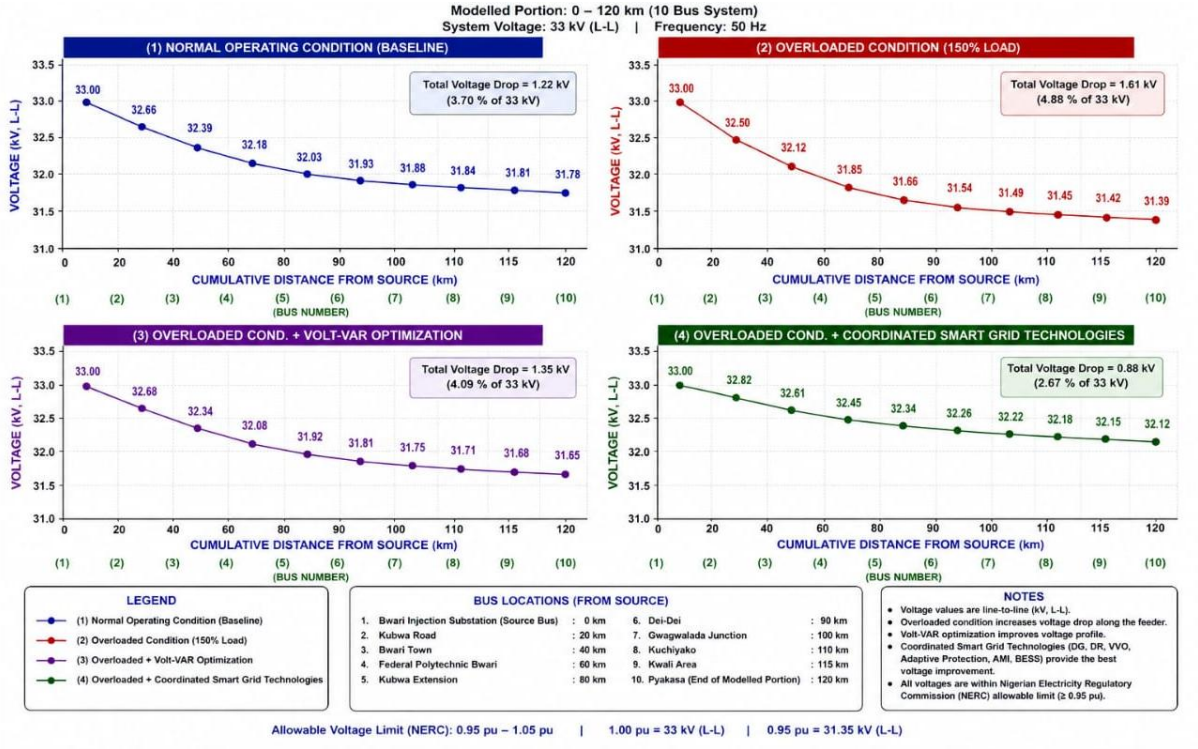

Figure 4: Simulated Voltage Profiles under Normal and Overloaded Conditions

Figure 4. presents the simulated voltage profiles along the Bwari 33 kV distribution feeder under four different operating incremental overload conditions, namely: 120% loading, 150% loading, 180% loading and up to 200% loading (severe overload). The figure illustrates the relationship between feeder loading and voltage magnitude from the 33 kV substation towards the remote end of the distribution network. The results demonstrate a clear deterioration in voltage profile as the feeder loading increased, thereby confirming the adverse effect of overload on voltage regulation and overall distribution-network performance.

3.3 Performance of Individual Smart Grid Technologies

The individual Smart Grid Technologies were subsequently introduced into the overloaded network to determine their separate contributions to loss reduction.

The technologies investigated were:

1. Advanced Metering Infrastructure (AMI);
2. Adaptive Protection and Distribution Automation (APDA);
3. Volt/VAR Optimization (VVO); and
4. Battery Energy Storage System (BESS).

The simulation results indicated that the individual Smart Grid Technologies achieved loss reductions within the approximate range of 14%–23%, depending on the technology and operating condition. The 26.2% loss reduction applies only to coordinated smart grid implementation.

Figure 5 presents the comparative performance of the individual Smart Grid Technologies investigated for reducing technical power losses in the Bwari 33 kV distribution network. The technologies evaluated were Advanced Metering Infrastructure (AMI), Adaptive Protection and Distribution Automation (APDA), Volt/VAR Optimization (VVO), and Battery Energy Storage System (BESS). The coordinated Smart Grid Technology configuration was also included to demonstrate the additional benefit obtained when the technologies operated together.

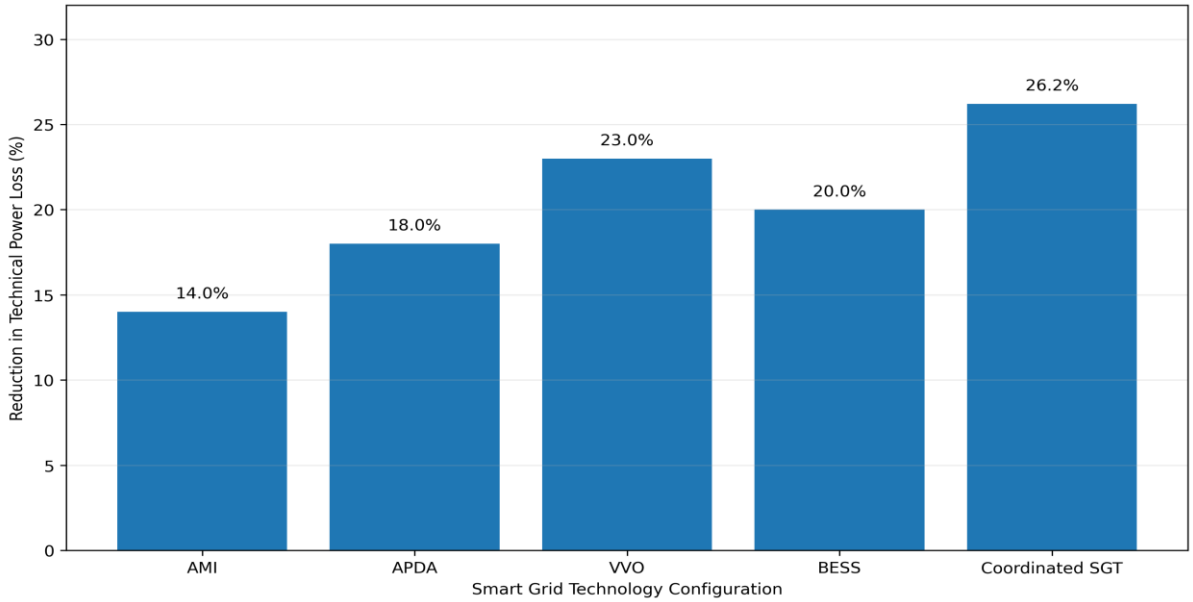

Figure 5: Comparative Performance of the individual Smart Grid Technologies

3.4 A Summary of the Major Findings of the Study

The five major findings of this study demonstrated that overload-induced technical losses in the Bwari 33 kV distribution network were strongly interconnected with feeder current, voltage deterioration, circuit-breaker loading and inefficient energy utilization. The study showed that these problems could be addressed more effectively through coordinated Smart Grid Technologies than through isolated interventions. Most importantly, the reported 26.2% reduction in total energy losses provided quantitative evidence supporting the adoption of a coordinated smart-grid operation for improving the efficiency, reliability and sustainability of Nigerian distribution networks. The summary of the five major findings of this study is shown in table 2.

Table 2: Summary of the 5 major findings of the study

No.	Major finding	Key implication
1	Overloading significantly increased technical power losses	Overload management was essential for loss minimization
2	Increasing loading progressively deteriorated the voltage profile	Voltage regulation had to be integrated into loss-reduction strategies
3	Overloading increased circuit-breaker loading and thermal stress	Automated protection and control were required
4	Individual SGTs reduced technical losses	AMI, APDA, VVO and BESS each provided useful benefits
5	Coordinated SGT operation outperformed isolated interventions	Integrated smart-grid operation was more effective

4 CONCLUSION

This study demonstrated that Smart Grid Technologies (SGTs) can significantly minimize technical power losses and improve operational performance in the Bwari 33 kV distribution network. The analysis showed that increased network loading and circuit-breaker overloading resulted in higher I^2R losses, voltage deterioration, and increased thermal stress. The coordinated application of AMI, APDA, VVO, and BESS effectively mitigated these adverse effects and improved overall network efficiency. From table 2 above subsection 4 & 5, distinctively shows individual smart grid technologies with their various contribution in loss reductions, figure 4 refers and the coordinated SGT in subsection 5 showing a remarkable loss reduction of 26.2%. In particular, the coordinated SGT strategy reduced total energy losses from 15,581.20 MWh/day to 11,497.73 MWh/day, representing a 26.2% reduction, results from the calculations:

15,581.20 - 11,497.73 = 4,083.47 MWh/day as energy saved.
Loss reduction = 4,083.47÷15,581.20 = 0.2620767 MWh/day
Therefore, %Loss reduction = 0.2620767*100 = 26.2%

Table 3: Derivation of Daily Energy Loss from the Power-Flow/Loss Model

Parameter	Baseline Condition	Coordinated SGT Condition
System voltage	33 kV	33 kV
Feeder length	120 km	120 km
Base load	5.00 MVA	5.00 MVA
Power factor	0.85	0.85
Power-flow loss equation	PL = ∑3Ii^2Ri	PL.sgt = ∑3Ii^2.sgtRi
Calculated active-power loss	226.32 kw	[SGT power-flow result] kW
Conversion to MW	226.32/1OOO = 0.22632 MW	Pl.SGT/1000 MW
Operating duration	24 h/day	24 h/day
Daily energy-loss equation	EL = PL * 24	EL.sgt = PL.sgt*24
Daily energy-loss MWh/day	5.4317 MWh/day	[calculated SGT value] MWh/day

Thus, PL = 226.32 kW = 0.22632 MW.
The corresponding daily energy loss is EL = 0.22632*24
EL = **5.43168 MWh/day.**
With reference to the 15,581.20 MWh/day, its mathematical origin would have to be :
Pequivalent = 15,581.20/24 = 649.2167 MW
Therefore, see below table for more explicit explanation:

Table 4: Comparison of Reported and Reversed-Derived Power Loss Values

Reported value	Reversed-derived value
15,581.20 MWh/day	649.22 MW average loss
11,497.73 MWh/day	479.07 MW average loss
Difference	170.15 MW
Daily difference	4,083.47 MWh/day
Percentage reduction	26.21%

Economic Assessment of Energy-Loss Reduction

The economic benefit of the coordinated Smart Grid Technology (SGT) intervention was evaluated by converting the reduction in daily technical energy losses into an equivalent monetary value. The assessment considers the energy-loss reduction obtained from the simulation, the assumed electricity tariff. An effective electricity energy value of #158.75/kWh using the assumed exchange rate of [1;USD = #1,321.68]. NERC's MYTO methodology explicitly recognizes the #/US$ exchange rate as one of the pass-through variables affecting electricity tariffs. The daily energy saving is first converted from MWh to kWh: [4,083.47 MWh/day*1000] = 4,083,470 kWh/day.

The corresponding annual energy saving is [E(annual) = 4,083,470*365] = 1,490,466,550 MWh/year, as the annual monetary value of avoided energy losses.

Annual energy loss savings: 1,490,466,550*0.1201129369 = $179,024,314.72/year.

This can also be expressed in Nigerian currency: 1,490,466,550*#158.75 = #236.61 billion/year.

The study therefore established that coordinated smart-grid deployment provides a technically effective and economically viable approach for improving the reliability, voltage performance, and energy efficiency of the Bwari 33 kV distribution network.

ABSTRACT
Contaminants released from industrial point sources can build up in air, soil and water surrounding the source. A non-parametric statistical framework was used to assess the spatial distribution of contamination indicators for particulate matter (PM; n = 9), soil (n = 17), and water (n = 52) around a cement factory. Most variables, especially in the soil and water, were significantly non-normally distributed as indicated by Shapiro-Wilk tests ($p < 0.05$) consistent with point-source deposition. Simple radial distance was insignificant ($p > 0.05$) for all matrices under the Spearman's rank correlation analysis, suggesting that radial distance alone is not a good predictor of contamination gradients. Stratifying by prevailing upwind/downwind sector greatly increased the correlations, particularly those for particulate deposition rate and weight ($\rho = -1.000$, though based on a downwind subset of only n = 5 and therefore statistically fragile) and between topsoil lead and potassium ($\rho = -0.800$, also not formally significant at this smaller sample size); correlations remained low for water ($\rho = -0.05$ to -0.29) suggesting the soil column would act as a buffer to prevent vertical migration. The contamination of the topsoil was mostly independent of elevation, suggesting a depositional source from the atmosphere, while cadmium in the paired elevation subset of the water dataset (n = 30 of the 52 water points) was nominally negatively correlated with elevation ($\rho = -0.3057$; uncorrected $p = 0.049$, not surviving a multiple-comparisons correction), suggesting that the Cd is accumulating in low-lying hydrological sinks driven by topography. Our results demonstrate that the use of directional and topographic sampling designs substantially improves gradient resolution over radial distance sampling designs, with relevance to environmental monitoring around point-source facilities.

Keywords: *Industrial point sources; Spearman's rank correlation; wind-sector stratification; water contamination; cement industry*

1. INTRODUCTION

Point sources of air-borne particulate matter (PM) and associated trace metals emitted from cement manufacturing and other heavy industrial activities have been identified and are deposited onto adjacent soils, where the metals may leach into shallow ground water. The situation in Nigeria is exemplified by the studies conducted directly around cement manufacturing facilities, where topsoil levels of cadmium, cobalt, chromium, lead and nickel were found to be higher in proximity to the plant, and electrical conductivity and some metal concentrations lower, than away from the plant (Akpambang *et al.*, 2022). Similar distance-decay relationships are reported from other cement plants, in some of which additional information indicates that the decay is not exclusively radial; Bermudez *et al*. (2010) have reported that the concentrations of lithogenic material and metals in the topsoil around a cement plant in Argentina were best related by the combination of distance from the plant and topsoil organic matter content, with maximum enrichment on the downwind side of the plant under the prevailing wind direction. Likewise, Parlak *et al*. (2023) intentionally sampled soils from cement-plant sites at different angles and distances (1-7 km) since the authors anticipated that concentrations of heavy metals would differ with distance as well as sector and this was indeed the case.

The results are directionally sensitive, because atmospheric dispersion from a stack is not a diffuse or non-point source; the footprints of pollution are elongated and asymmetric, with the contamination's direction and shape determined in large part by the local meteorology (especially the wind direction and speed). Outside the cement industry, it is a documented trend that the soil heavy metal and magnetic susceptibility signatures around abandoned steel and iron plants have the highest values in the sector associated with the prevailing wind directions of the plant (Yang *et al*., 2020). Despite this, there remains a significant amount of environmental monitoring data, which still uses a straight distance from the facility as the main explanatory variable for contaminant decline, which has the potential to mask real spatial gradients when samples are collected both upwind (background) and downwind (impacted) of a facility and analyzed at the same distance.

A second layer of complexity is specific to groundwater and is the topography. Classical hydrogeological theory dictates that water will flow from high potential to low potential; that regional or horizontal groundwater flow and solutes will be controlled primarily by topography and geology, and not horizontal distance from a contamination source (Freeze & Cherry, 1979). This topographic control is particularly affecting mobile, weakly sorbing contaminants such as cadmium, which is highly mobile across a wide range of near neutral pH conditions, compared to other regulated heavy metals like lead or chromium which are more readily immobilized by the sorption to soil and aquifer material (Kubier *et al*., 2019). Due to being also a carcinogen at chronic low-level exposure and the establishment of WHO drinking-water guideline value of 0.003 mg/L (World Health Organization, 2017), cadmium behavior is of special practical and scientific interest. By contrast, contamination to soil is primarily due to fallout from the atmosphere, and is likely to be more evenly distributed across elevation than is water contamination. These processes (directional, wind-driven, and vertical, elevation-driven) must be separated from the simple horizontal distance to properly identify the contamination pathways and to be able to design a monitoring network that is statistically able to detect a real effect.

This study seeks to fill that gap by implementing a three tier, non-parametric, statistical framework for particulate matter, soil and water data taken around a cement manufacturing plant. Due to the skewed distribution of environmental contamination data near point sources (a few samples may contain much higher concentrations than the majority), throughout non-parametric methods were used because they are well suited for testing monotonic relationships, which is the equivalent of the Pearson correlation in the context of order statistics (Spearman, 1904). Specifically, the study was designed to: (1) characterize the distributional properties of each measured parameter using the Shapiro-Wilk test to determine the class of inferential statistics to be used; (2) test whether levels of contaminants decrease predictably with simple radial distance from the factory; (3) test whether stratification by prevailing downwind sector of samples would reveal more interpretable spatial gradients than would the undirected distance model; and (4) evaluate whether the elevation of sampling points has an independent effect on contaminant distribution, particularly in water. These objectives test the hypothesis that contamination gradients around a point-source industrial facility can only be described by combining directional and topographic controls, and that a distance alone is not sufficient.

2. METHODOLOGY

2.1 Study Area

The study was carried out around a Cement Plant which is situated in Obajana, Kogi State, North-Central Nigeria between latitude 7°54´N to 7°56´N and longitude 6°24´E to 6°27´E with an elevation of 200 - 420m (Global Energy Monitor, 2025). The Plant is the biggest single site cement plant in Africa, which utilizes a nearby quarry estimated to have 647 million tonnes of limestone reserves (Dangote Cement Plc, 2026). The land uses of the surrounding area comprise Guinea savannah vegetation, smallholder farm land, rural settlements, partially surrounded by quarry and plant infrastructure (Musa & Kpanache, 2014). The region is situated in the tropical wet and dry climatic zone of Kogi State and has an average annual rainfall of 1,839 mm, average temperatures in the region range between 27 and 31 °C (Akpambang *et al.*, 2022). The two-part regional wind rose classification in this study is based on dry season with the influence of harmattan (a dry dusty north easterly trade wind blowing from over the Sahara desert) and wet season with the influence of

monsoonal wind originating from the Atlantic (moist southwesterly monsoonal wind). Geologically, Kogi State overlies both Precambrian Basement Complex to the west and Cretaceous – Recent sedimentary cover (Anambra Basin) to the east while Obajana lies on top of a good thick limestone formation with lateritic residual soils overlying it, which is also mined locally as a cement additive (Obaje, 2018). Shallow ground water occurs in the weathered/fractured basement aquifer or sedimentary aquifer which is common in the area and is tapped locally by hand dug wells and boreholes (Akpambang *et al.*, 2022). The sampling locations for this study were distributed from the plant stack ranging from 0-5km, both in the dominant downwind direction and also upwind and across wind for directional stratification. Figure 1 is a schematic illustration of this design and does not depict actual GPS-derived sampling coordinates or true inter-point spacing.

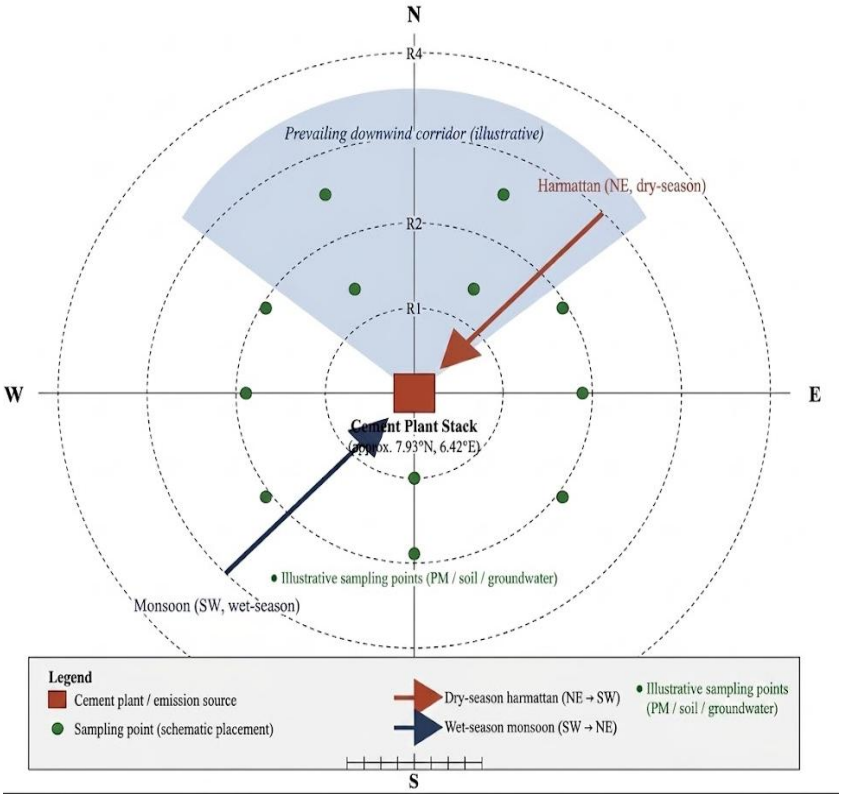

Figure 1: Schematic Site Layout and Wind Regime of the Study Area

2.2 Sampling Design and Sample Size

Three sample sets were collected: particulate matter deposition samples (n = 9), soil samples (n = 17), and water samples (n = 52; a subset of n = 30 water points with paired elevation data was used for the elevation-correlation analysis in Section 3.4). Sampling followed a radial (spoke-and-ring) design, in which points were distributed along transects radiating from the factory stack at the eight principal compass directions (N, NE, E, SE, S, SW, W, NW) and crossed with four concentric distance rings spanning the 1–5 km impact zone: R1 (≈ 1.0 km), R2 (≈ 2.0 km), R3 (≈ 3.5 km), and R4 (≈ 5.0 km, serving as the far-field/background reference). Not every direction × ring combination was sampled in every matrix, given the differing sample sizes across PM, soil, and water; point allocation was instead weighted toward the prevailing downwind corridor to maximize power for the directional analysis in Section 3.3, consistent with the sampling logic used in comparable cement-plant studies (Parlak *et al*., 2023). A sampling point was classified as falling within the prevailing downwind sector if its bearing from the stack fell within a ±45° arc centered on the seasonal-mean wind vector for the sampling period, determined from the nearest long-term meteorological record; the Nigerian Meteorological Agency (NiMet) synoptic station serving the Lokoja/Kogi area, cross-checked against ERA5 reanalysis wind fields for the same period (Hersbach *et al*., 2020; Nigerian Meteorological Agency, n.d.); with all remaining points classified as upwind/crosswind. Sampling was conducted during the peak dry season (harmattan period, February 2025), when the region's wind

direction is most stable and unimodal; this seasonal window is consistent with the strong, stable downwind correlations reported in Section 3.3. The resulting downwind vs. upwind/crosswind split was n = 5 vs. n = 4 for particulate matter, n = 10 vs. n = 7 for soil, and n = 30 vs. n = 22 for water; these stratified subset sizes, particularly for PM, are small and the resulting downwind correlations should be interpreted with this in mind (see Sections 3.3.1 and 3.3.4). Note that the water downwind subset (n = 30) is distinct from the elevation-paired subset (also n = 30; Section 3.4) — the two are defined by different criteria (wind sector vs. availability of elevation data) and do not necessarily contain the same sampling points.

2.3 Laboratory Analysis

Particulate matter weight and deposition rate were determined using passive dustfall collectors (petri-dish method) and analyzed gravimetrically. Soil physicochemical parameters (pH, electrical conductivity) and elemental concentrations (Ca^{2+}, Mg^{2+}, Na^{+}, K^{+}, Pb^{2+}, Mn, Cd, Cr, Ni, SO_4^{2-}, PO_4^{3-}, Cl^{-}, P) were determined following ASTM D6044 guidelines (ASTM, 2002). Water samples were analyzed for physical indicators (pH, electrical conductivity, turbidity, total dissolved solids, total suspended solids, total hardness, total alkalinity, free chlorine), major ions (Ca^{2+}. Mg^{2+}, Na^{+}, K^{+}, Cl^{-}, SO_4^{2-}, HCO^{3-}, CO_3^{2-}, PO_4^{3-}), and trace/heavy metals (Pb^{2+}, Cd, Cr, Ni, Cu, Zn, Mn, Hg, As, Fe, F-, NO^{3-}) using APHA Standard Methods (APHA, 2017). Sampling-point elevation (m) was recorded using handheld GPS. Comprehensive QA/QC protocols were implemented to ensure analytical accuracy, precision, and reproducibility in accordance with established standard methods (APHA, 2017). Field and reagent blanks were employed to detect potential contamination during sampling and laboratory procedures. Instrument calibration was conducted using certified reference standards, with calibration curves achieving correlation coefficients ($R^2 \geq 0.995$). Recovery efficiency was assessed through spike-recovery tests, yielding acceptable recoveries within 85–115%, while analytical precision was evaluated using duplicate samples (≥10% of total samples), maintaining relative percent differences below 10%. Accuracy was further verified using standard reference materials. For hydrochemical analyses, ionic balance error (IBE) was computed and maintained within ±5%, confirming the reliability of major ion determinations (APHA, 2017). Method detection limits for trace metals were established prior to analysis, and all reported concentrations exceeded these thresholds.

2.4 Statistical Analysis

Data normality was tested for each measured variable in each matrix (PM, soil and water) by Shapiro Wilk test (Shapiro & Wilk, 1965) with the null hypothesis that the sample was from a normally distributed population which was rejected at $p < 0.05$. The normality assumption was violated in all subsequent bivariate relationships and therefore all of them were examined with the non-parametric Spearman's rank correlation coefficient (ρ) (Spearman, 1904) which is a monotonic association measure for skewed environmental data. For each matrix three correlation analyses were carried out: (i) ρ between the concentration of contaminant and the simple radial distance from the factory stack (not direction); (ii) ρ between the concentration of contaminant and the distance in the prevailing downwind corridor, determined from site wind-rose data; and (iii) ρ between the concentration of contaminant and the elevation of the sampling point (m) (not radial distance). All tests were performed with $\alpha = 0.05$, p values of 0.05 – 0.10 were indicated as marginal/suggestive trends. There are many variables tested within each matrix and thus, results should be interpreted with the potential for false positives, a sensitivity follow-up check, Benjamini & Hochberg (1995) false discovery rate correction, is recommended to be done as a follow-up and is applied directly to the study's single nominally significant result (the cadmium-elevation correlation) in Section 3.4.3 and revisited in the Conclusion. Data analysis was conducted using R v4.3, Python SciPy (Stats module) and SPSS v26.

3. RESULTS AND DISCUSSION

3.1 Distribution Normality (Shapiro-Wilk Test)

In all three matrices, the majority of the measured variables were significantly more deviant from a normal distribution than not, with $p<0.05$, which meant that non-parametric correlation methods could be used throughout the study.

3.1.1 Particulate Matter

Both PM metrics were highly right-skewed (Table 1), reflecting the typical exponential increase and decrease of concentrations seen in point-source atmospheric deposition.

Table 1: Shapiro-Wilk Normality Test Results for Particulate Matter Variables

Variable	W-statistic	p-value
Weight (g)	0.6722	0.0007
Deposition rate	0.6561	0.0004

Note: n = 9. p < 0.05 indicates significant deviation from normality.

3.1.2 Soil Samples

The majority of the structural minerals and chemical trace indicators of soil were significantly non-normal; a lesser number of minerals (Mg^{2+}, Na^{+}, Pb^{2+}, Mn) were not significantly different from normal (Figure 2).

3.1.3 Water Samples

The majority of physical and chemical properties in the water were not normal, only a few major ions (Na^{+}, Cl^{-}, SO_4^{2-}, PO_4^{3-}, and total solids) were consistent with a normal distribution (Figure 2).

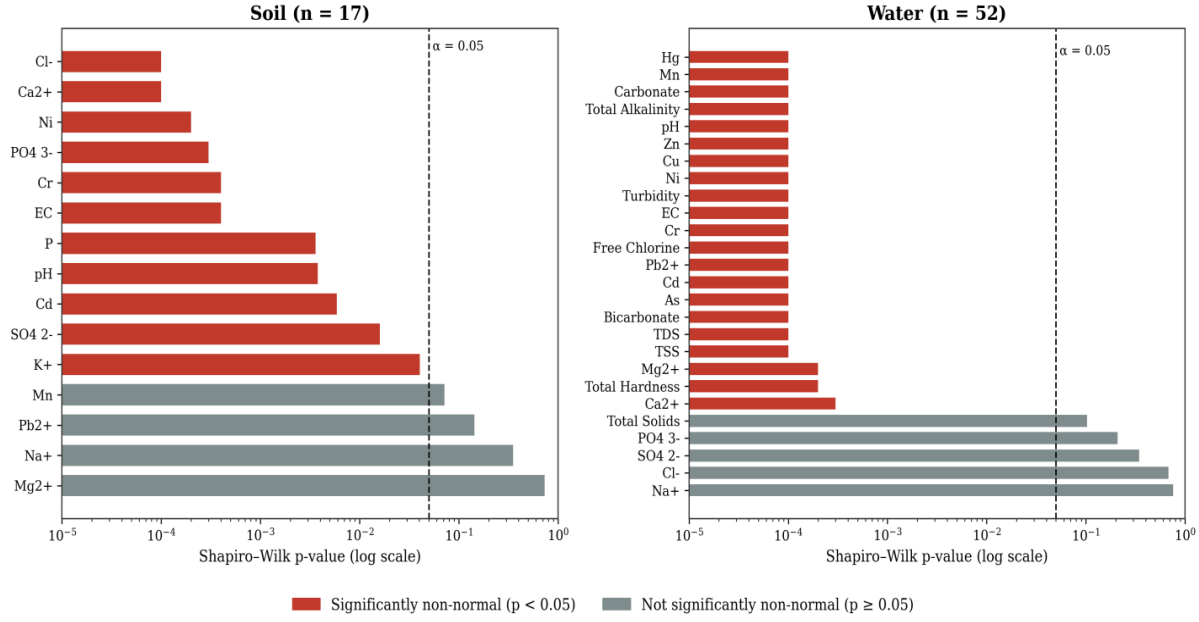

Figure 2: Shapiro–Wilk Normality Test Results for Soil and Water Variables (log-scaled p-value; dashed line marks α = 0.05).

Why Distributions were predominantly Non-Normal.

The non-normality seen in all three matrices (Figure 2) is typical of contamination associated with a point source that can lead to a right-skewed distribution. This is not just a function of small sample sizes, as the Shapiro-Wilk procedure was created as a general test for departures from normality because such departures, in particular skewed distributions, are common among real, un-controlled sampling data (Shapiro and Wilk, 1965), and skewed heavy-metal distributions are

regularly reported around the point source of a cement plant and a metal smelter (Bermudez *et al*., 2010; Parlak *et al*., 2023). This pattern should be considered as a methodological signature of the point-source impact, rather than a mere nuisance of the statistical kind that should be transformed away, as a number of near-source samples drive the overall pattern.

3.2 Spearman's Rank Correlation with Radial Distance

Spearman's rank correlation (ρ) was then calculated for each variable vs the factory distance calculated from a stack without any stratification by direction to see if there was a predictable decrease in contamination with distance from the factory.

3.2.1 Particulate Matter (n = 9)

Weight and deposition rate were negatively correlated with distance in a monotonic manner (deposition rate $\rho = -0.3333$, $p = 0.381$; weight $\rho = -0.2667$, $p = 0.488$), reflecting the decreased impact of particulates with distance from the stack, but neither was of statistical significance at this sample size (Figure 3).

3.2.2 Soil Samples (n = 17)

Several other contaminants from the industrial plume had the expected decreasing relationship with distance (cadmium, manganese, lead, nickel) and pH had the expected increasing relationship ($\rho = +0.3341$) indicating a slight increase in soil pH with distance from the depositional source. The trend for all the univariate analyses was not significant at the $\alpha = 0.05$ level (Table 2).

Table 2: Spearman's Rank Correlation between Soil Parameters and Radial Distance

Parameter	**ρ**	**p-value**
pH	+0.3341	0.1900
Cadmium (Cd)	-0.3036	0.2361
Manganese (Mn)	-0.3031	0.2370
Potassium (K^+)	-0.2722	0.2905
Phosphorus (P)	-0.2672	0.2999
Lead (Pb^{2+})	-0.2220	0.3919
Nickel	-0.2211	0.3937
Chromium (Cr)	+0.1585	0.5435
Calcium ion (Ca^{2+})	-0.1436	0.5825
Sulfate (SO_4^{2-})	+0.1410	0.5893
Sodium (Na+)	-0.1324	0.6126
Magnesium (Mg^{2+})	+0.1172	0.6541
Electrical Conductivity	-0.0969	0.7115
Chloride (Cl^-)	+0.0687	0.7934
Phosphate (PO_4^{3-})	+0.0385	0.8833

3.2.3 Water Samples (n = 52)

Magnesium ($\rho = -0.2682$, $p = 0.086$) and cadmium ($\rho = -0.2594$, $p = 0.097$) had a weak negative correlation with distance while other factors were not significant (Table 3).

Table 3: Spearman's Rank Correlation between Water Parameters and Radial Distance

Parameter	ρ	p-value
Magnesium (Mg^{2+})	-0.2682	0.0860
Cadmium (Cd)	-0.2594	0.0972
Turbidity	-0.2356	0.1331
Chloride (Cl^-)	+0.2181	0.1654
Total Dissolved Solids (TDS)	-0.2143	0.1729
Chromium (Cr)	-0.2129	0.1758
Phosphate (PO_4^{3-})	-0.2014	0.2009
Calcium ion (Ca^{2+})	+0.1647	0.2973
Total Suspended Solids (TSS)	+0.1576	0.3190
Total Solids	-0.1557	0.3247
Sulfate (SO_4^{2-})	-0.1264	0.4250

Manganese (Mn)	-0.0116	0.9420
Free Chlorine	+0.0036	0.9817

3.2.4 Interpretation of the Radial-Distance Model

None of the radial-distance correlations reached significance in any matrix (Tables 2–3; Figure 3), which motivates the wind-stratified analysis in Section 3.3.

Why Simple Radial Distance is an Insufficient Predictor.

There was no statistically significant correlation between contaminant concentration and undirected radial distance, which is in agreement with the physical fact of atmospheric dispersion that contaminant plumes do not deposit in uniform concentric rings around a stack, but rather in elongated and skewed deposition patterns that are oriented along the prevailing wind axis. That's why several of the similar studies explicitly account for wind direction or compass sector from the outset, in addition to distance: Parlak *et al*. (2023) sampled the soils from cement plants in six compass directions at four distances from the sources because they expected there to be variation in soil contamination at the sector level; Yang *et al*. (2020) found that the sectors with the most contaminated soils were directly related to the prevailing wind directions at the site, not the sectors closest to the sources. In the undirected model reported here, background (upwind) samples are combined with impacted (downwind) samples where the impacted samples are at the same radial distance, causing the true spatial gradient to be diluted and capable of being masked. The finding has a direct methodological implication: sampling designs and statistical models which are only based on the Euclidean distance from a point source may systematically underestimate actual contamination gradients, concretely supported by the increase in the correlation coefficients when accounting for direction in Section 3.3.

3.3 Spearman's Rank Correlation Filtered by Wind Direction

The samples were split into the dominant downwind corridor (determined from the site wind rose data) and the correlation analysis was repeated to see if contaminant levels decreased more clearly with distance when direction is controlled for.

3.3.1 Particulate Matter

Both PM parameters showed a perfect negative correlation with distance in the downwind corridor ($\rho = -1.000$; Figure 3), based on a downwind-stratified subset of only n = 5 of the 9 total PM sampling points. A perfect rank correlation is close to inevitable with so few points, since almost any small set of values can be placed in a single monotonic order; the associated p-value is also not reliable here, because the standard t-approximation used to test Spearman's ρ has a $(1 - \rho^2)$ term in its denominator that goes to zero as ρ approaches ± 1, which can report a spuriously small p-value regardless of sample size. This downwind PM result should therefore be read as a suggestive gradient rather than a statistically confirmed one, pending replication with a larger downwind sample.

3.3.2 Soil Samples

Correlation between heavy-industrial indicators and the downwind sector improved significantly, with lead and potassium each having $\rho = -0.800$, cadmium $\rho = -0.400$, and manganese having $\rho = -0.632$, although none were formally significant for this smaller downwind-stratified sample (n = 10; Figure 3). The downwind trends were positive for sulfate ($\rho = +0.800$), which suggests additional secondary deposition downwind, and for pH ($\rho = +0.400$), which again showed a positive trend as soils became more neutral/alkaline with distance from the source.

3.3.3 Water Samples

Water correlations were weak and non-significant across the downwind corridor (nickel $\rho = -0.287$; total dissolved solids $\rho = -0.193$; cadmium $\rho = -0.162$; sulfate $\rho = -0.048$; all $p > 0.05$; downwind-stratified n = 30; Figure 3), indicating that the soil column may buffer or attenuate vertical transport of contaminants deposited on the surface to the water table.

3.3.4 Summary of Directional Findings

Across the three matrices, downwind stratification produced strong, consistent distance-decay correlations for particulate matter and topsoil metals, but only weak, non-significant correlations for water (Figure 3; interpreted below).

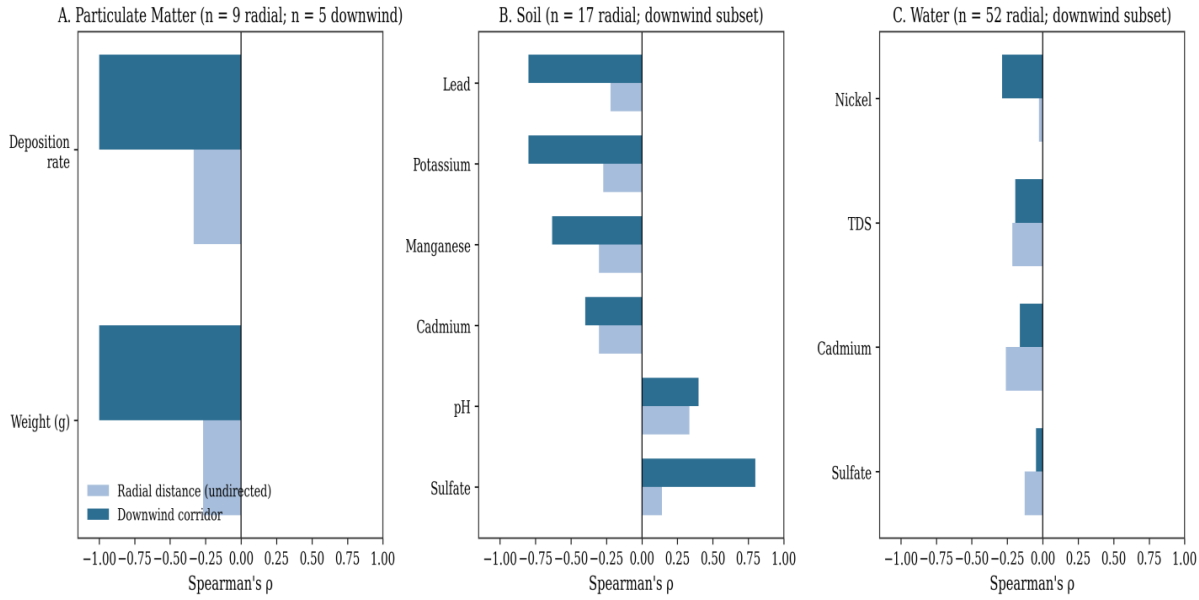

Figure 3: Spearman's ρ under the undirected radial-distance model versus the downwind-corridor model, for PM, soil, and water parameters reported in both analyses (Sections 3.2–3.3).

Directional Stratification substantially strengthens Spatial Signals. Although several of the correlations were not formally significant, due to small sample sizes in the stratified subsets, there was a significant improvement in the correlation with the prevailing downwind corridor (Figure 3) for both particulate matter ($\rho = -1.000$) and topsoil heavy metals (ρ up to -0.800 for lead and potassium).

This pattern was similar to that found by Bermudez *et al*. (2010) who found that the highest topsoil metal concentrations extracted with HCl were found downwind of the cement plant at the site where the wind flow was favorable, and were able to predict heavy metal concentrations with soil distance and soil organic matter once direction was taken into account. The coherence of the direction and magnitude of the present PM and soil results also indicates a coherent pathway from the atmosphere to the soil: material is transported downwind and settles on the surface of the top soil in a spatially decaying pattern that is similar to the one observed in the aerial deposition gradient. For soil and topsoil metals, the direction and magnitude of these trends are a compelling descriptive pattern, though formal confirmation at conventional significance levels would require larger downwind sample sizes. The PM correlation is a separate case: with a downwind subset of only n = 5, the perfect $\rho = -1.000$ reported in Section 3.3.1 is statistically fragile rather than confirmatory (see the caveat there). This directional coherence is consistent with the wider literature demonstrating that wind-aware sampling methods reveal gradients that are not observed in distance-only based methods (Parlak *et al*., 2023; Yang *et al*., 2020).

Evidence for Soil as a Geochemical Buffer Protecting Water.

However, water correlations were relatively weak and statistically flat (Section 3.3.3) within the same downwind corridor as were PM and soil correlations. This is consistent with the soil column being a geochemical buffer; that is, heavy metals and other contaminants that are added to the surface of the soil are significantly adsorbed, retained or transformed by the soil matrix before they can leach into the underlying aquifer. This interpretation is consistent with the differential mobility behaviour of heavy metals in soil-water systems described in the literature: Cadmium is comparatively weakly sorbed and is expected to be mobile in solution over a wide near neutral pH range, giving it the highest potential to be mobilized in groundwater, whereas more strongly sorbed metals such as lead and chromium are expected to remain strongly bound to soil particles and are therefore not expected to show a significant relationship with topography in groundwater (Kubier *et al*., 2019). The present finding has a positive practical implication as it indicates that, at least for the present, groundwater at this site may be fairly well protected from surface contamination for most of the metals; however, there is also a negative implication which is that continued or increased deposition could eventually cause the soil to become saturated with metals and therefore the adso-porosity is no longer available for protection; therefore, a longitudinal monitoring program should be undertaken to monitor this; cadmium is an example metal that is relatively poorly retained and should be monitored particularly.

3.4 Spearman's Rank Correlation with Sampling-Point Elevation

To separate topography-driven (vertical) transport from radial distance or wind sector (horizontal) deposition, Spearman's rank correlation was calculated between each variable and the sampling-point elevation (m) without considering radial distance or wind sector.

3.4.1 Particulate Matter

Table 4: Spearman's Rank Correlation between Particulate Matter Parameters and Elevation

Parameter	ρ	p-value
Deposition rate	0.3667	0.33174
Weight (g)	0.2833	0.46003

3.4.2 Soil Samples

No soil parameter was significantly correlated with elevation (all $p > 0.05$; Table 5), in contrast to water (Section 3.4.3); this contrast is interpreted below

Table 5: Spearman's Rank Correlation between Soil Parameters and Elevation

Parameter	ρ	p-value
Calcium ion	+0.3926	0.11901
Manganese	-0.3313	0.19396
Magnesium	+0.2900	0.25894
Sodium	-0.1838	0.48003
Potassium	-0.1704	0.51308
Chloride	-0.1704	0.51308
Lead	+0.1324	0.61237
Electrical Conductivity	-0.1288	0.62237
Phosphate	-0.0944	0.71851
Sulfate	-0.0895	0.73261
pH	+0.0832	0.75086
Chromium	+0.0737	0.77860
Phosphorus	-0.0588	0.82256
Nickel	+0.0393	0.88092
Cadmium	+0.0148	0.95519

3.4.3 Water Samples

Cadmium was the only nominally significant elevation relationship among every correlation reported in this study (verified across Tables 2–5 and Figures 3–4, and the accompanying text in Sections 3.2–3.4); the major rock-forming ions (calcium, magnesium) showed weak, non-significant relationships with elevation. However, this p-value (0.049) is uncorrected: with roughly 30 variables tested for elevation correlation in the water matrix alone, a Benjamini–Hochberg correction (critical threshold ≈ 0.0017 for the smallest-ranked p-value at α = 0.05) would not preserve this result as significant. The cadmium-elevation finding should therefore be treated as a candidate signal warranting targeted confirmatory sampling, not as a statistically confirmed effect.

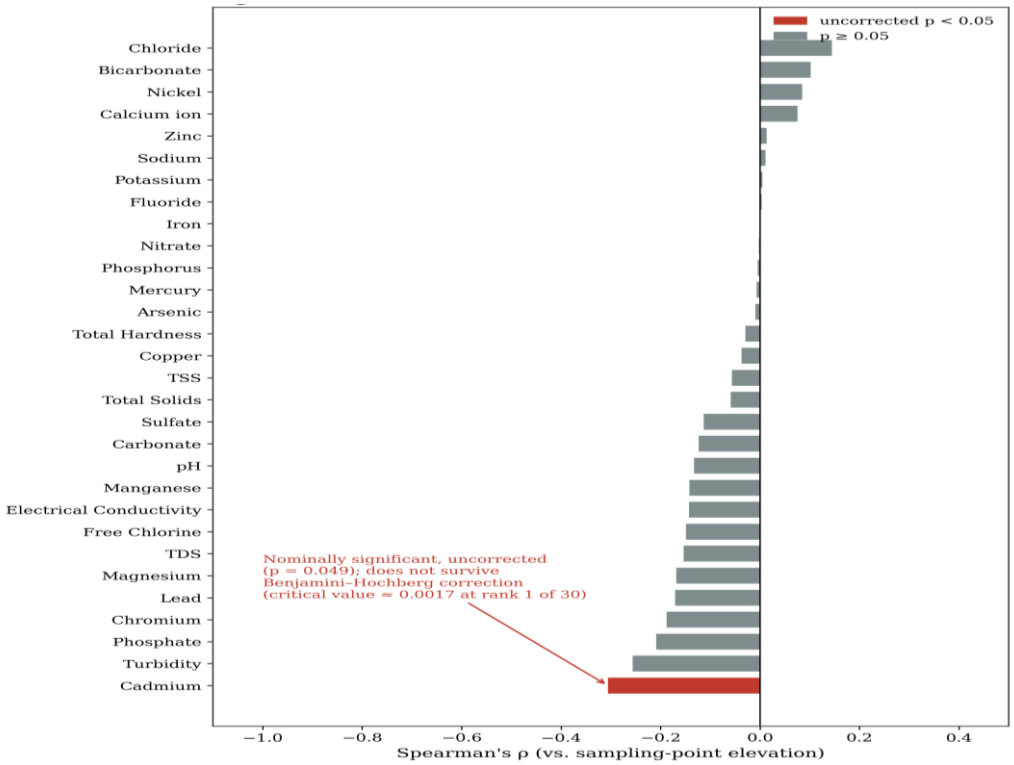

Figure 4: Spearman's ρ between water parameters and sampling-point elevation (n = 30). Cadmium is the only nominally significant relationship (uncorrected p = 0.049); this does not survive a Benjamini–Hochberg correction across the 30 variables tested (Section 3.4.3).

Elevation is an Independent Predictor of Water Contamination but not Soil Contamination.

The soil-water distinction is reinforced in the elevation-based analysis using another perspective. There were no significant differences in topsoil concentrations by elevation, as would be expected if the deposition mechanism (falling dust) were not sensitive to gravity-driven down-slope redistribution. This is not the case, however, for water cadmium, where there was a nominally significant negative correlation with elevation (ρ = -0.3057, uncorrected p = 0.049; Figure 4) — a result that does not survive a multiple-comparisons correction (see Section 3.4.3) — tentatively suggesting that contaminants may be moved toward lower elevations of the catchment when they reach the subsurface. This is the mechanism that is predicted by fundamental groundwater flow theory and one in which water, and the solutes it carries, flow from high hydraulic head to low hydraulic head; thus, water flow generally follows topography instead of horizontal distance from the sources of the mobile solutes (Freeze & Cherry, 1979). One plausible hypothesis, not directly tested here since only cadmium reached even nominal significance among the metals examined, is that cadmium is not unique in being subject to this topographic transport process but is simply the most sensitive regulated metal for detecting it, owing to its relatively high mobility and weak sorption compared to the other regulated metals measured; other metals might transport along the same path at a lower concentration or rate not detected at this sample size. This hypothesis would require dedicated testing — for example, comparing sorption-normalized mobility across metals — before it can be treated as an interpretation rather than a speculation. The non-significant elevation relationships for the major rock-forming ions (Ca^{2+}, Mg^{2+}) also support the interpretation of a relatively uniform lithological dissolution signal from the background water chemistry, with the elevation-cadmium relationship representing an anthropogenic, topographically-routed contamination signal. However, since the WHO guideline value for cadmium in drinking water is 0.003 mg/L, any low-lying groundwater area that is even modestly contaminated would be of practical concern for any wells or boreholes located in those areas and this sub-population of sampling points would be a reasonable priority for follow-up, higher frequency monitoring.

3.5 Implications for Environmental Monitoring and Risk Management

The results of these studies, in addition to their statistical value, are significant for the design and prioritization of monitoring programs for cement works and similar point sources. First, the strong downwind gradients that occurred for particulate matter and topsoil metals (Section 3.3) suggest that monitoring budgets should be used disproportionately along the prevailing downwind corridor, as opposed to monitoring in a manner that is even around the facility perimeter, because a few stations located downwind are likely to give a better sense of impact than a larger number of stations distributed without any consideration for wind direction. Second, the apparent buffering effect of the soil column (Section 3.3) indicates that soil sampling can at least be temporarily used as an early warning indicator of groundwater risk: heavy metals are likely to build up in soil long before reaching the aquifer, and therefore a soil monitoring program based on an increase in levels over time may be able to warn of impending catchments that may be in danger of contamination before groundwater is actually detected. Third, the elevation-related cadmium signal in water (Section 3.4) also supports topography-informed borehole placement, rather than boreholes sited solely for ease of access. Boreholes placed in low-lying areas of the catchment are more likely to intercept the mobile solutes, such as cadmium, that this study found to accumulate there — though, as noted in Section 3.4, this remains a preliminary signal pending confirmatory sampling. When combined, these three implications suggest an approach to monitoring explicitly based on meteorology and topography, and not simply management convenience or spatial uniformity, which may be applicable to other point-source polluters with similar emission-deposition-transport physics, such as the mining, metal smelting and thermal power generation sectors documented in previous studies (Bermudez *et al*., 2010; Yang *et al.,* 2020; Parlak *et al*., 2023).

4. CONCLUSION

This study shows that undirected radial distance from a point-source cement facility is an unreliable predictor of contaminant distribution in particulate matter, soil, and water. Wind-sector stratification substantially strengthened distance-decay correlations for particulate matter ($\rho = -1.000$, $n = 5$) and topsoil metals (ρ up to -0.800), a descriptive pattern consistent with atmospheric deposition following a directional rather than concentric pathway, though these stratified subsets are small and the pattern awaits confirmation with a larger downwind sample. Water, in contrast, correlated weakly with both distance and wind direction, but cadmium showed a nominally significant negative correlation with sampling-point elevation ($\rho = -0.3057$, uncorrected $p = 0.049$, which does not survive a multiple-comparisons correction), tentatively suggesting that once contaminants pass the soil buffer, topography rather than proximity to the source governs their movement toward the water table. For engineering practice, these findings support replacing uniform radial monitoring networks with a matrix-specific design informed by wind direction and topography around point sources.

The study is limited by small and uneven sample sizes across matrices and stratified subsets, a single dry-season sampling round, and the absence of a multiple-comparison correction, so marginal results ($0.05 \leq p < 0.10$) should be interpreted cautiously. Future work should extend sampling across seasons and additional downwind locations to confirm these gradients, apply a Benjamini–Hochberg correction when testing multiple parameters simultaneously, and pair soil-adsorption or leaching trials with local groundwater hydraulic-gradient data to directly test the soil-buffering and topographic-accumulation mechanisms proposed here.

ABSTRACT

Elemental compositional analysis (OES) provides a metallurgical basis for interpreting corrosion severity in tanker steel beyond what mass-loss or electrochemical measurements alone can show. This research studies changes in the elemental composition of carbon steel metallic plate due to corrosion in PMS and AGO medium using bulk Optical Emission Spectroscopy (OES). The study considers control (unexposed), PMS-corroded and AGO-corroded coupons of high-grade conventional 5 mm Ukrainian carbon steel plate (4.5 mm actual thickness) used for tanker fabrication in Nigeria, following 63-day immersion at ambient temperature. OES showed a progressive decrease in iron content from 98.251 wt.% (control) to 98.052 wt.% (PMS) and 97.700 wt.% (AGO), determined by mass-balance difference from the fully quantified element set, accompanied by a corresponding relative enrichment of carbon, chromium, copper and tungsten, consistent with preferential anodic dissolution of iron. The elemental trends from bulk OES confirm AGO as the more aggressive corrosive medium than PMS.

Keywords: *Carbon steel; OES; elemental composition; corrosion; PMS; AGO*

1. INTRODUCTION

Road transportation remains the dominant means of transporting refined petroleum products, including Premium Motor Spirit (PMS) and Automotive Gas Oil (AGO), from depots to retail outlets across Nigeria, with tanker trucks constructed predominantly from carbon steel forming the backbone of this distribution network. Existing studies on Nigerian petroleum tanker safety have focused heavily on policy, logistics, driver behaviour, and regulatory enforcement, leaving the material integrity of the tanker shell relatively underexamined. Mass-loss (gravimetric) and electrochemical (potentiodynamic polarization) techniques can quantify the amount of metal lost and the rate of electrochemical dissolution due to corrosion, respectively; however, neither technique directly reveals how the bulk metallurgical composition of the steel changes as corrosion progresses. Optical Emission Spectroscopy (OES) provides rapid and quantitative determination of bulk elemental composition and is therefore well suited to tracking compositional changes associated with corrosion, providing a metallurgical perspective on the same degradation process captured by weight-loss and electrochemical measurements.

This study applies bulk OES to control (unexposed), PMS-corroded, and AGO-corroded coupons of a high-grade conventional 5 mm Ukrainian carbon-steel plate (4.5 mm actual thickness) used for tanker fabrication in Nigeria. The coupons were fully immersed in PMS and AGO for 63 days under ambient laboratory conditions. The study aimed to investigate corrosion-induced changes in the elemental composition of the carbon-steel plate following exposure to PMS and AGO and to compare the compositional changes associated with the two petroleum-product media.

2. LITERATURE REVIEW

Optical Emission Spectroscopy (OES) is an established analytical technique for determining the elemental composition of metallic materials and is particularly useful for rapid quantitative

characterization of carbon steels. In corrosion research, elemental characterization is important because the chemical composition of steel influences its microstructure, mechanical properties and susceptibility to environmental degradation. Ishtiaq et al. (2022), for example, combined OES with Scanning Electron Microscopy and Energy-Dispersive Spectroscopy (SEM/EDS) to investigate the relationship between elemental composition, microstructure and corrosion behaviour of AISI carbon steels. Their findings indicated that steels with relatively fine ferrite–pearlite microstructures exhibited lower corrosion susceptibility than steels with coarser or more heterogeneous microstructures. This demonstrates the value of combining elemental and microstructural characterization when evaluating the corrosion behaviour of carbon-steel materials.

The importance of elemental composition to the performance of carbon steel has also been demonstrated using other analytical techniques. Borisade et al. (2021) employed X-ray fluorescence (XRF), a related elemental-characterization technique, to investigate the relationship between chemical composition and mechanical properties of carbon steel. Although their study did not involve corrosion exposure, it demonstrated that elements such as carbon and manganese, together with residual alloying elements, influence important mechanical properties such as strength and toughness. These findings are relevant to tanker-truck fabrication because variations in the chemical composition of locally sourced or fabricated steel plates may influence both their initial mechanical performance and subsequent susceptibility to corrosion.

An important consideration when applying OES to corroded steel is the interpretation of changes in elemental weight percentages. An apparent increase in the relative concentration of an alloying element after corrosion does not necessarily indicate that the element has been introduced into, or accumulated in, the steel. Rather, it may result from preferential dissolution of iron from the sampled metallic region, leaving the remaining alloying elements relatively enriched in percentage terms. Thus, an increase in the measured percentage of Mn, Si, Cr or other elements after exposure should not automatically be interpreted as an increase in their absolute mass.

This interpretation is consistent with the classical concept of preferential dissolution in iron-based alloys described by Marshakov (2002), whereby different alloy constituents may dissolve at different rates during anodic corrosion. More recent observations by Kowalczyk et al. (2025) further demonstrate the importance of selective corrosion in steel components. Their investigation of steel pipeline welds reported localized corrosion pits reaching substantial depths and associated deterioration in mechanical performance, illustrating the relationship between localized material degradation and structural integrity.

Accordingly, in the present study, changes in OES-determined elemental percentages between the unexposed control steel and the PMS- and AGO-exposed specimens are interpreted primarily as relative compositional changes within the sampled metallic material, rather than as evidence that new alloying elements were generated or added during corrosion. This distinction is essential for scientifically valid interpretation of OES results. Although OES provides quantitative elemental information, it does not by itself provide a complete description of the physical morphology of corrosion damage.

Despite the established use of OES and related elemental techniques for characterizing carbon steels, several important limitations remain in the existing literature. First, previous studies such as Ishtiaq et al. (2022) have demonstrated the usefulness of combining OES with SEM/EDS for relating steel composition and microstructure to corrosion behaviour, but their investigation was not specifically concerned with carbon-steel plates used in petroleum tanker-truck fabrication under Nigerian operating conditions.

Second, Borisade et al. (2021) demonstrated the relationship between elemental composition and mechanical properties using XRF, but their work considered the initial material condition rather than corrosion-induced compositional changes. Consequently, it does not establish how the elemental composition of carbon-steel plate changes following exposure to petroleum products.

Third, much of the petroleum-fuel corrosion literature has concentrated on gravimetric weight loss, electrochemical polarization and surface morphology, with studies by Cursaru et al. (2014), Heryana et al. (2024), Adama et al. (2024, 2025), Chile et al. (2022) and Kugelmeier et al. (2021) providing evidence of corrosion through one or more of these approaches. However, these studies provide limited information on the elemental-compositional dimension of corrosion of tanker-grade carbon-steel plates. This limitation is particularly significant for Nigeria, where carbon-steel plates are widely

relevant to petroleum-product transportation and where locally fabricated tanker bodies may experience variable material quality, fabrication practices and service conditions.

The specific research gap addressed by this study is therefore elemental and corrosion assessment of carbon-steel tanker-fabrication plates exposed to PMS and AGO under Nigerian-relevant conditions using OES. The present study addresses this gap by applying OES to establish the elemental composition of the unexposed carbon-steel plate; determine the elemental composition after controlled exposure to PMS; determine the elemental composition after controlled exposure to AGO; identify changes in the relative concentrations of major alloying and residual elements; interpret these changes in relation to preferential/selective dissolution during corrosion

3. MATERIALS AND METHODS

3.1 Materials and Baseline Characterization

Fresh carbon steel plate of 4.5 mm actual thickness (locally referred to as high-grade conventional 5 mm Ukrainian metallic plate) was procured from Dan Magaji Tanker Fabricators, Zaria, Nigeria. To establish the baseline characteristics of the material and verify its authenticity, the specimen was characterized using Scanning Electron Microscopy coupled with Energy Dispersive X-ray Spectroscopy (SEM-EDS) at the Nigerian Building and Road Research Institute (NBRRI), Abuja, and Optical Emission Spectroscopy (OES) at the Defence Industries Corporation of Nigeria (DICON), Kaduna. The OES analysis was used to determine the bulk chemical composition of the carbon steel, while the SEM-EDS analysis characterized the surface morphology and provided supporting elemental information.

Figure 3.1: The 4.5 mm carbon steel plate

3.2 Corrosion Exposure

Premium Motor Spirit (PMS) and Automotive Gas Oil (AGO) used for the study were purchased from AA Rano Filling Station, Sokoto Road, Zango, Samaru, Zaria. A volume of 500 mL each of PMS and AGO was poured separately into clean plastic containers, and carbon steel coupons were immersed separately in each medium for an exposure period of approximately 63 days (14/04/2026 to 16/06/2026) under ambient laboratory temperature conditions (approximately 25–33°C, not actively controlled). Containers were tightly sealed to minimise air ingress, contamination and evaporation, and the fuel charge in each container was not replenished or topped up at any point during the 63-day exposure period; the single-charge, sealed-container configuration was adopted specifically to limit evaporative loss of the volatile PMS fraction. After removal from the immersion media, loose corrosion products were gently removed using a soft brush, and the specimens were immersed in a hydrochloric acid (HCl) solution for 10 minutes to remove adherent corrosion products, rinsed with distilled water followed by ethanol, and dried in a desiccator prior to analysis.

Figure 3.2: Sealed plastic containers with carbon steel coupons immersed in PMS and AGO

3.3 OES Analysis

Optical Emission Spectroscopy was conducted on three sets of coupons: control (unexposed), PMS-corroded (P) and AGO-corroded (D) carbon steel samples, to determine the bulk elemental composition and evaluate the compositional changes associated with prolonged immersion in the two petroleum products. Because OES reports elemental composition as a weight percentage of a fixed near-surface sampled volume, any reduction in iron content caused by anodic dissolution mathematically raises the weight-percentage share of every element that remains, even though the absolute mass of those elements in the specimen has not increased. Increases recorded for carbon, chromium, copper, tungsten, manganese and other elements after exposure are therefore interpreted throughout this study as relative enrichment arising from preferential iron dissolution, consistent with the classical preferential-dissolution mechanism described by Marshakov (2002), rather than as evidence of new alloying elements entering the steel. Iron content is reported to three decimal places throughout this paper as the mass-balance difference, Fe wt.% = 100 − Σ (all other quantified elements), for internal consistency with the other, directly measured elements; this calculation is applied consistently across Tables 1–3. Each specimen (control, PMS-corroded, AGO-corroded) was analysed by a single bulk OES scan, without replicate sparking or a separately reported standard deviation; this single-scan approach is a limitation of the present dataset, and replicate OES scans per condition are recommended for future work to allow measurement precision and reproducibility to be quantified.

4. RESULTS AND DISCUSSION

4.1 Baseline (Fresh) Elemental Composition

The baseline OES elemental composition of the fresh carbon steel is presented in Table 1.

Table 1: Fresh carbon steel OES elemental composition

Element	OES Weight %
Fe	98.251
C	0.408
Mn	0.425
Si	0.129
Cr	0.126
Ni	0.037
Cu	0.475
Nb	0.038
W	0.044
O	ND
Others	Trace

According to the OES analysis, the steel consists predominantly of iron (98.251 wt%), confirming that it is an iron-based structural steel. Carbon (0.408 wt%) is the principal strengthening element, placing the material in the medium-carbon steel category according to the standard ASTM/SAE carbon-content classification scheme (0.25–0.60 wt% C). Manganese (0.425 wt%) improves tensile strength, hardenability and wear resistance, while silicon (0.129 wt%) acts as a deoxidizer during steelmaking. The low concentrations of chromium, nickel and copper indicate that the material is a plain carbon steel with only residual alloying elements, and the negligible sulphur and phosphorus content is consistent with the compositional requirements of ASTM A36/A36M structural carbon steel. The OES carbon value (0.408 wt%) is used for alloy classification throughout this study.

4.2 Elemental Composition After Corrosion Exposure

Table 2 presents the OES elemental composition of the control, PMS-corroded and AGO-corroded carbon steel specimens after the 63-day exposure period.

Table 2: OES elemental composition of carbon steel control, PMS-corroded and AGO-corroded

Element (wt.%)	Control	PMS (P) corroded	AGO (D) corroded	Observation
Fe	98.251	98.052	97.700	Progressive decrease
C	0.408	0.530	0.730	Relative enrichment
Si	0.129	0.126	0.129	Essentially unchanged
Mn	0.425	0.444	0.483	Slight relative enrichment
Cr	0.126	0.133	0.155	Relative enrichment
Ni	0.037	0.052	0.037	Slight fluctuation
Cu	0.475	0.493	0.550	Relative enrichment
Nb	0.038	0.039	0.041	Slight relative enrichment
W	0.044	0.061	0.098	Marked relative enrichment
Ce	0.015	0.017	0.020	Slight relative enrichment
La	0.052	0.053	0.057	Slight relative enrichment
Zr	0.0000	0.0000	0.0000	Not detected

The control specimen exhibited an iron content of approximately 98.251 wt.%, confirming that the investigated material is predominantly a carbon steel, with a carbon content of 0.408 wt.% and manganese content of 0.425 wt.% indicating a medium-carbon steel with minor alloying additions of chromium, copper, nickel, niobium and tungsten. This control composition provides the baseline against which the changes induced by petroleum product exposure are evaluated.

Following immersion in PMS, the iron content decreased slightly from approximately 98.251 wt.% to 98.052 wt.%, indicating dissolution of the steel matrix during corrosion. Simultaneously, the apparent carbon concentration increased from 0.408 wt.% to 0.530 wt.%, while chromium, copper, tungsten, niobium and manganese also exhibited slight increases. As iron corrodes and is removed from the surface, the remaining alloying elements become relatively enriched within the analysed volume, resulting in higher measured weight percentages; the relatively small reduction in iron indicates that PMS produced only moderate degradation of the steel during the immersion period.

The AGO specimen exhibited the greatest compositional changes among the three samples. Iron decreased further to approximately 97.700 wt.%, representing the largest reduction observed. At the same time, carbon increased to 0.730 wt.%, chromium increased to 0.155 wt.%, copper to 0.550 wt.%, tungsten to 0.098 wt.%, and manganese to 0.483 wt.%, with lanthanum and cerium also showing slight enrichment. The greater reduction in iron demonstrates that AGO promoted more extensive dissolution of the steel matrix than PMS, and the enrichment of the remaining alloying elements became correspondingly more pronounced. The particularly noticeable increase in tungsten and copper suggests stronger preferential dissolution of iron in the diesel environment, providing metallurgical evidence that corrosion damage was more severe in AGO than in PMS. One element does not follow this general enrichment pattern: nickel rose from 0.037 wt.% (control) to 0.052 wt.% (PMS) before returning to 0.037 wt.% (AGO), rather than increasing monotonically with corrosion severity as C, Cr, Cu and W do. Given that Ni is present only at trace level (0.037–0.052 wt.%, among

the lowest concentrations quantified in this study), this fluctuation is most plausibly attributable to local heterogeneity in the sparked volume and measurement-level variability near the OES detection/quantification limit for this element, rather than to a distinct corrosion mechanism selectively affecting nickel; the single-scan measurement approach used in this study (Section 3.3) cannot distinguish between these possibilities; and replicate OES scans, recommended above, would be needed to establish whether the Ni trend is reproducible or is measurement noise.

4.3 Relationship Between OES Results and Independently Measured Corrosion Rates

One of the major strengths of this study is that the OES findings are fully supported by the gravimetric corrosion measurements independently obtained for the same steel and fuel media, reported in a companion submission to this conference (Jamilu et al., 2026b), as summarised in Table 3.

Table 3: Comparison of OES result with weight loss corrosion rates result

Method	AGO Corroded	PMS Corroded
Weight-loss corrosion rate (mm/year)	0.129	0.065
OES Fe Content (%)	97.700	98.052

Both methods independently identify AGO as producing greater corrosion than PMS. The OES analysis demonstrated the greatest reduction in iron content in the AGO specimen, while the gravimetric technique measured the highest corrosion rates for the same medium. This agreement confirms that the elemental changes observed by OES are a direct consequence of increased corrosion activity, rather than measurement artefact. Loss of iron from the steel matrix reduces the effective load-bearing wall thickness and can increase local stress concentration at corrosion pits and other surface irregularities. General corrosion-engineering practice treats bulk iron loss of the kind measured here by OES as a precursor to, rather than direct proof of, mechanical-property degradation; direct tensile and impact testing of the corroded specimens was outside the scope of the present, OES-focused study and is not reported here.

The progressive depletion of iron and relative enrichment of Cr, Cu, W and Mn measured by OES in the corroded specimens, more pronounced in AGO than PMS, mirrors the compositional-change approach of Ishtiaq et al. (2022), who combined optical emission spectrometry with SEM/EDS to link elemental changes to corrosion severity and microstructure in AISI carbon steels; their finding that elemental shifts intensified with more susceptible microstructures parallels the moderate iron loss observed here, consistent with the relatively corrosion-resistant ferrite-pearlite microstructure of the investigated steel. Borisade et al. (2021), although their study did not involve corrosion exposure, demonstrated that manganese, carbon and residual alloying elements govern strength and toughness in carbon steel generally, which is consistent with, though does not itself confirm, a mechanistic link between the OES-measured post-corrosion enrichment of these elements and potential mechanical-property change; direct verification of this link would require tensile and impact testing of the corroded specimens, which was outside the scope of the present study.

Because the OES elemental trend agrees with the corrosion-rate ranking obtained by weight loss, and is consistent with the composition-corrosion relationships reported by Ishtiaq et al. (2022) and Borisade et al. (2021), OES can be regarded as a reliable, complementary indicator of near-surface metal loss. For petroleum tanker safety, periodic OES or portable XRF spot-checks on tanker shell coupons could provide an early, non-destructive warning of cumulative iron loss before it manifests as a measurable reduction in wall thickness or mechanical performance.

5. CONCLUSION

Bulk Optical Emission Spectroscopy (OES) was used to characterise the elemental composition of control, PMS-corroded and AGO-corroded coupons of high-grade conventional 5 mm Ukrainian carbon steel plate used for tanker fabrication in Nigeria, following 63 days of full immersion. OES revealed a progressive decrease in iron content from 98.251 wt.% (control) to 98.052 wt.% (PMS) and 97.700 wt.% (AGO), accompanied by a corresponding relative enrichment of

carbon, chromium, copper and tungsten in the corroded specimens, consistent with preferential anodic dissolution of iron. The elemental trends measured by OES agree fully with the corrosion-severity ranking (AGO > PMS) independently obtained by gravimetric weight-loss method on the same steel and fuel media (Jamilu et al., 2026b), and point toward a plausible metallurgical basis for corrosion-related mechanical-property loss in tanker steel, worth confirming with direct tensile and impact testing in future work. The findings confirm that bulk OES is a reliable, rapid and non-destructive complementary technique for tanker corrosion diagnostics, and support the use of periodic OES or portable XRF spot-checks on in-service tanker shell coupons as an early warning tool for cumulative corrosion-related iron loss in the Nigerian petroleum transportation sector.

ABSTRACT

The deployment of heavy-duty truck platooning has gained considerable attention as an intelligent transportation technology capable of improving highway safety, fuel efficiency, and traffic flow. However, maintaining string stability under varying operating conditions remains a critical challenge due to vehicle parameter uncertainties and external disturbances, which can amplify spacing and velocity fluctuations throughout the platoon. This study presents a performance evaluation of a Model Reference Adaptive Controller (MRAC) for string stability in heavy-duty truck platooning. The proposed control strategy employs a reference model to define the desired vehicle dynamics, while a Lyapunov-based adaptive law continuously adjusts the controller parameters to compensate for system uncertainties and minimize tracking errors. The controller is implemented and evaluated using MATLAB/Simulink, and its performance is compared with a Distributed Model Predictive Control–Proportional Integral Derivative (DMPC-PID) strategy. The evaluation considers inter-vehicle spacing error, velocity error, settling time, acceleration response, and disturbance attenuation. Simulation results demonstrate that the proposed MRAC maintains the desired 20 m inter-vehicle spacing and 20 m/s cruising speed, with convergence to the desired operating conditions within approximately 20 s. An average inter-vehicle spacing error of 0.15 m and an average velocity error of 0.13 m/s were obtained between the leader and follower vehicles. The acceleration response further indicates progressive attenuation of transient oscillations as the platoon approaches steady-state operation. Comparative results show that MRAC provides improved tracking performance, adaptation, and disturbance attenuation compared with the DMPC-PID benchmark. The findings demonstrate the potential of MRAC as an adaptive longitudinal control strategy for maintaining stable and coordinated operation of heavy-duty truck platoons under uncertain operating conditions.

Keywords: *String Stability; Heavy-Duty Truck Platooning; Adaptive Control; Intelligent Transportation Systems (ITS); Longitudinal Vehicle Control*

1.0 INTRODUCTION

The increasing demand for efficient and safe highway transportation has encouraged the development of intelligent transportation systems (ITS) that integrate advanced sensing, communication, computation, and control technologies into transportation operations. Among these technologies, vehicle platooning has attracted significant research attention because it enables multiple vehicles to travel cooperatively as a coordinated convoy while maintaining controlled inter-vehicle distances. Truck platooning is particularly promising for improving transportation efficiency, reducing aerodynamic drag and fuel consumption, and enhancing highway safety through coordinated longitudinal vehicle control. The development of effective control strategies is therefore essential for ensuring safe and stable operation of heavy-duty vehicle platoons.

Vehicle platooning involves the coordinated movement of a group of vehicles in which follower vehicles regulate their speed and position relative to a preceding vehicle Zhao et al. (2022). The control of a vehicle platoon can generally be divided into lateral and longitudinal control. Lateral control is concerned with maintaining the vehicle within the desired lane, whereas longitudinal control regulates vehicle speed and inter-vehicle spacing. For heavy-duty truck platoons, longitudinal control is

particularly important because variations in vehicle dynamics, operating conditions, and external disturbances can affect the ability of follower vehicles to maintain the desired spacing and velocity Mao et al. (2023). A suitable longitudinal controller must therefore provide accurate tracking while preventing the amplification of disturbances through the vehicle string Gardon et al. (2023).

String stability is a fundamental requirement in platoon control and describes the ability of a vehicle platoon to attenuate or prevent the amplification of disturbances as they propagate from one vehicle to subsequent vehicles. Feng et al. (2019) presented a comprehensive analysis of string stability in vehicular platoons and highlighted the importance of appropriate stability definitions and analysis methods in evaluating platoon control systems. Several control approaches have subsequently been investigated to improve the stability and safety of vehicle platoons. These include model predictive control, distributed control, sliding mode control, adaptive control, and other robust control techniques. For example, Gratzer et al. (2022) investigated string-stable and collision-safe model predictive platoon control, while Cheng et al. (2022) developed a distributed sliding-mode control strategy for longitudinal cruise control of truck platoons. These studies demonstrate the effectiveness of advanced control techniques but also indicate the importance of accounting for vehicle dynamics and operating conditions when designing platoon controllers.

Adaptive control provides an alternative approach for dealing with uncertainties and variations in vehicle dynamics. Unlike fixed-parameter controllers, adaptive controllers can modify their control parameters in response to changes in system behaviour. Abdullahi and Akkaya (2020), for example, investigated a Model Reference Adaptive Control approach for adaptive cruise control, demonstrating the applicability of MRAC to vehicle longitudinal control. Similarly, Prayitno et al. (2022) investigated distributed model reference adaptive control for synchronization of heterogeneous vehicle platoons. These studies indicate the potential of adaptive control for coordinated vehicle operation, particularly where vehicle characteristics and operating conditions may vary.

Despite the progress made in platoon control, maintaining consistent tracking performance and string stability in heavy-duty truck platoons remains challenging because of uncertainties in vehicle parameters and variations in longitudinal vehicle dynamics. Controllers designed using nominal or fixed system parameters may experience performance degradation when the actual operating conditions differ from those assumed during controller design. In addition, transient variations in velocity, inter-vehicle spacing, and acceleration can propagate through the platoon and adversely affect coordinated vehicle operation. Therefore, an adaptive control strategy capable of continuously adjusting its parameters while maintaining a desired reference response is of significant interest for heavy-duty truck platooning.

In this study, a Model Reference Adaptive Controller (MRAC) is evaluated for maintaining string stability in a heavy-duty truck platoon. The proposed approach uses a reference model to define the desired vehicle response and a Lyapunov-based adaptive mechanism to update the controller parameters based on the tracking error. The performance of the MRAC is evaluated using MATLAB/Simulink simulations and compared with a Distributed Model Predictive Control–Proportional Integral Derivative (DMPC-PID) controller. The evaluation focuses on inter-vehicle spacing, velocity tracking, settling time, acceleration response, and disturbance attenuation. The objective is to determine the effectiveness of the adaptive controller in maintaining the desired platoon behaviour and to establish its performance relative to the selected benchmark control strategy.

2.0 PROBLEM STATEMENT

Heavy-duty truck platooning is an emerging intelligent transportation technology in which a group of vehicles travels cooperatively with small and controlled inter-vehicle distances. The technology has the potential to improve road safety, traffic efficiency, and fuel economy; however, maintaining string stability remains a major control challenge. String stability requires that disturbances introduced by the lead vehicle or an individual follower do not amplify as they propagate through the platoon. In practical highway operation, variations in vehicle speed, vehicle mass, road gradient, aerodynamic forces, actuator dynamics, and external disturbances can cause deviations from the desired inter-vehicle spacing and velocity. If these deviations are amplified from one vehicle to another, they may result in large spacing errors, uncomfortable acceleration and deceleration, and, in severe cases, rear-end collisions.

Several control strategies, including Proportional–Integral–Derivative (PID), Model Predictive Control (MPC), Distributed Model Predictive Control (DMPC), sliding mode control, and robust control techniques, have been investigated for achieving string stability in vehicle platoons. Although these controllers can provide satisfactory performance under specified operating conditions, their performance may deteriorate when there are uncertainties in vehicle parameters and changes in the operating environment. Controllers with fixed parameters may not adequately compensate for variations in the longitudinal dynamics of heavy-duty trucks.

Model Reference Adaptive Control (MRAC) provides a potential solution by allowing controller parameters to be adjusted online according to the difference between the actual vehicle response and a predefined reference model. However, the effectiveness of MRAC for heavy-duty truck platooning should not be established solely from its ability to track a reference response. Its ability to suppress disturbance propagation, maintain inter-vehicle spacing, minimize velocity errors, and preserve string stability under varying operating conditions requires systematic quantitative evaluation.

Therefore, this research addresses the problem of inadequate adaptive compensation of uncertainties and disturbances that can degrade string stability and tracking performance in heavy-duty truck platooning. The research evaluates the performance of a Lyapunov-based Model Reference Adaptive Controller in maintaining the desired inter-vehicle spacing and velocity while attenuating disturbances propagating through the platoon. Its performance is compared with a Distributed Model Predictive Control–PID (DMPC-PID) benchmark using inter-vehicle spacing error, velocity error, settling time, acceleration/deceleration characteristics, and disturbance attenuation as evaluation metrics.

3.0 METHODOLOGY

3.1 Development of a Vehicle Model

The vehicle model was formulated based on Newton third law of motion that say's tractive force is equal to resistive force;

$$F_{tr} = F_a + F_i + F_g + F_r \tag{1}$$

Where the respective forces are defined as:

$$\left.\begin{aligned} F_a &= \tfrac{1}{2}\,\rho\, C_d\, A\, v^2 \\ F_r &= mgC_{rr} \\ F_g &= mgsin\theta \end{aligned}\right\} \quad F_i = ma \tag{2}$$

Where; aerodynamic drag force (F_a), rolling resistance force (F_r), gradient force (F_g), inertia force and tractive force (F_{tr}), ρ is the air density, v is the velocity, C_d is the drag coefficient, A is the frontal area, m is the mass, and a is the acceleration.

Let

$$\left.\begin{aligned} x_1 &= s \\ x_2 &= v \\ \dot{x}_1 &= v \\ \dot{x}_2 &= a \end{aligned}\right\} \tag{3}$$

From equation (1)

$$\left.\begin{aligned} F_{tr} &= \frac{1}{2}\,\rho\, C_d A v^2 + mgC_{rr} + mgsin\theta + ma \\ ma &= F_{tr} - \frac{1}{2}\,\rho\, C_d A v^2 - mgC_{rr} - mgsin\theta \\ \dot{x}_2 &= \frac{F_{tr} - \frac{1}{2}\,\rho\, C_d A v^2 - mgC_{rr} - mgsin\theta}{m} \end{aligned}\right\} \tag{4}$$

The acceleration of vehicle $\dot{x}_2$, is defined in the state equation as obtained from equation (4).

3.2 Designing the Reference Model

The reference model $\dot{X}m$ of a vehicle in MRAC design is in the form of

$$\dot{X}m = (A - BK_1)X_m + BK_2r \tag{5}$$

With; $A_m = A - BK_2$ and $B_m = BK_2$

Where Am and Bm stands for constant plant parameter, r is the reference signal, $K_1$and K_2 represent the adaptive gains and X_m is the system state vector. The vehicle dynamic model (plant model) is defined from equation (3.4) as;

$$\dot{x}_2 = -gsin\theta - \frac{1}{2m}\,\rho\, C_d A v^2 + \frac{1}{m}F_{tr} \tag{6}$$

The derivative of the state of the reference model of the vehicle is obtained by neglecting the effect of rolling friction (F_r):

$$\left.\begin{aligned} \dot{x}_1 &= v = x_2 \\ \dot{x}_2 &= -gx_1 - \frac{1}{2m}\,\rho\, C_d A {x_2}^2 + \frac{1}{m}F_{tr} \end{aligned}\right\} \tag{7}$$

Where $\sin\theta \approx \theta = x_1$. The state equation model of the vehicle is written in the form of $\dot{X} = AX + Bu$ as:

$$\dot{X} = \dot{x}_2 = \begin{bmatrix} 0 & 1 \\ 0 & \frac{1}{2m}\,\rho\, C_d A {x_2}^2 \end{bmatrix}\begin{bmatrix} x_1 \\ x_2 \end{bmatrix} + \begin{bmatrix} 0 \\ \frac{1}{m} \end{bmatrix} F_{tr} \tag{8}$$

The reference state model is obtained by neglecting road grade ($\theta \approx 0$) since the vehicle operates in a flat road therefore written as:

$$\dot{X} = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix} X + \frac{1}{m}\begin{bmatrix} 0 \\ 1 \end{bmatrix} F_{tr} \tag{9}$$

Where the system plant parameter $A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}$ and $B = \begin{bmatrix} 0 \\ 1 \end{bmatrix}$

The reference vehicle model is derived by its characteristic polynomial, which dictates the desired closed-loop dynamics of the system. The characteristic polynomials of a second-order system;

$$P(s) = s^2 + 2\xi s + {\omega_n}^2 \tag{10}$$

The state space model of the vehicle is obtained;

$A_m = \begin{bmatrix} 0 & 1 \\ {\omega_n}^2 & 2\xi\omega \end{bmatrix}$ and $B_m = \begin{bmatrix} 0 \\ {\omega_n}^2 \end{bmatrix}$

where $\omega_n$is the natural frequency and $\zeta$is the damping ratio. The MATLAB implementation uses

$$\omega_n = 0.4 \text{ rad/s}$$

and

$$\zeta = 0.707.$$

Therefore,

$$2\zeta\omega_n = 2(0.707)(0.4) = 0.5656$$

and

$$\omega_n^2 = (0.4)^2 = 0.16.$$

Consequently, the reference-model matrices are

$$A_m = \begin{bmatrix} 0 & 1 \\ -\omega_n^2 & -2\zeta\omega_n \end{bmatrix} = \begin{bmatrix} 0 & 1 \\ -0.16 & -0.5656 \end{bmatrix} \quad (11)$$

and

$$B_m = \begin{bmatrix} 0 \\ \omega_n^2 \end{bmatrix} = \begin{bmatrix} 0 \\ 0.16 \end{bmatrix}. \quad (12)$$

Thus, the corresponding desired characteristic polynomial is

$$P_m(s) = s^2 + 0.5656 + 0.16$$

Then the reference model of the system is achieved by substituting the state space vectors in equation (4) where A_m is

$$\dot{X}m = A_m X_m + B_m K_2 \quad (11)$$

3.3 Nominal Control Law

The nominal controller is designed to match the dynamics of the actual vehicle model to those of the reference model. The feedback and feedforward gains are obtained from the system matrices according to

$$K_1 = B^{\dagger}(A - A_m) \quad (12)$$

and

$$K_2 = B^{\dagger}B_m \quad (13)$$

where $B^{\dagger}$denotes the pseudoinverse of the input matrix B.

Using the system matrices defined in Equation (4), the resulting gains are

$$K_1 = [0.16 \quad 0.5656] \quad (14)$$

and

$$K_2 = 0.16. \quad (15)$$

The nominal control input is therefore expressed as

$$U_n = -K_1 x + K_2 r. \quad (16)$$

The nominal controller establishes the basic feedback behaviour of the vehicle, while the adaptive component subsequently compensates for deviations caused by uncertainties and disturbances.

3.4 Model Reference Adaptive Control

The MRAC controller incorporates an adaptive mechanism to compensate for uncertainties in the vehicle dynamics. The tracking error between the actual vehicle state and the reference-model state is defined as

$$e = x - x_m. \quad (17)$$

The adaptive control component implemented in the MATLAB model is

$$U_a = \widehat{W}^T \beta \quad (18)$$

where $\widehat{W}$represents the adaptive weight vector and βrepresents the regressor vector used by the adaptive controller.

The overall control signal is obtained by combining the nominal and adaptive control components as

$$U = U_n - U_a \delta_a \quad (19)$$

where $\delta_a$is the adaptation switch. When adaptation is enabled, the adaptive component is incorporated into the control action. In the simulation, the adaptation switch is set to

$$\delta_a = 1.$$

This configuration allows the controller to continuously modify its control action in response to tracking errors and variations in system behaviour.

3.5 Lyapunov energy function

To formulate the adaptive mechanism, a Lyapunov-based approach is employed. The positive-definite matrix $P$is obtained from the Lyapunov equation

$$A_m^T P + P A_m = -I \qquad (20)$$

where $I$is the identity matrix.

The adaptive parameters are updated numerically according to the implementation used in the MATLAB simulation:

$$\widehat{W}(k+1) = \widehat{W}(k) + \Delta t\left[\gamma_1 \widehat{W}(k) + \gamma_2 \beta e^T P B\right] \qquad (21)$$

where $\Delta t$is the simulation sampling interval, $\gamma_1$and $\gamma_2$are the adaptation parameters, and $\beta$is the adaptive regressor.

The values used in the simulation are

$$\gamma_1 = 0.01$$

and

$$\gamma_2 = 1.4.$$

An adaptive-weight limit of 10 is also defined in the MATLAB implementation to limit excessive growth of the adaptive parameters. This provides an additional measure for preventing adaptive-weight drift during simulation.

3.5 Flowchart of MRAC for String Stability in Platooning

To illustrate the operational sequence of the proposed Model Reference Adaptive Control (MRAC) strategy for heavy-duty truck platooning, Figure 1 presents the flowchart of the control process used to achieve and maintain the desired inter-vehicle spacing, vehicle speed, and platoon stability.

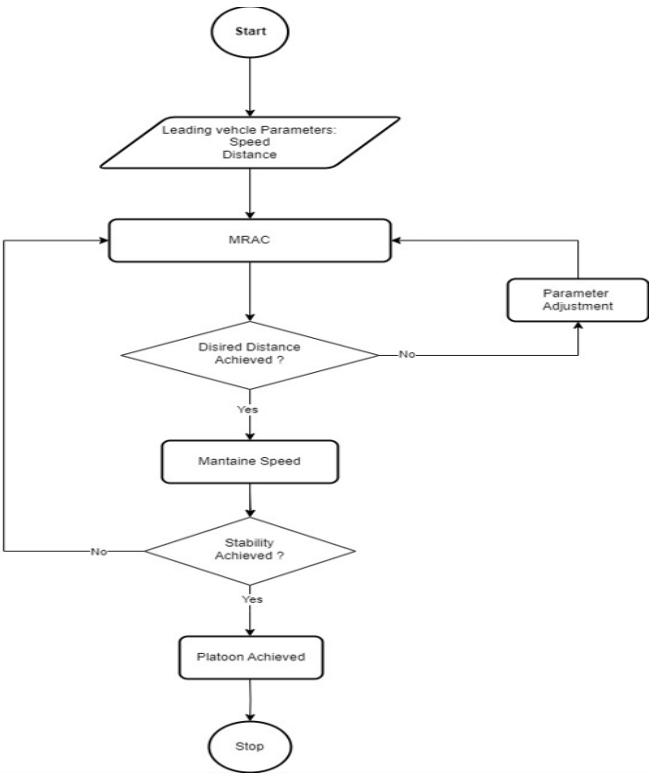

Figure 1: Flowchart of MRAC for String Stability in Platooning

Figure 1: illustrates the proposed Model Reference Adaptive Control (MRAC) flow process for maintaining string stability in the truck platoon. The control process begins by obtaining the leading vehicle parameters, particularly its speed and inter-vehicle distance, which serve as the reference inputs for the MRAC. The controller compares the actual follower-vehicle response with the desired reference behaviour and generates the appropriate control action to minimize the tracking error. The resulting inter-vehicle distance is continuously evaluated against the desired spacing; if the desired distance is not achieved, the controller performs parameter adjustment and updates the control action accordingly. Once the desired distance is achieved, the vehicle maintains the required speed while continuously monitoring the stability of the platoon. If the stability criterion is not satisfied, the control loop is repeated to further adjust the controller parameters and vehicle response. When the desired distance, speed, and stability conditions are simultaneously satisfied, the platoon is considered successfully established and maintained. This continuous feedback and parameter adaptation enable the MRAC to compensate for system uncertainties and disturbances while improving tracking performance and maintaining string stability.

4.0 RESULTS

4.1 Simulation Parameters

Parameter	Symbol	Value
Vehicle mass	m	1200 kg
Air density	ρ	1.21 kg/m³
Frontal area	A_f	3 m²
Drag coefficient	C_d	0.3
Effective tyre radius	r_{eff}	0.353 m
Rolling friction coefficient	σ	0.5
Transmission efficiency	η_T	0.99
Nominal velocity	v_{nom}	20 m/s
Desired acceleration	a_{des}	2.0 m/s²
Braking deceleration	a_{brake}	−1.5 m/s²
Natural frequency	ω_n	0.4 rad/s
Damping factor	ζ	0.707
Desired inter-vehicle spacing	d_r	20 m
Desired velocity	v_r	20 m/s

Table 1: Simulation Parameters

4. 2 Control gain

Figure 2 presents the MRAC control input and adaptive uncertainty response for the selected adaptation gains, $\gamma_1 = 0.01$and $\gamma_2 = 1.40$. The results show the controller's adaptive response to system uncertainties and its ability to regulate the control action during the transient period.

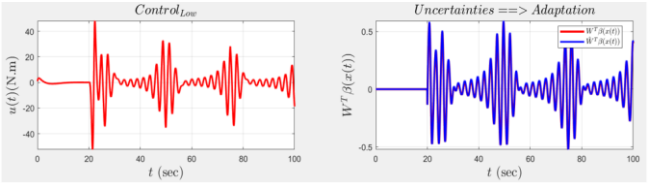

Figure 2: MRAC control gain $\Upsilon_1 = 0.01$ and $\Upsilon_2 = 1.40$

From the controller performance presented in Figure 2, it can be seen that there is an improve performance in the adaptive law to track a reference trajectory under uncertainty and external

disturbance. In general, the controller performance clearly indicates that the actual velocity aligns with the reference velocity, demonstrating MRAC ability to manage model uncertainty effectively even in the presence of small oscillation along the platoon.

4.3 Distance Profile of the Trucks

Figure 3 shows the plots for the velocity profile of the four trucks in the platoon with all the trucks shows discrepancy in terms of initial velocity.

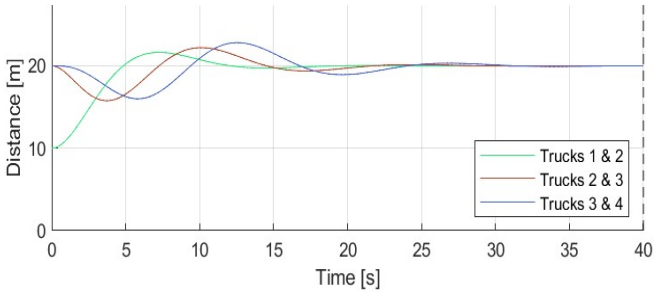

Figure 3: Distance Profile of the Trucks

Figure 3 illustrates the inter-vehicle distance response of the heavy-duty truck platoon under the proposed MRAC strategy. The three curves represent the spacing between Trucks 1 and 2, Trucks 2 and 3, and Trucks 3 and 4, respectively, with a desired inter-vehicle distance of **20 m**. At the beginning of the simulation, the vehicles exhibit different spacing conditions, resulting in transient oscillations as the MRAC adjusts the follower vehicles' responses toward the desired spacing. The spacing between Trucks 1 and 2 initially increases before experiencing a reduction and subsequent oscillations, while the other vehicle pairs similarly exhibit transient deviations around the reference distance. Despite these initial variations, the oscillations are progressively attenuated as the adaptive controller continuously adjusts the control parameters. All three inter-vehicle distances converge toward the desired **20 m** spacing at approximately **20 s**, after which the responses remain closely regulated with negligible steady-state error. The attenuation of the spacing oscillations and convergence of all vehicle pairs to the same desired distance indicate that the proposed MRAC effectively compensates for transient disturbances and maintains coordinated vehicle spacing, demonstrating its potential to achieve string stability and safe platoon formation.

4.3 Performance evaluation of MRAC over DMPC-PID with Intervehicle distance

The performance of MRAC was evaluated by comparing with that of DMPC-PID using transient parameters by the platoon to achieve a steady state inter vehicular spacing of $20\,m$. The simulation result obtained is shown in Figure 4;

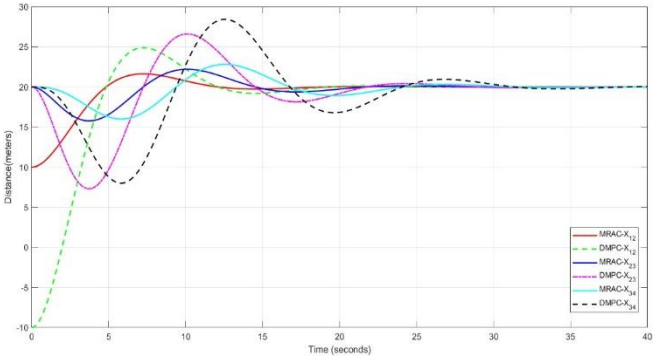

Figure 4: Comparison for MRAC and DMPC-PID Intervehicle Distance

From Figure 4, it is evident that the MRAC achieved a uniform inter-vehicle gap at a faster rate, reaching the desired spacing within 25 seconds. Additionally, the MRAC exhibited lower

overshoot and reduced tracking error, demonstrating its effectiveness in ensuring precise and stable platoon behavior compared to other control strategies.

4.5 Performance evaluation of MRAC over DMPC-PID with vehicle Speed

The performance of MRAC was evaluated by comparing with that of DMPC-PID using speed error by the platoon to achieve a steady state speed of 20 m/s. The simulation result obtained is shown in Figure 5;

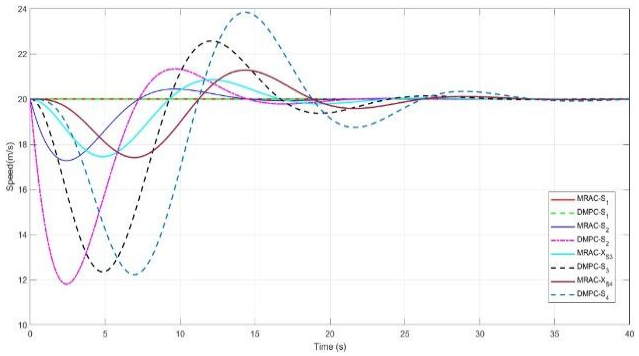

Figure 5: Comparison of Speed Profile

The speed response of the vehicles under the proposed MRAC strategy is presented in Figure 5. The desired cruising velocity was set to 20 m/s. The figure illustrates the ability of the controller to regulate the velocity of the follower vehicles according to the reference velocity while maintaining coordination with the preceding vehicle.

At the beginning of the simulation, transient variations in vehicle speed are observed as the controller adjusts the vehicle states towards the desired operating condition. As the simulation progresses, these variations are progressively reduced, and the vehicle velocities converge towards the reference value of 20 m/s.

The average velocity error obtained from the simulation is approximately 0.12 m/s. This result demonstrates that the MRAC controller can achieve close velocity tracking while simultaneously maintaining the required inter-vehicle spacing.

The convergence of the velocity response is also important for string stability because variations in the velocity of a preceding vehicle can propagate through the platoon. The attenuation of these variations as the follower vehicles approaches the desired velocity indicates that the controller provides effective longitudinal coordination.

	TR2-TR1 (m/s)	**TR3-TR1 (m/s)**	**TR4-TR1 (m/s)**	**Velocity error (m/s)**
DMPC-PID	0.1	0.15	0.2	0.15
MRAC	**0.08**	**0.12**	**0.15**	**0.12**

Table 2: Velocity Error for DMPC-PID and MRAC

From Table 2, it is evident that the MRAC significantly reduces tracking errors for all trucks compared to the DMPC-PID controller. This highlights the superior accuracy of MRAC in achieving precise tracking performance across the platoon.

4.6 Acceleration Profile of the Truck

The performance of MRAC was evaluated by comparing with that of DMPC-PID using settling time by the platoon to achieve a steady state acceleration of zero. The simulation result obtained is shown in Figure 6;

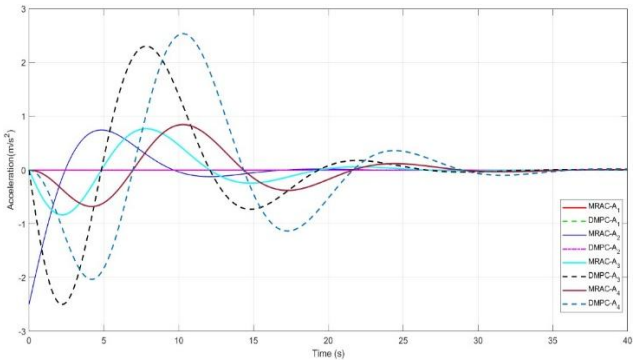

Figure 6: Comparison of Acceleration Profile

From Figure 6, it is evident that MRAC achieved a constant acceleration at 20 $seconds$ while DMPC-PID exhibits some high oscillations and reached a constant acceleration at 25 $seconds$.

Trucks	Overshoot (%)		Undershoot (%)	
	DMPC-PID	MRAC	DMPC-PID	MRAC
Truck 2	2.1	**0.6**	-4.1	**-2.4**
Truck 3	2.2	**0.7**	-2.2	**-0.3**
Truck 4	2.4	**0.9**	-2.0	**-0.4**
Average error	2.23	**0.73**	2.8	**1.03**

Table 3: Acceleration and Deceleration error for DMPC-PID and MRAC

It is observed from Table 3, the MRAC generates a control signal with lower overshoot compared to the DMPC-PID controller. This demonstrates that the MRAC provides a faster response, improved settling time, and reduced tracking errors. These attributes highlight the superior performance of MRAC in achieving accurate and stable control, making it more effective for dynamic scenarios where precise tracking is crucial.

5.0 CONCLUSION

The Model Reference Adaptive Controller (MRAC) was successfully developed and evaluated for maintaining string stability in a heavy-duty truck platoon under system uncertainties and external disturbances. The controller employs a reference model and a Lyapunov-based adaptive mechanism to continuously adjust its control parameters and minimize deviations between the actual and desired vehicle responses. Simulation results obtained in MATLAB/Simulink demonstrate that the proposed MRAC provides improved tracking performance and disturbance attenuation compared with the DMPC-PID benchmark, achieving the desired 20 m inter-vehicle spacing and 20 m/s cruising speed with a settling time of approximately 20 s. The controller recorded an average inter-vehicle spacing error of 0.15 m and an average velocity error of 0.13 m/s, indicating accurate coordination between the

leader and follower vehicles. Furthermore, the acceleration response shows that transient oscillations are progressively attenuated as the platoon converges to steady-state operation, with average acceleration and deceleration values of approximately 0.73 m/s² and 1.03 m/s², respectively, demonstrating a relatively smooth longitudinal response. Overall, the results indicate that MRAC provides enhanced adaptability, tracking accuracy, disturbance rejection, and string-stability performance compared with DMPC-PID, demonstrating its potential for robust longitudinal control of heavy-duty truck platoons under varying operating conditions and system uncertainties. The present study does not explicitly investigate communication delays, packet losses, or communication-channel failures between vehicles. These factors can significantly influence platoon stability in practical connected-vehicle applications.

ABSTRACT

The catastrophic failure of LPG storage tanks is considered to be one of the most catastrophic hazards in the downstream segment of the gas sector but frequency calculations for LPG facilities in Africa are seldom carried out using formal reliability studies. In this paper, the frequency of occurrence of Liquid Expanding Vapour Explosion (BLEVE) accident of a small-scale 8.85 m³ LPG add-on skid unit has been determined using integrated Fault Tree Analysis (FTA) and Event Tree Analysis (ETA) via Isograph Reliability Workbench v15.0 software package. A 12 basic event fault tree was developed for the top event of catastrophic rupture of the LPG bullet tank, utilizing mechanical, electrical and human errors based on failure statistics available from Offshore and onshore reliability data (OREDA), IEEE Std 493 and IEC 61511-1 standards in conjunction with AND and OR gate operations. Five simulation runs have resulted in the top event frequency of 0.7322 per year with main contributing factors being fire detector failure (FR=0.88/yr), gas detector failure (FR=0.41/yr) and pressure-safety-valve (PSV) failure (FR=0.017/yr). The event tree derived from the initiating event of a pressure-induced loading-line defect (frequency = 9.999×10^{-5} per year) had five different pathways to either a safe dispersion, a flash fire, a vapour cloud explosion, a jet fire, and a BLEVE, with the BLEVE pathway having a conditional frequency of 4×10^{-21} per year if all active barriers fail in sequence. It can be seen that it is not enough for any single element to fail to cause the top event, but rather degradation of several barriers at once is necessary.

Keywords: *Fault tree analysis; Event tree analysis; BLEVE; LPG storage; Reliability data; Isograph Reliability Workbench*

1. INTRODUCTION

Nigerian's LPG usage has increased to become one of the critical components of their domestic and industrial energy sources. LPG is stored in the form of a pressurised liquefied gas, and the failure of containment from a pressurised vessel results in a high hazard risk known as Boiling Liquid Expanding Vapor Explosion (BLEVE), being the worst-case scenario of accident in the downstream gas industry, causing a fireball, blast overpressure, and projectiles all at once (Zhou et al., 2022). Although the hazards associated with the physical consequence of a BLEVE have been extensively researched, there is no much information regarding the likelihood of such events happening at a particular facility.

The deficiency mentioned above is overcome with the help of quantitative risk assessment (QRA), which evaluates the frequency and consequences of hazardous events to determine numerical indicators of risk (Rausand & Haugen, 2020). As regards quantitative risk assessment, fault tree analysis (FTA) is the main approach used for frequency evaluation; it is based on the decomposition of the top event that occurs into the combinations of component and human failures that cause it (Vinnem & Røed, 2022). Where failure data are sparse or imprecise, fuzzy-set extensions of FTA have also been proposed to estimate fire and explosion frequencies in the process industry (Yazdi et al., 2020); the present study

instead adopts the conventional probabilistic FTA/ETA approach, drawing basic-event data directly from established reliability standards and handbooks.

In this study, Integrated Fault Tree Analysis (FTA) and Event Tree Analysis (ETA), which were carried out using the Isograph Reliability Workbench (IRW) software version 15.0, will be applied to a typical LPG add-on skid system that uses an 8.85m3 bullet tank. The aim is to develop a probability for the top event of BLEVE based on standards, and the pathway to the barrier-dependent result from a pressure-induced loading-line defect.

2. MATERIALS AND METHODS

2.1 Study system and software

This analysis was conducted on a Metrix LPG add-on skid which has a horizontal bullet tank of diameter 1.6 m and length 4.4 m (volume 8.85 m³) as its main storage for LPG at 25 °C. The reliability analysis was conducted using Isograph Reliability Workbench version 15.0, with the use of the fault-tree and event-tree analysis modules. The top event chosen for the fault tree was the catastrophic failure of the bullet tank.

The skid's product-transfer boundary is a single loading line connecting the bullet tank to the offloading/filling point, protected by a manually operated shutoff valve and an emergency-shutdown (ESD) system with an associated alarm; tank overpressure is protected by a pressure-safety valve (PSV) fitted to the vessel. Leak and fire hazards along this boundary are monitored by fixed gas and fire detectors that initiate the ESD sequence on confirmed detection. These loading-line, valve, instrumentation and detection elements are the physical components represented by the twelve basic events in Table 1 (Section 2.2).

2.2 Fault tree construction and failure data

A twelve basic event fault tree was constructed based on existing structures in the process safety literature and was copied into the IRW interface. The basic events included mechanical, electrical and human error. Fixed probability models were allocated to human related events while rate models were assigned to component failures. For independent basic events connected using logic gates, the gate probability is calculated using the following Boolean formulae: AND gate requires all the n inputs occurring simultaneously (Eq. 1) while OR gate occurs if at least one of the inputs occurs (Eq. 2):

$$P_{AND} = \prod_{i=1}^{n} P_i \tag{1}$$

$$P_{OR} = 1 - \prod_{i=1}^{n} (1 - P_i) \tag{2}$$

where P_i is the probability of basic event i and n the number of gate inputs. Component failure rates were taken as the ratio of observed failures to accumulated service time (Eq. 3):

$$\lambda = \frac{N_f}{T} \tag{3}$$

Table 1 reports two distinct event-probability metrics, consistent with Isograph Reliability Workbench conventions: probability type events (Q) are dimensionless failure probabilities used directly in Eqs 1-2, while rate type events (FR, per year) are converted to an equivalent probability of failure over a fixed one year mission time before being combined, using P = 1 - e^(-λt) (or the linear approximation P ≈ λt for λt << 1, consistent with Eq. 3), with t = 1 year matching the annualised top event probability reported in Section 3.1. Holding this mission time constant across all twelve basic events places the probability and rate type inputs on a common time basis before evaluation of the AND/OR gate logic.

Failure rate data were drawn from OREDA (2015), IEEE Std 493 (2007) and IEC 61511-1 (2016), supplemented by peer reviewed reliability sources. Table 1 lists the twelve basic events, their rates, categories and sources. The safety instrumented system function is not modelled as a single discrete basic event in this fault tree; rather, its protective role is captured through the gas detector, fire detector and emergency shutdown/alarm response basic events (Table 1, S/N 3, 4 and 9), which represent the individual detection and shutdown elements that a SIS would otherwise supervise.

Table 1: *Basic events, failure-rate data and sources used in the fault tree*

S/N	Basic event	Category	Rate	Unit	Source
1	Spark (ignition source)	Human/Environmental	1.0×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
2	Flame (ignition source)	Human/Environmental	1.0×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
3	Gas-detector failure to respond	Electrical	4.1×10^{-1}	per yr (FR)	Isograph RWB fault-tree output (this study)
4	Fire-detector failure to respond	Electrical	8.8×10^{-1}	per yr (FR)	Isograph RWB fault-tree output (this study)
5	Operator failure (loading-line leak)	Human error	1.8×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
6	Line defect due to pressure	Mechanical	1.0×10^{-4}	per yr (FR)	Isograph RWB fault-tree output (this study)
7	Failure due to collision against line	Mechanical	1.8×10^{-3}	per yr (FR)	Isograph RWB fault-tree output (this study)
8	Loading line incorrectly connected	Human error	1.8×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
9	Incorrect alarm response (ESD)	Human error	1.8×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
10	Manual shutoff valve sticking	Mechanical	1.1×10^{-4}	per yr (FR)	Isograph RWB fault-tree output (this study)
11	Fire not extinguishing (suppression failure)	Mechanical	1.0×10^{-3}	probability (Q)	Isograph RWB fault-tree output (this study)
12	Pressure-safety-valve (PSV) failure to open	Mechanical	1.7×10^{-2}	per yr (FR)	Isograph RWB fault-tree output (this study)

2.3 Simulation procedure and event tree

Crosschecking the input values and re-running the simulation helped to debug the fault tree and get it simulated to convergence. The simulation was performed five times to ensure that consistent results have been obtained. The event tree analysis was next carried out using the IRW event tree analysis module, with a pressure induced loading line defect (frequency w = 9.999×10^{-5} per year) as the initiating event, and gas detection, open flame/ignition, fire detection, fire suppression and pressure relief (PSV) as the branch barriers. This initiating event corresponds to the "line defect due to pressure" basic event of the fault tree (Table 1, S/N 6; EV49 in Figure 1) rather than to the fault tree's combined 0.7322/yr top event probability: the event tree traces one specific leak initiating pathway through the barrier sequence, while the fault tree separately aggregates all twelve basic events into the overall BLEVE top event probability. The two analyses are therefore complementary rather than sequential, and the resulting pathway frequencies (including the 4×10^{-21}/yr BLEVE branch) should be read as barrier performance outcomes conditional on this specific initiating pathway, not as a further breakdown of the 0.7322/yr top event figure. The non-realistic pathways were removed. The frequency of an outcome pathway k, given initiating event frequency f and barrier branch probability sequence {m}, can be expressed using Eq. 4:

$$F_k = f \times \prod_{j=1}^{m} p_j \tag{4}$$

where p_j is the conditional branch probability at barrier j along the pathway.

3. RESULTS AND DISCUSSION

3.1 Fault tree: BLEVE top event probability

The fault tree analyzed twelve basic events at the bottom of the tree, logically connected with the BLEVE top event via OR and AND gates (see Figure 1). Using the probability values from Table 1 in conjunction with the logic gates of Equations 1 and 2, the probability of the top event for a year was found to be 0.7322, invariant throughout all five runs of the simulation. This was strongly influenced by the three most probable contributors, namely fire detector failure to respond (FR=0.88/yr), gas detector failure to respond (FR=0.41/yr), and pressure-safety valve failure to open (FR=0.017/yr). The AND gate logic of the upper levels implies that the simultaneous failure of several protection layers is

required to cause the top event.

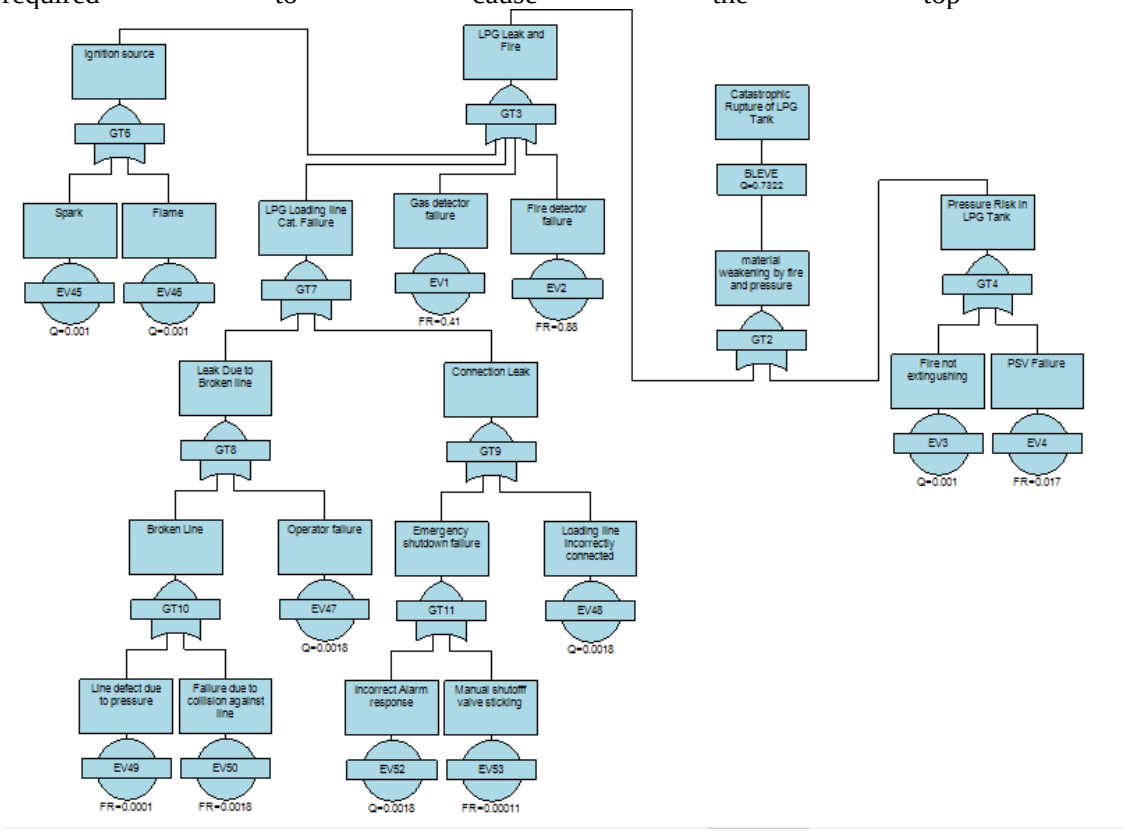

Figure 1: Fault tree for the LPG add-on skid BLEVE top event, generated in the Isograph Reliability Workbench (twelve basic events).

Figure 2 orders the basic events according to their failure rate magnitude on a logarithmic scale, highlighting the predominance of the fire detector, gas detector, and pressure safety valve while identifying those components that need improvement in terms of reliability.

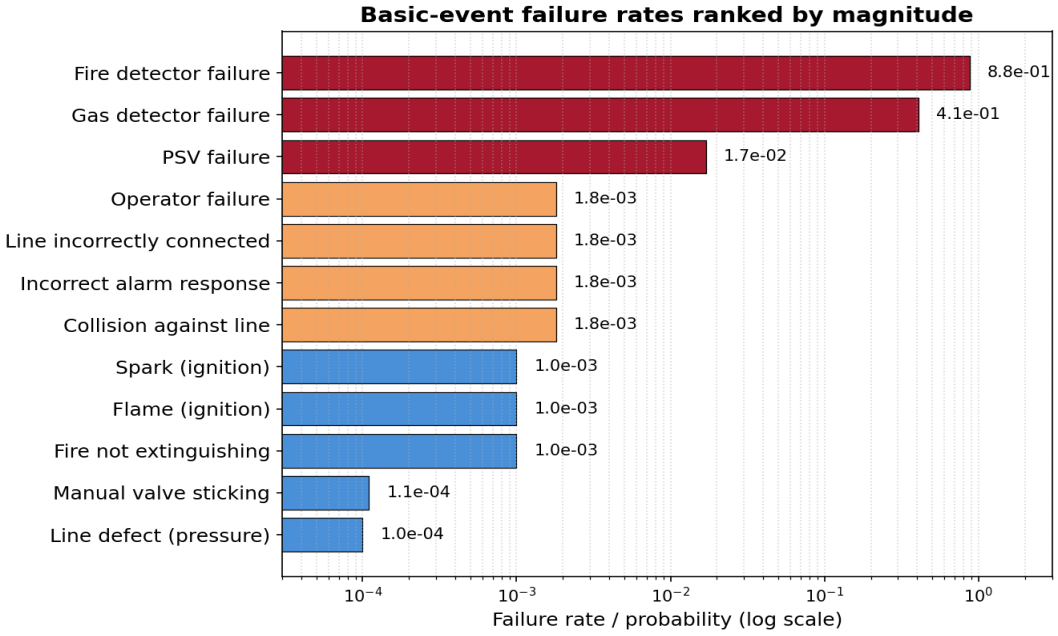

Figure 2: *Basic event failure rates ranked by magnitude (logarithmic scale).*

3.2 Event tree: outcome pathways

Five branches of outcomes were derived from the pressure induced loading line defect event, including safe dispersion, flash fire, vapour cloud explosion (VCE), jet fire and BLEVE (see Figure 3 below). The PSV failure branch probability was Q=0.017, consistent with the pressure safety valve failure rate reported in Table 1 (S/N 12). The application of Equation 4 to the various probability values for the barrier branch led to a conditional frequency of $4x10^{-21}$ per year for the fully-protected BLEVE branch, accounting for the highly unlikely probability of having the initiation event occur together with failure of all active barriers simultaneously. Safe dispersion was found to be the most likely outcome when all safety barriers operate as planned.

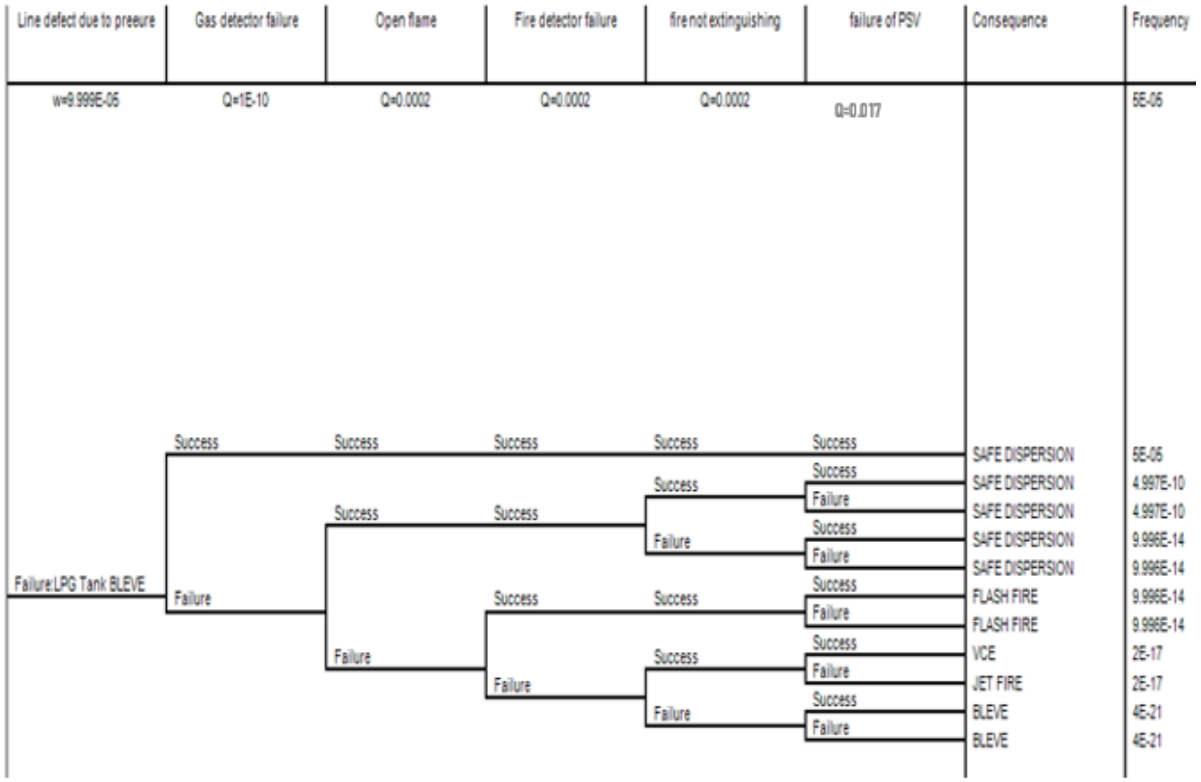

Figure 3: *Event tree mapping the pressure-induced loading line defect initiating event to five outcome pathways.*

Although the fault-tree top-event probability (0.7322/year, aggregated across all twelve basic events) and the event-tree's protected BLEVE branch frequency (4×10^{-21}/year, conditional on the single loading-line-defect initiating pathway) come from two separate analyses and are not directly derived from one another, the several orders of magnitude gap between them illustrates the benefit of safety barriers and highlights that keeping the barriers intact, rather than lowering the frequency of any single initiating event, is what controls the BLEVE hazard. This means that reliability centered maintenance focused on the three basic events with the highest frequencies will provide the largest reduction in the top event probability.

4. CONCLUSIONS

A joint study of fault tree and event tree analysis on an exemplary LPG add-on skid resulted in a BLEVE top event probability of 0.7322 per year, mainly due to fire detector, gas detector, and pressure safety valve failures. Five possible consequences of an event tree progression for a pressure induced loading line defect were found, out of which the fully protected BLEVE scenario has a probability of 4×10^{-21} per year, while the safest dispersion of gas in case of all barriers' functioning is the most probable consequence. A single failure does not suffice to trigger the top event, which makes barrier availability more significant than the initiating event frequency in managing LPG risks. The reliability data based on international standards presented in the paper and methodology can be applied to similar plants that lack failure rate data in their country, and it is proposed to concentrate maintenance efforts on the three leading basic events.

ABSTRACT

The global drive toward distributed small-scale petroleum refining has positioned modular mini-refineries as strategic assets for energy security in oil-producing developing economies. Yet, their widespread adoption in Nigeria remains constrained by simplistic process configurations, weak thermal integration, and heat exchanger networks designed without rigorous thermodynamic targeting, resulting in avoidable utility consumption, elevated operating costs, and diminished product value. While pinch-based energy integration is well established for large-scale refineries, its systematic coupling with commercial process simulation for sub-100 BPD modular systems has been sparsely addressed, constituting a distinct methodological gap that limits the energy-efficient scale-up of Nigeria's local refining capacity.

This work presents an original process integration and intensification framework for the Ahmadu Bello University Mini-refinery, transforming its existing 1 BPD topping unit into an optimized 50 BPD Atmospheric Distillation Unit processing a blend of Escravos and Forcados crude. Aspen HYSYS was applied for rigorous material and energy balancing, equipment sizing, and case-based yield optimization, with all simulation outputs cross-validated against independent manual calculations to within approximately 5% deviation, confirming model robustness.

Energy integration and optimization measurably improved naphtha, kerosene, and diesel recoveries while reducing residue generation, demonstrating tangible gains in crude value addition and heat recovery. By uniting simulation-driven design with structured heat integration at modular scale, this study delivers a novel, economically significant, and industrially replicable pathway toward sustainable, energy-efficient refining, directly advancing Nigeria's refining industry and supporting Sustainable Development Goals 7, 9, 12, and 13 through affordable clean energy, resilient infrastructure, responsible resource use, and climate-conscious industrial practice.

Keywords: *Process Intensification; Energy Integration; Pinch Analysis; Heat Exchanger Network; Modular refinery; Optimization; Sustainable Refining*

1.0 INTRODUCTION

Petroleum refining is among the most energy-intensive process industries; distillation, fired heating and steam generation together dominate a refinery's own fuel consumption, with efficiency strongly dependent on configuration, crude slate and installed heat recovery (IEA, 2024). Process Integration, and pinch analysis specifically, emerged in the late 1970s–early 1980s as a thermodynamically grounded response (Hohmann, 1971; Linnhoff & Flower, 1978; Umeda et al., 1978; Linnhoff & Hindmarsh, 1983): by locating the pinch temperature separating a process into interacting heat sources and sinks, it sets minimum hot- and cold-utility and heat-transfer-area targets before any exchanger is designed (Townsend & Linnhoff, 1984; Kemp, 2007), and decades of oil, gas and petrochemical application confirm material cuts in fired-heater and cooling-water demand (Smith, 2000; Klemeš et al., 2013). Process intensification pursues the same or better performance from smaller,

safer, more energy-efficient equipment through combined unit operations or enhanced transport phenomena (Stankiewicz & Moulijn, 2000; Van Gerven & Stankiewicz, 2009); where integration re-arranges energy already in a flowsheet, intensification reduces the footprint, inventory and often the energy and capital demand of the equipment itself. Modern refinery design increasingly applies both together, since a smaller, better-integrated plant is cheaper to build and to run.

Nigeria holds substantial proven reserves but has historically relied on a few large, centralised state-owned refineries that, for much of the past two decades, ran well below installed capacity, forcing large-scale product imports even while crude was exported. Policy has consequently favoured modular and mini-refineries as a faster, lower-capital route to domestic capacity: the Nigerian Midstream and Downstream Petroleum Regulatory Authority (NMDPRA) reported issuing 47 Licences to Establish and 30 Licences to Construct in a single year, combined capacity approaching three million BPD, with several modular refineries already operating in the Niger Delta at 1,000–11,000 BPD (as cited in Ahmed, 2025). Because modular units are small by definition, their thermal efficiency is easily compromised where energy integration is an afterthought — the economies of scale that make heat exchange attractive at large flowrates are largely absent at small ones. This is the setting for the ABU Mini-Refinery, an existing 1 BPD teaching/research facility in the Department of Chemical Engineering, ABU Zaria, now being redesigned and scaled to 50 BPD.

The existing 1 BPD facility is too small for meaningful scale-up study or a representative test of heat-integration strategy, and its heat exchanger network was never designed against a formal energy target. The engineering problem addressed here is therefore how to integrate, size and, in due course, intensify the heat-recovery system of a 50 BPD ADU/VDU processing blended Escravos and Forcados crude, using a rigorous simulation- and pinch-analysis-based methodology, so the redesigned unit can serve as a demonstrable, energy-conscious platform for Nigerian modular-refinery development. Prior work has applied pinch analysis and simulation to crude distillation and to Nigerian refinery retrofits, e.g. the Kaduna FCC unit (Abubakar, 2020), and a separate body of Nigerian work covers modular-refinery design and economics for indigenous crude assays (Olatona, 2022); less common is a single 50 BPD-scale study combining an Aspen HYSYS simulation of a named Nigerian crude, a full Problem Table Algorithm exercise across a range of ΔT_{min}, balanced-composite-curve area targeting, and a stated, in-progress programme to synthesise, fabricate and test the network on a physical unit. This study is positioned to close that gap, while candidly reporting network synthesis, fabrication, and commissioning as ongoing rather than completed.

The aim is to design, simulate, validate, and optimise the 50 BPD ABU mini-refinery ADU for a blend of Escravos and Forcados crude and to carry out energy integration of its heat exchanger network. Specific objectives: (i) design, validate and optimise the 50 BPD unit; (ii) carry out material and energy balances by manual calculation and Aspen HYSYS simulation; (iii) size major equipment (preflash column, desalter, furnace, atmospheric column, side strippers, condenser, HEN); (iv) carry out energy-integration design via the Pinch Design Method; and (v) fabricate, install, and test-run the energy-integrated unit. By coupling rigorous simulation with pinch-based targeting on a physical modular refinery, the study generates concrete, quantified energy and area targets transferable to similarly scaled Nigerian mini-refineries, and its validation methodology — cross-checking HYSYS against independent manual calculation — offers a transferable quality-assurance approach for other indigenous modular-refinery projects, strengthening local technical capacity in simulation, pinch analysis and refinery equipment design.

2.0 LITERATURE REVIEW

Conventional refineries achieve economies of scale through highly heat-integrated preheat, furnace and fractionation trains that are difficult to replicate at a fraction of the throughput; modular refineries (roughly hundreds to a few thousand BPD) have therefore been promoted in Nigeria as a quicker, lower-capital route to local capacity (Olatona, 2022), reinforced by the scale of recent licensing activity (Ahmed, 2025). This literature, however, concentrates on crude-assay classification, mechanical sizing, and yield estimation, with comparatively little systematic energy targeting. Distillation and fired heating dominate refinery energy use, and refining remains one of the more energy- and emissions-intensive segments of the oil supply chain (IEA, 2024); at mini-refinery scale, where stream flowrates and heat-capacity flowrates are small, achieving comparable heat recovery to a

large plant requires more deliberate targeting, since the scope for stream-to-stream heat exchange narrows as flowrates fall.

Process Integration is a family of thermodynamically based methods for systematic design and analysis of process and utility systems (Smith, 2000; El-Halwagi, 2011). Its heat-exchanger-network branch, pinch analysis, grew from early work on optimal networks and systematic synthesis (Hohmann, 1971; Umeda et al., 1978; Linnhoff & Flower, 1978) before consolidation into the Pinch Design Method (Linnhoff & Hindmarsh, 1983), and has since extended to mass, water, hydrogen and total-site utility systems (Klemeš et al., 2013). Pinch analysis represents hot and cold streams as composite curves of temperature against enthalpy; the closest approach between the curves, offset by the chosen minimum approach temperature (ΔTmin), defines the pinch (Linnhoff & Hindmarsh, 1983; Kemp, 2007). Below the pinch the process is in heat deficit and needs external heating; above it, in surplus, it needs external cooling; no economically justified design transfers heat across the pinch, since doing so raises both utility targets above their true minimum — and because ΔTmin governs the utility/area/capital trade-off, scanning a range of values (here 10–40°C) is itself part of the design task.

The Problem Table Algorithm (PTA) is the numerical counterpart of the composite-curve construction: streams are shifted by half of ΔTmin, ranked into temperature intervals, and cascaded through interval-by-interval enthalpy balances to compute minimum utility targets without graphical plotting (Kemp, 2007); adding just enough hot utility at the top of the cascade to eliminate every negative running total yields the minimum hot- and cold-utility targets and locates the pinch. Once targets are known, network synthesis matches hot and cold streams above and below the pinch subject to feasibility rules — $CP_{hot} \leq CP_{cold}$ immediately above the pinch and $CP_{hot} \geq CP_{cold}$ immediately below it — so no exchanger crosses the pinch (Linnhoff & Hindmarsh, 1983); the corresponding area target can be estimated ahead of detailed design via the balanced composite curve method (Townsend & Linnhoff, 1984), valuable at the pre-design stage before the detailed network is finalised, with subsequent mathematical-programming and metaheuristic extensions catalogued by Furman and Sahinidis (2002).

Process Intensification seeks step-change gains in performance, smaller equipment and lower energy/material inventories by combining unit operations or exploiting more favourable driving forces (Stankiewicz & Moulijn, 2000), classified by the structure-energy-synergy-time framework according to whether they intensify the equipment or the process itself (Van Gerven & Stankiewicz, 2009); divided-wall columns and heat-pump-assisted distillation are commonly cited refining examples. Process integration and intensification are conceptually distinct — the former re-arranges existing flowsheet energy, the latter changes the equipment or process route — but complementary, and both are examined here. Commercial simulators such as Aspen HYSYS are widely used to generate the material/energy balances and preliminary sizing a pinch study requires, particularly for multi-component crude fractions where hand calculation of vapour-liquid equilibrium is impractical; sustainable refinery development links this energy efficiency directly to resource conservation and emissions reduction, since every unit of avoided fired-heater duty is a unit of crude-derived energy not burned to run the plant (El-Halwagi, 2011; Klemeš et al., 2013). Overall, what remains comparatively underexplored is the combination of these strands — HYSYS simulation, full PTA energy targeting, area targeting, and a stated network-synthesis/fabrication programme — on one physically realisable 50 BPD Nigerian platform; this study addresses that gap.

3.0 METHODOLOGY

3.1 Research Framework and Facility

The existing ABU Mini-Refinery, a 1 BPD ADU/VDU teaching and research facility in the Department of Chemical Engineering, ABU Zaria, served as the design basis for a scaled-up, energy-integrated replacement. The research framework proceeds sequentially from design-basis definition and process-option selection, through PFD development, manual-and-simulation material/energy balancing, base-versus-optimised case-study comparison, equipment sizing, energy-integration/HEN design, mechanical and P&ID drawing, and finally fabrication, installation, operating-procedure preparation and test-running. At the time of reporting, the sequence is complete as far as equipment sizing and pinch-based energy/area targeting; HEN synthesis, fabrication, installation, and test-running remain ongoing and are reported as such. The redesign retains the existing ADU-VDU configuration

with side strippers but re-establishes the crude preheat, distillation and heat-recovery scheme from first principles using simulation and pinch analysis.

3.2 Feedstock Characterisation

The design basis specifies a 50 BPD ADU capacity, an ambient temperature of 25°C, and an operating pressure of 760 mmHg. The blended crude comprises of Escravos characterised in Aspen HYSYS using the PIMS-based Escravos-2012 assay for West Africa/Nigeria, and Forcados crude characterised using the Forcados Blend-2014 assay. Evaluation of both assays indicates that Escravos is relatively lighter and sweeter, with an API gravity of 33.84° and sulphur content of 0.17 wt.%, whereas Forcados is slightly heavier, higher in sulphur content, and is more acidic, with an API gravity of 32.22°, sulphur content of 0.22 wt.%, and total acid number of 0.46 mg KOH/g, as shown in Table 1.

Table 1: Design Basis and Crude Oil Properties of the Blend (Escravos/Forcados Ratio 50:50)

Parameter	**Escravos**	**Forcados**	**Units**
Capacity of ADU	25	25	BPD
Ambient temperature	25	25	°C
Pressure	760	760	mmHg
API gravity	33.84	32.22	—
Standard liquid density	53.37	53.90	lb/ft³
Molecular weight	203.52	204.66	—
Sulphur content	0.17	0.22	wt.%
Pour point	16.38	18.27	°C
Watson K factor	11.57	11.38	—
Total acid number	0.24	0.46	mg KOH/g
Viscosity @ 37.78°C	4.44	4.02	cSt

3.3 Process Configuration

Five candidate configurations were screened at the process-selection stage (Table 2): a conventional ADU with preheat train and side strippers; a preflash-column configuration with heat integration; a divided-wall-column (DWC) ADU; a heat-pump-assisted ADU; and a hybrid combining preflash, DWC and heat integration. The flowsheet developed and simulated for the 50 BPD unit (Figure 1) retains a preflash drum ahead of the fired heater and a full set of pump-around loops, consistent with the preflash-with-heat-integration option identified in screening. It comprises crude feed and metering; wash-water mixing and desalting; a preflash stage; a top/middle/bottom pump-around preheat train; a fired heater; an atmospheric column with kerosene, diesel and AGO side strippers (each steam-reboiled); an overhead condenser and reflux drum; and product routing to naphtha, kerosene, diesel, AGO and atmospheric-residue storage. The atmospheric residue is processed in a VDU, with its own preheater and pump-around coolers, to recover light and heavy vacuum gas oil (LVGO, HVGO) and vacuum residue.

Table 2: Process Configuration Options Evaluated for the ABU Mini-Refinery ADU

Option	Configuration	Key features	Yield / quality	Environmental impact / advantages
1	Conventional ADU	Preheat train, furnace, side strippers	Moderate naphtha yield; standard quality	High CO2 from furnace; simple, low CAPEX
2	Preflash + heat integration	Preflash removes light ends before furnace, cutting furnace load	Improved naphtha yield; better fractionation	Lower energy/emissions; smaller furnace
3	DWC ADU	Single column, divided wall for kerosene/diesel	High yield, less reflux; sharper cuts	Lower energy; fewer columns; lower CAPEX/OPEX
4	Heat-pump-assisted ADU	Overhead vapour recompression recovers heat for reboilers	Similar yield; high purity	30–50% energy savings; best at low ambient temp.
5	Hybrid (preflash+DWC+HI)	Combines preflash, DWC and heat recovery	Highest yield; optimised, premium cuts	Lowest emissions, max recovery; higher complexity

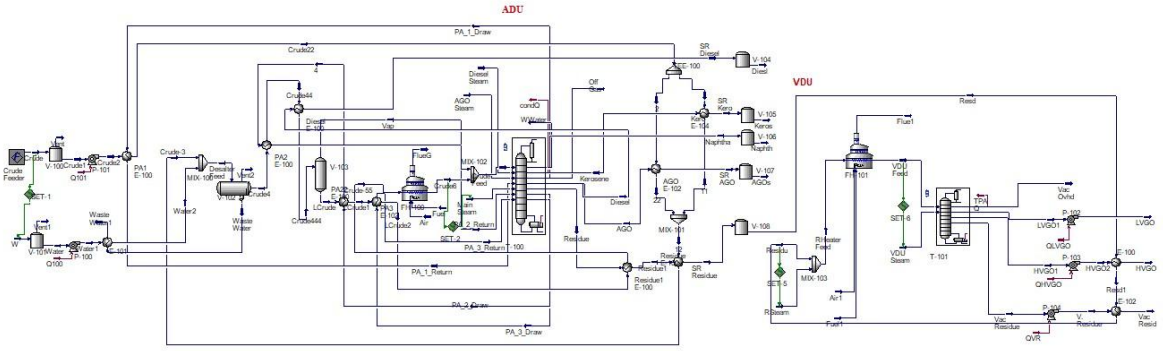

Figure 1: Detailed Developed Process Flow Diagram of the 50 BPD ABU Mini-Refinery ADU/VDU with Heat Exchanger Network

3.4 Simulation, Stream Identification and Pinch Procedure

The flowsheet was built and solved in Aspen HYSYS using the Peng-Robinson equation of state. The Escravos and Forcados assays were installed from the PIMS crude-oil databank and characterised into pseudo-components before introduction at 50 BPD; column specifications (draw rates, side-stripper steam rates, pump-around duties/return temperatures, reflux ratio, condenser temperature) were entered on the atmospheric column, and the flowsheet solved to convergence for a base case and an optimised case (the latter adjusting specifications to improve recovery). Material and energy balances were extracted for every major unit and mixing point. Process integration began with identifying, from the converged flowsheet, eight hot streams (top pump-around, naphtha, kerosene, mid pump-around, diesel, bottom pump-around, AGO, atmospheric residue) and four cold streams representing successive crude-preheat stages (pre-desalted, preflashed, pre-heated/furnace-feed, heated/furnace-outlet crude), plus steam and cooling-water utilities. Supply temperature, target temperature and heat-capacity flowrate (CP) were extracted or computed for each stream (Table 3).

Table 3: Pinch-Analysis Stream Data for the ADU/VDU Heat Integration Study

No.	Stream	Type	Ts (°C)	Tt (°C)	CP (kJ/°C·s)
1	Top pump-around	H1 (hot)	169	110	0.069
2	Naphtha	H2 (hot)	73	40	0.035
3	Kerosene	H3 (hot)	230	40	0.025
4	Mid pump-around	H4 (hot)	236	152	0.050
5	Diesel	H5 (hot)	250	50	0.048
6	Bottom pump-around	H6 (hot)	305	232	0.034
7	Atmospheric gas oil	H7 (hot)	294	50	0.014
8	Atmospheric residue	H8 (hot)	304	118	0.057
9	Pre-desalted crude	C1 (cold)	25	95	0.161
10	Preflashed crude	C2 (cold)	95	118	0.169
11	Pre-heated crude (furnace feed)	C3 (cold)	118	180	0.182
12	Heated crude (furnace outlet)	C4 (cold)	180	360	0.212
13	Steam	Hot utility	305	304	26.468
14	Cooling water	Cold utility	20	60	0.052

Pinch analysis was carried out by shifting each stream by half of the chosen ΔTmin and applying the PTA to the shifted temperatures for seven values spanning 10–40°C in 5°C increments; for each ΔTmin the shifted temperatures were recomputed, streams ranked into intervals, and an unconstrained-then-constrained enthalpy cascade constructed to obtain QHmin, QCmin and the pinch temperature. The full PTA computation is reported for the design case ΔTmin = 35°C, with targets for all seven ΔTmin values reported alongside it (Section 4). Area targeting for ΔTmin = 35°C used the balanced composite curve method: utility duties were added to the streams so the composite curves coincide at every interval, and area contributions computed from each interval's log-mean temperature difference and aggregate CP. Detailed stream-by-stream network matching by the Pinch Design Method is identified as pending, ongoing work. Intensification considerations were incorporated principally at process selection (Table 2), where DWC and heat-pump-assisted options were evaluated, and in the adopted flowsheet through the preflash stage (reducing downstream vapour load and equipment size) and pump-around loops (combining reflux control with preheat duty in-column rather than in additional external exchangers). Validation compared HYSYS material/energy balances against independent MathCAD manual calculations using the same assay, design basis and specifications, on a percentage-deviation basis (Section 4.10).

4.0 RESULTS

The Aspen HYSYS flowsheet (Figure 1) converged for both the base case and the optimised case, generating full material and energy balances across every mixing point, the desalter, fired heater, condenser, each side stripper and the overall atmospheric column. Representative and summarised results are reported below.

4.1 Material Balance

Table 4 summarises the overall material balance for the 50 BPD atmospheric column. Steam introduced to the column and side strippers totals 10.406 kg/h against a crude feed of 284.747 kg/h; the column produces wastewater (10.247 kg/h), off-gas (3.153 kg/h), naphtha (59.256 kg/h), kerosene (40.595 kg/h), diesel (77.397 kg/h), AGO (21.510 kg/h) and residue (82.994 kg/h), this indicates a differential of + 0.001 kg/h (0.00034%) which is attributed to rounding error closing at 295.153 kg/h inlet and 295.152 kg/h outlet, however, balances closed across the crude/wash-water mixing points, desalter, fired heater and each side stripper as shown in (Table 5), which confirmed an internal consistency.

Table 4: Overall Material Balance for the Designed 50 BPD Atmospheric Distillation Column

Component	**Inlet (kg/h)**	**Outlet (kg/h)**
Main steam	8.592	0.000
Diesel side-stripper steam	0.907	0.000
AGO side-stripper steam	0.907	0.000
Crude feed	284.747	0.000
Waste water	0.000	10.247
Off-gas	0.000	3.153
Naphtha	0.000	59.256
Kerosene	0.000	40.595
Diesel	0.000	77.397
AGO	0.000	21.510
Residue	0.000	82.994
Total	**295.153**	**295.152**

Table 5: Selected Unit Material Balances Across the ADU Flowsheet

Unit / component	**Inlet (kg/h)**	**Outlet (kg/h)**
MIX-100 – Water / Crude / Desalter feed	23.1 / 284.6 / –	– / – / 307.7
Desalter – Feed / Crude (desalted) / Waste water	307.7 / – / –	– / 284.7 / 23.0
Furnace – Crude in / Air / Fuel	284.7 / 108.0 / 5.3	–
Furnace – Crude out / Flue gas	–	284.7 / 113.3
Condenser – Feed	234.9	–
Condenser – Off-gas / Naphtha / Reflux / Waste water	–	3.2 / 59.3 / 162.2 / 10.3
Kerosene stripper – Draw / Boil-up	58.4 / 28.9	–
Kerosene stripper – Reboiler out / Return	–	69.5 / 17.8
Diesel stripper – Draw / Steam	88.7 / 0.9	–
Diesel stripper – Reboiler out / Return	–	77.4 / 12.2
AGO stripper – Draw / Steam	27.2 / 0.9	–
AGO stripper – Reboiler out / Return	–	21.5 / 6.6

4.2 Energy Balance

Table 6 reports the energy balance. The fired-heater/preheat-train duty on the crude side (CDU preheater) shows a net enthalpy gain of +157,981.85 kJ/h; the atmospheric condenser removes 120,912.86 kJ/h; and the three pump-around coolers remove 14,553.01, 15,166.55 and 8,942.28 kJ/h (top, middle, bottom). On the vacuum side, the VDU preheater gains 53,196.00 kJ/h, while its top and bottom pump-around coolers remove 16,784.74 and 19,472.53 kJ/h respectively.

Table 6: Energy Balance for the Designed ABU Mini-Refinery's ADU and VDU

Component	Input streams (kJ/h)	Output streams (kJ/h)	Duty (kJ/h)
CDU preheater	-521,249.43	-363,267.58	+157,981.85
ADU condenser	-509,500.73	-630,413.59	-120,912.86
Top-stage PA cooler	-197,367.83	-211,920.84	-14,553.01
Middle-stage PA cooler	-125,366.81	-140,533.36	-15,166.55
Bottom-stage PA cooler	-69,536.10	-78,478.38	-8,942.28
VDU preheater	-169,799.90	-116,603.90	+53,196.00
VDU top-stage PA cooler	-67,569.39	-84,354.14	-16,784.74
VDU bottom-stage PA cooler	-135,638.52	-155,111.05	-19,472.53

4.3 Product Yields

Table 7 compares base-case and optimised-case yields. Relative to base case, the optimised case increased naphtha yield 9.0% (11.000→11.994 BPD), kerosene 21.5% (6.000→7.291 BPD), diesel 2.2% (13.000→13.288 BPD), AGO fell 0.001% (3.559→3.558 BPD) which is an insignificant change, atmospheric residue fell 11.3% and vacuum residue fell 63.8% — a shift of material from low-value bottoms toward higher-value light/middle distillates. Off-gas and HVGO increased sharply in percentage terms (+86.5%, +285.5%) though both remain small absolute streams relative to the 50 BPD total.

Table 7: Product Yields — Base Case versus Optimised Case 50 BPD (Escravos/Forcados Blend Ratio 50:50)

Product	Base case (BPD)	Optimised case (BPD)	Variation (%)
Off-gas	1.691	3.153	+86.482
Naphtha	11.000	11.994	+9.040
Kerosene	6.000	7.291	+21.509
Diesel	13.000	13.288	+2.215
Atmospheric gas oil (AGO)	3.559	3.558	-0.001
Atmospheric residue	14.877	13.195	-11.306
Light vacuum gas oil (LVGO)	2.761	2.524	-8.584
Heavy vacuum gas oil (HVGO)	1.798	6.932	+285.540
Vacuum residue	10.300	3.731	-63.776

4.4 Equipment Sizing

Table 8 summarises sizing for the principal units, sized directly from converged HYSYS hydraulic and rating calculations. The column sections operate at 69–70% approach-to-flood in the sieve-tray sections and about 9% in the valve-tray section, with tray pressure drops of 1.1–4.0 kPa and vapour residence times of 22–35 s, indicating hydraulically stable operation with margin before flooding.

Table 8: Equipment Sizing Summary for the 50 BPD ABU Mini-Refinery ADU

Equipment	Key dimensions	Other parameters
Desalter	Diameter 1.252 m*; length 0.9146 m; head height 0.1636 m	Boot dia. 0.25 m; boot height 0.50 m; volume 0.3545m³
Preflash column	Diameter 0.6473 m; length 0.9710 m; elevation 0.50 m	Boot dia. 0.2158 m; boot height 0.3237 m; volume 0.3313m³
Furnace – tube bank	ID 0.089 m; OD 0.102 m; 20 tubes/pass	Inner area 21.23 m²; outer area 24.26 m²; net vol. 0.4718m³
Furnace – shell	ID 1.700 m; OD 2.000 m; zone height 4.280 m	Inner area 22.86 m²; outer area 26.89 m²; net vol. 9.0982m³
ADC section 1 (sieve)	Diameter 0.23 m; height 3.75 m	ΔP 4.045 kPa; 70.13% flood; 26.82 s residence; 26 holes
ADC section 2 (sieve)	Diameter 0.23 m; height 2.76 m	ΔP 1.595 kPa; 69.91% flood; 35.3 s residence; 50 holes
ADC section 3 (ballast valve)	Diameter 0.23 m; height 0.69 m	ΔP 1.075 kPa; 9.21% flood; 21.67 s residence

4.5 Pinch Analysis Results

Table 9 reports the detailed PTA cascade for the design case ΔTmin = 35°C. Working down the shifted-temperature intervals, the unconstrained cascade (Cascade I) reaches its most negative value of -26.468 kJ/s at the interval bounded by 212.5°C; adding this quantity of hot utility at the top produces the constrained cascade (Cascade II), which first reaches zero at that same interval — identifying 212.5°C as the pinch on the shifted scale, corresponding to an actual hot-stream pinch of 230°C and cold-stream pinch of 195°C.

Table 9: Problem Table Algorithm Cascade for ΔTmin = 35°C

Int.	Temp. Profile (°C)	Streams Population	ΔT °C	ΣCPH	ΣCPC	Q (kJ/s)	Cascade I u = 0.000	Cascade II u = 26.468

*PINCH POINT

4.6 Energy Targets Across ΔTmin

Table 10 summarises pinch-analysis energy targets for seven ΔTmin values. As ΔTmin rises from 10°C to 40°C, QHmin rises from 24.44 to 27.44 kJ/s and QCmin from effectively zero to 3.04 kJ/s, while the pinch condition moves from a threshold-problem at ΔTmin = 15°C (overall heat surplus; in principle only one utility required) to a working pinch of 212.5°C (shifted) at ΔTmin = 35°C. This is in conformity with the literature that utilities requirement increases as the approach temperature widens further. For the design case (ΔTmin = 35°C), confirmed targets are QHmin = 26.47 kJ/s and QCmin = 2.07 kJ/s.

Table 10: Summary of Energy Targets and Pinch Points for ΔTmin = 10–40°C

ΔTmin (°C)	QHmin (kJ/s)	QCmin (kJ/s)	Pinch (shifted, °C)	Hot pinch (°C)	Cold pinch (°C)
10.0	24.44	0.00	TP	TP	TP
15.0	23.45	0.00	TP	TP	TP
20.0	24.70	0.30	40.0	50.0	30.0
25.0	25.00	0.60	60.5	73.0	48.0
30.0	25.61	1.21	58.0	73.0	43.0
35.0	26.47	2.07	212.5	230.0	195.0
40.0	27.44	3.04	210.0	230.0	190.0

*TP - Threshold Problem

4.7 Heat Exchanger Area Requirements

Detailed stream-by-stream HEN matching by the Pinch Design Method has not yet been completed; this remains pending, alongside fabrication, installation, operating-procedure preparation and test-running of the energy-integrated unit. Table 11 reports the interval-by-interval log-mean-temperature-difference and area computation for the balanced composite curves at ΔTmin = 35°C. Summing the eighteen interval area contributions gives a minimum HEN area target of 8.86 m² for the redesigned 50 BPD ADU heat-recovery system — an early, network-independent estimate usable for preliminary capital-cost screening ahead of detailed exchanger design.

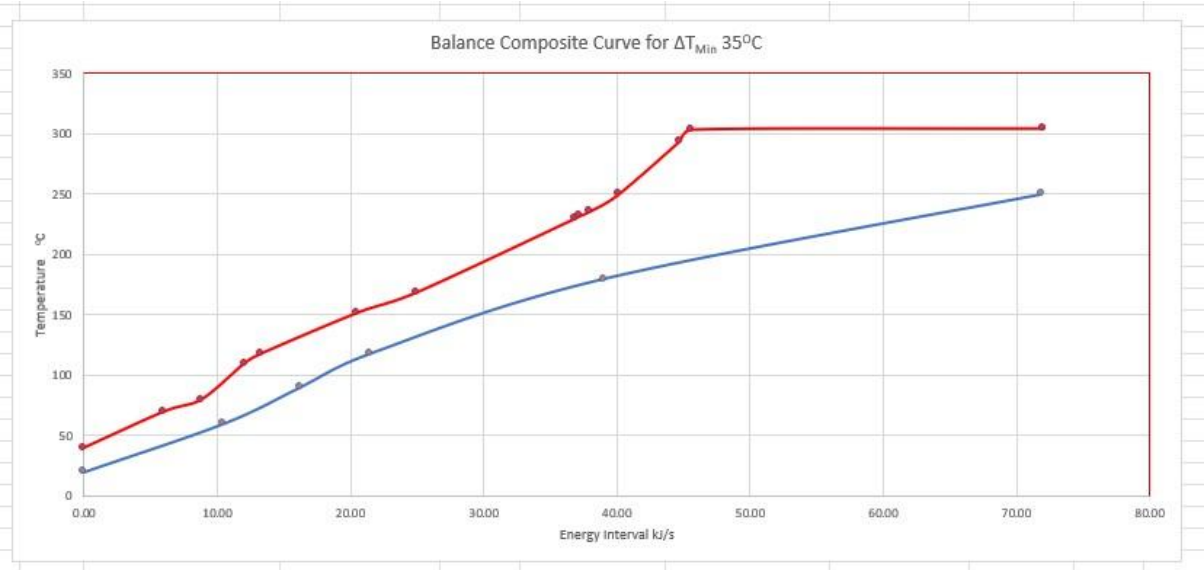

Figure 2: Balanced Composite Curve Graph for the ADU/VDU Heat Integration Study (ΔTmin = 35°C)

Table 11: Balanced Composite Curve Area-Targeting for (ΔTmin = 35°C). Total heat-exchanger area target = 8.86 m²

Int.	Thi(°C)	Tci(°C)	ΣCPH/h	ΣCPC/h	ΣQ/h,i(kJ/s)	LMTD(°C)	Area(m²)

4.8 Validation of HYSYS and Manual Calculations

Table 12 compares HYSYS-simulated and manually calculated (MathCAD) product yields, and Table 13 the corresponding heat-exchanger duties. Yield deviations range from -3.12% (LVGO) to +1.17% (diesel), and duty deviations from -3.27% (condenser) to +5.32% (ADU preheater); all deviations lie within approximately ±5.3%. This level of agreement supports the internal consistency of the HYSYS flowsheet and its manual cross-check, giving confidence in the stream data subsequently used for pinch analysis.

Table 12: Validation of Product Yields — Aspen HYSYS versus Manual (MathCAD) Calculation

Product	HYSYS yield (BPD)	Manual yield (BPD)	Deviation (%)
Off-gas	1.691	1.723	-1.86
Naphtha	11.000	11.200	-1.79
Kerosene	6.000	6.150	-2.44
Diesel	13.000	12.850	+1.17
Atmospheric gas oil (AGO)	3.559	3.600	-1.14
Atmospheric residue	14.877	15.000	-0.82
Light vacuum gas oil (LVGO)	2.761	2.850	-3.12
Heavy vacuum gas oil (HVGO)	1.798	1.780	+1.01
Vacuum residue	10.300	10.500	-1.90

Table 13: Validation of Heat Exchanger Duties — Aspen HYSYS versus Manual (MathCAD) Calculation

Component	HYSYS duty (kJ/h)	Manual duty (kJ/h)	Deviation (%)
CDU preheater	+157,981.85	+150,000	+5.32
ADU condenser	-120,912.86	-125,000	-3.27
Top-stage PA cooler	-14,553.01	-14,000	+3.95
Middle-stage PA cooler	-15,166.55	-14,500	+4.59
Bottom-stage PA cooler	-8,942.28	-9,000	-0.64
VDU preheater	+53,196.00	+52,000	+2.30
VDU top-stage PA cooler	-16,784.74	-17,000	-1.27
VDU bottom-stage PA cooler	-19,472.53	-20,000	-2.64

5.0 DISCUSSION

The Problem Table results show the redesigned 50 BPD unit has a genuine, quantifiable minimum energy requirement: at the design ΔTmin of 35°C, only 26.47 kJ/s of hot utility and 2.07 kJ/s of cold utility are thermodynamically necessary to satisfy all process heating and cooling simultaneously. Because these figures come directly from validated HYSYS stream data, they are a reasonably reliable lower bound against which any HEN eventually installed — including the existing, non-pinch-designed 1 BPD network — can be benchmarked once scaled and re-commissioned. The pinch-point behaviour across ΔTmin = 10–40°C is informative in its own right: at the tightest approach temperatures (10°C and 15°C) the process behaves as a threshold problem, in overall heat surplus with, in principle, only one utility required; as ΔTmin widens, a genuine pinch emerges and both targets increase, since a larger ΔTmin always trades reduced exchanger area for increased utility consumption. The working pinch at a shifted 212.5°C (actual hot/cold pinch 230°C/195°C) at ΔTmin = 35°C sits high in the column's temperature range, near the bottom pump-around and atmospheric-residue streams, indicating the highest-temperature hot streams and the furnace-outlet cold stream sit thermally close together, leaving little scope for further preheat recovery above this point without intensifying that match or accepting additional furnace duty.

Although the detailed exchanger network has not yet been synthesised, the area target of 8.86 m² gives an early indication that the heat-recovery surface required to approach the energy targets is modest, consistent with the small absolute duties at 50 BPD — useful for planning the forthcoming network-design and fabrication stage, since it suggests the redesigned network need not be large or capital-intensive, provided matches are selected per the pinch-design feasibility rules (Section 2).

Process intensification is reflected primarily at the process-selection stage, where DWC and heat-pump-assisted configurations were evaluated as more compact or less utility-intensive alternatives, and in the retention of a preflash stage and multiple pump-around loops in the developed flowsheet, reducing the duty (and hence size) that would otherwise fall on the fired heater and on separate external exchangers; the compact equipment sizing obtained (column diameters ~0.23 m, section heights under 4 m) is itself evidence of successful scale intensification relative to a conventional refinery train, even though a full DWC or heat-pump-assisted column was not carried into the final flowsheet.

The case-study comparison shows the optimised case recovers materially more kerosene and naphtha, and less low-value residue, from the same blended crude feed — significant for a 50 BPD unit supplying a local market, since it improves the revenue mix per barrel processed without altering crude feed rate, directly supporting the value-addition objective motivating modular refining in Nigeria. The study's validated deviations (~±5.3%) are consistent with the general expectation that independently cross-checked balances for well-characterised hydrocarbon systems agree closely and compare favourably with the agreement reported in the Kaduna FCC pinch study (Abubakar, 2020). Whereas earlier Nigerian modular-refinery studies have tended to report design parameters and yields without a full PTA exercise (Olatona, 2022), the present study extends that literature by carrying a validated HYSYS model through explicit pinch-analysis targeting across a range of ΔTmin values — comparatively underrepresented for mini-refineries at this scale.

For Nigerian modular refinery development, the practical implication is that pinch-based energy targeting is achievable and worthwhile even at 50 BPD, not reserved for large conventional refineries: an operator able to specify a HEN designed against an explicit QHmin/QCmin target, rather than an ad hoc exchanger arrangement, stands to reduce fired-heater and cooling-utility demand, reducing dependence on imported fuel or diesel firing on site, strengthening the local-content case for indigenous engineering design, and supporting value addition to Nigerian crude closer to the point of production. Every kilojoule of hot-utility duty avoided is, in effect, a kilojoule of crude-derived fuel the mini-refinery need not burn to heat itself, with corresponding reductions in flue-gas emissions and in the fraction of processed crude consumed as fuel rather than converted to marketable product; at 50 BPD this reduction is small in absolute terms, but the methodology is directly transferable to the larger population of modular refineries (hundreds to low thousands of BPD) now being licensed across Nigeria, where the cumulative effect of routine pinch-based targeting could be considerably more significant.

Several limitations should be acknowledged. First, the energy and area targets rest on a steady-state HYSYS simulation and manual cross-check that have not been confirmed against physical plant data, since the energy-integrated unit has not yet been fabricated, installed or test-run. Second, pinch analysis and area targeting were carried out in full detail for a single ΔTmin (35°C), with the remaining values reported only at the target-summary level; a fuller utility-cost/exchanger-area economic trade-off across all seven ΔTmin values remains to be completed. Third, crude oils characterisation relies on a PIMS-based Escravos and Forcados assays rather than a laboratory assay of a specific delivered batch, so batch-to-batch variability is not captured. Finally, the heat-exchanger network itself, together with its fabrication and commissioning, remains pending, so the as-built performance of the redesigned ABU Mini-Refinery cannot yet be reported.

6.0 ENGINEERING INNOVATION AND CONTRIBUTION

The engineering innovation lies less in any single novel unit operation than in the systematic combination, on a physically realisable 50 BPD Nigerian modular refinery, of validated Aspen HYSYS simulation, a full Problem Table Algorithm exercise across a realistic range of ΔTmin, and balanced-composite-curve area targeting, carried out for an identified indigenous blended crude oils (Escravos and Forcados) rather than a generic feedstock. The process-integration innovation is the explicit establishment of quantified hot- and cold-utility targets (26.47 and 2.07 kJ/s at ΔTmin = 35°C) and a heat-exchanger area target (8.86 m²) at a scale where such targeting is comparatively rare in the accessible literature, providing a concrete benchmark for the forthcoming HEN design. The intensification dimension — evaluating DWC and heat-pump-assisted alternatives at process selection and retaining a preflash stage and pump-around-integrated preheat in the adopted flowsheet — keeps equipment count and size close to what a modular, skid-mountable refinery can accommodate. Applied to blend of Escravos and Forcados crude on a unit intended for local fabrication and operation, the work shows, with real numbers rather than generic claims, how a small, locally built refining unit can be designed against the same thermodynamic rigour used in large, conventional plants, so growth in local refining capacity need not come at the cost of avoidable energy waste.

7.0 CONCLUSION

This study sets out to design, simulate, and energy-integrate a 50 BPD ABU mini-refinery ADU processing blended Escravos and Forcados crude in the ratio 50:50, and to establish how process integration and intensification could be embedded in that design. A validated Aspen HYSYS flowsheet cross-checked against independent manual calculation to within approximately ±5.3%, provided the material and energy balance basis. Pinch analysis via the Problem Table Algorithm across ΔTmin = 10–40°C established minimum hot- and cold-utility targets of 26.47 and 2.07 kJ/s at the design condition (ΔTmin = 35°C), a pinch temperature of 212.5°C on the shifted scale, and a minimum heat-exchanger area target of 8.86 m² by the balanced composite curve method. A base-versus-optimised case-study comparison showed the redesigned unit can recover more kerosene and naphtha, and less low-value residue, from the same blended crude feed. These results confirm that systematic energy targeting, not previously applied to the ABU Mini-Refinery's existing 1 BPD network, is feasible and worthwhile at modular scale, and provides the quantified basis on which the unit's heat-exchanger

network can now be synthesised. Network design, fabrication, installation, and test-running remain ongoing, and their completion is the natural next step. The study demonstrates that energy efficiency and modular-scale refining are not competing objectives, and that process integration and intensification can, and should, be designed into modular refineries from the outset.

8.0 RECOMMENDATIONS

Arising directly from this study: the heat-exchanger network for the 50 BPD ABU mini-refinery ADU should be synthesised using the Pinch Design Method, matching hot and cold streams above and below the established pinch per the feasibility rules in Section 2; the resulting network should be checked against the 8.86 m² area target established here; and the ΔTmin values not yet analysed in full detail (10, 15, 20, 25, 30 and 40°C) should be carried through the same area-targeting procedure used for 35°C, so an economically optimum ΔTmin can be selected before final network design. For future research beyond the present scope: the synthesised network should be fabricated, installed and test-run, with measured performance compared against the targets reported here; a techno-economic evaluation covering capital cost, utility savings and payback should be conducted once network design is complete; an environmental assessment should quantify the emission reduction associated with the lower fired-heater duty implied by the pinch targets; intensification options such as a divided-wall column or heat-pump-assisted distillation, evaluated only at screening stage here, should be investigated in more design detail; and crude oils characterisation should be extended to laboratory assay data for specific delivered Escravos and Forcados crude batches.

9.0 CONFERENCE THEME ALIGNMENT

This study responds directly to the conference theme, "Innovating Tomorrow: Harnessing Engineering to Drive Nigerian Growth for Sustainable Development," by applying rigorous, internationally established process-integration and process-intensification methods to an indigenous Nigerian crude on a Nigerian university-based modular refining platform. In relation to SDG 7 (Affordable and Clean Energy), the pinch-based utility targets point toward a redesigned refinery drawing less fired-heater and cooling-utility duty per barrel than an unintegrated equivalent. In relation to SDG 9 (Industry, Innovation, and Infrastructure), the work builds indigenous simulation, pinch-analysis, and equipment-design capability around the ABU Mini-Refinery, deliberately scaled up as a demonstration and training platform. In relation to SDG 12 (Responsible Consumption and Production), improved recovery of higher-value light and middle distillates from the same blended Escravos and Forcados crude feed represents fuller use of the resource extracted. In relation to SDG 13 (Climate Action), a validated reduction in fired-heater duty would be expected to reduce associated combustion emissions per barrel processed, although this study establishes the energy targets that would enable such a reduction rather than measured emissions data, and the claim is framed as a plausible, targets-based implication rather than a demonstrated outcome.

ABSTRACT

Groundwater is the primary water source for over 60 % of Nigerians, but uncontrolled urban pollution infiltrates and contaminates the aquifer. Groundwater samples for the current study were collected from Iwo Local Government Area to investigate groundwater resources and generate spatial water-quality variation maps across seasons. The groundwater samples were chosen to represent the entire study area's built-up portion adequately. The physico-chemical parameters were measured during rainy and dry seasons. Parameters analysed were temperature, turbidity, pH, electrical conductivity, total suspended solids, total dissolved solids, total alkalinity, total hardness, chloride, sulphate, nitrate, phosphate, magnesium, total coliform, and calcium. The simple kriging interpolation method was used to generate groundwater quality maps for the selected groundwater quality parameters. The water quality data were linked to the sampling location (spatial) in ArcGIS, and maps were generated to show spatial distribution. Although most of the water quality parameters median range values of the various groundwater resources were satisfactory throughout the seasons, total hardness of 228.3 mg/l – 596.6 mg/l, calcium of 16 mg/l - 236.8 mg/l, sulphate of 219 mg/l – 354 mg/l, and phosphate of 0.30 mg/l – 3.42 mg/l were the groundwater quality parameters with spatial variations over the World Health Organisation standard values of 150 mg/l, 75 mg/l, 250 mg/l, and 0.05 mg/l respectively, for both rainy and dry seasons. It is suggested that all sources be monitored regularly and that treatments to improve total hardness be implemented.

1. INTRODUCTION

Increasing attempts for a better living level include reinstating a sufficient supply of drinkable water (United Nations Environment Programme, 2011). According to Abel and Adebayo (2017), water quality is defined as the physical, chemical, and microbiological attributes of water, which are evaluated by comparing concentrations of water quality measures to acceptable levels. Water of high quality has been defined as that supplied by waterworks and groundwater (Yan *et al.*, 2022; Kløve *et al.*, 2017).

However, the lack of high-quality surface water has increased groundwater consumption due to fast industrialisation and population growth (Ezechinyere and Stanislaus, 2023; Nas, 2009). Recently, many parts of the world, particularly Nigeria, have seen a decline in both the quantity and quality of groundwater sources (Adetona and Oladepo, 2021; Mahapatra *et al.*, 2012). These studies have used a water quality index to identify specific contaminated groundwater sources, without considering spatial kriging mapping for unsampled regions. Atobatele *et al.* (2026) have reported toxic heavy metal parameters in Iwo Local Government Area. While studies have reported microbial contamination in some of these groundwater sources in Nigeria (Izah *et al.*, 2022).

Some of the reported groundwater sources were close to contamination sources such as septic tanks and refuse dumpsites. Due to a lack of enough land space, septic tanks were mainly placed very close to groundwater sources. Insufficient sanitary landfills also caused refuse dumpsites to be commonly located near undeveloped land or foundations (Olayinka *et al.*, 2025). Abel and Adebayo (2017) stated that awkward and unsystematic waste discharged into the environment had increased the rate of sickness from groundwater.

Groundwater quality studies conducted in the Iwo Local Government Area demonstrated the need for regular groundwater quality assessments. Olutona *et al.* (2012) proposed that the physicochemical and microbiological analyses of groundwater in the Iwo Local Government Area be assessed regularly. The regular evaluation will aid in the early detection of any potential future degradation. Ogunbode and Ifabiyi (2014) also recommended that more research be done on the water quality in the Iwo Local Government Area. At the regional level, enough research has been done on the drinking and irrigation aspects of groundwater. On the other hand, little research has been done on groundwater quality assessment in the Iwo Local Government Area of Southwestern Nigeria. It is, therefore, essential to take representative samples according to the political wards in Iwo Local Government Area and evaluate the spatial distribution of groundwater quality from those sampled locations across the Iwo Local Government Area.

A more comprehensive diagnosis of the current state of contamination and close monitoring of its evolution is critical for preserving this resource. The fundamental goal of a monitoring programme is to collect and analyse a large number of groundwater samples in order to assess spatial changes (Ahmed, 2017). As a result, geographical monitoring of groundwater quality parameters is crucial, which is why this research was carried out. The present study aims to assess the spatial variations of groundwater quality parameters in Iwo Local Government Area, Osun State, Southwestern Nigeria. It's critical to understand the nature and chemistry of groundwater fluctuations because of natural and anthropogenic processes (Richardson *et al.,* 2024).

2. METHODOLOGY

2.1 Description of the Study Area

Iwo is one of the local government areas of Osun State, Nigeria. It is 245 km^2 in size. It is grouped according to local government clusters, namely: Isale Oba, Molete, Oke Adan, Gidigbo, and Oke Oba. These were subdivided further into the established 15 political wards. Rural, agricultural, and urban areas are all covered by the local government. Iwo town is formed by the urban region, located between Latitude $07^{o}38'$ N to $07^{0}40'$ N and Longitude $004^{0}09'$ E to $004^{o}11'$ E.

The Aiba water reservoir, which is located within a government forest reservation area in Iwo, is the town's principal source of drinkable water. Unfortunately, poor management and a rise in the area's population have resulted in an insufficient supply of drinkable water from the waterworks. The town's subsurface water sources were exploited as a result of this.

2.2 Climatic Setting

In the southern area of Nigeria, yearly rainfall ranges from 150 to 300 cm. Mean maximum ambient temperatures range from 33.84 ^{o}C in February to 28.8 ^{o}C in August, with mean minimum temperatures ranging from 25.18 ^{o}C in March to 23.0 ^{o}C in August.

2.3 Experimental Setup and Methods

Water samples were collected from 30 different locations and sources as detailed in Table 1. The population that relies on groundwater for drinking was the focus of the sampling. Groundwater sources were stratified and located at random using hand-held Global Positioning System (GPS) technology. In urban areas, most wells were lined; however, in rural regions, wells were unlined and operated by hand pumps. A hand-held GPS was used to record the location of each well.

The sampling was done twice, first during the rainy season (October) and again during the dry season (January). Samples were collected during these representative months of the two seasons, which were later periods of the two seasons, so that the samples could be a true representation of the seasons. There was a lot of rain during October and November, and the month of January was extremely cold. The samples were pulled from shallow wells with a plastic bucket and gathered from the taps of hand pump wells and boreholes.

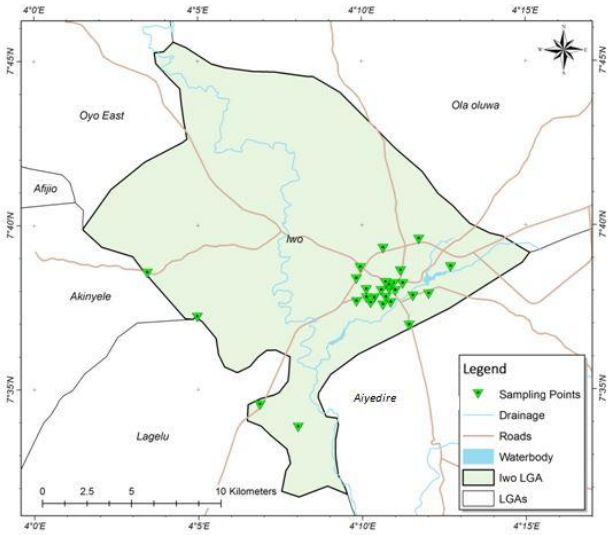

Figure 1: *Study Area Map*

Some experimental values were obtained on the spot, while others were obtained in the lab using three replicates and standard procedures. Before sampling, all glassware and sample bottles were cleansed with liquid detergents and rinsed with distilled water. To minimise confusion, the plastic bottles used for sampling were labelled according to political wards and then rinsed three times on-site with the groundwater being sampled. A two-litre water sample was obtained for physical and chemical characteristics, while a small, autoclaved glassware sample was collected for microbiological investigation. Before analysis, the samples were kept in the refrigerator for 5 hours (Jeje and Oladepo, 2014b). This was done to keep the physical, chemical, and microbiological qualities intact.

Table 1: *Locations of Selected Hand Pump Boreholes, Boreholes, and Shallow Wells Within the Study Area*

S/N	Political ward	Location	Type of well	Depth (m)
1	Isale Oba Ward 01	Oke–Ola	Motorized Borehole	45

Note: Hand pump boreholes were inaccessible for the measurement of depth.

The physical, chemical, and microbiological parameters such as temperature, turbidity, pH, electrical conductivity, total suspended solids, total dissolved solids, total alkalinity, total hardness, chloride, sulphate, nitrate, phosphate, magnesium, calcium, and total coliform were determined for the

collected water samples. All tests were conducted in line with research carried out by Olutona *et al.* (2012) and Ogunbode and Ifabiyi (2014).

With the help of a pH metre, a thermometer, and a platinum electrode conductivity metre, water samples were evaluated for hydrogen ion concentration (pH), temperature, and electrical conductivity (EC). A total dissolved solids meter was used to calculate the total dissolved solids (TDS). Titrimetric determination of chloride (Cl-) was performed using standard silver nitrate titration. The phosphate content (PO_4^{3-}) of the water samples was evaluated using a colourimetric technique after digestion with concentrated sulfuric acid. The turbidimetric method with a spectrophotometer was used to determine the sulphate (SO_4^{2-}). The standard Ethylene Diamine Tetra Acid (EDTA) titration method was used to determine the hardness (TH), which was buffered at pH 10. The amount of calcium (Ca) in water hardness was determined using the complexometric titration method, which involved titrating the water sample with a known concentration and volume of EDTA.

The difference between total and calcium hardness, reported as $CaCO_3$ equivalent, was used to calculate the presence of magnesium (Mg). Using phenolphthalein and mixed indicators, the total alkalinity (T. Al.) of the water samples was evaluated by titrating 100 mL of the samples with 0.2 N sulfuric acid solution. Total suspended solids (TSS) were determined using gravimetric measurement involving heating the sample in an oven, followed by cooling in a desiccator. An electronic turbidimeter with scattered-light detectors was used for turbidity (Turb.) measurement. Nitrate (NO_3^-) was determined by the colourimeter method using a UV-VIS spectrophotometer. The membrane filtration method was used to get total coliform (TCC) in the water samples (microbiological analysis). The simple kriging method of interpolation was used to determine the groundwater quality of unsampled regions of Iwo Local Government Area.

2.4 Spatial Variation Assessment

The simple kriging method was used to generate groundwater quality maps for the selected groundwater quality parameters. The water quality data were linked to the sampling location (spatial) in ArcGIS, and maps showing spatial distribution were prepared to easily identify the variation in concentrations of the groundwater parameters at various study area locations. Spatial variation was evaluated using Simple Kriging (SK), which assumes a known stationary mean (μ) across the study area. Experimental semivariograms were computed to quantify spatial continuity using the isotropic semivariance equation:

$$\gamma(h) = \frac{1}{2N(h)} \sum_{i=1}^{N(h)} [Z(x_i) - Z(x_i+h)]^2 \quad (1)$$

where;
$\gamma(h)$ is the semivariance at lag distance h,
N(h) is the number of paired measurement points separated by distance h, and
$Z(x_i)$ and $Z(x_i + h)$ represent parameter values at spatial locations x_i and $x_i + h$.

The Simple Kriging estimator was defined as:

$$Z^*(x_0) = \mu + \sum_{i=1}^{n} \lambda i \, [Z(x_i) - \mu] \quad (2)$$

Where;
$Z^*(x_0)$ is the estimated value at unsampled location x_0,
μ is the stationary sample mean,
n is the number of neighbouring observations, and
λi are the kriging weights derived from the covariance matrix.

Empirical semivariograms were fitted against theoretical models (Spherical, Exponential, and Gaussian) using non-linear least squares. The optimal model was selected based on minimizing the mean squared error. Geostatistical parameters nugget variance (C_0), structural variance (C), total sill ($C_0 + C$), and spatial range (a) were extracted. The spatial dependence ratio ($[C_0 / (C_0 + C)] \times 100$) was calculated to classify spatial autocorrelation as strong (<25%), moderate (25%–75%), or weak (>75%). Model performance and interpolation reliability were validated using Leave-One-Out Cross-Validation

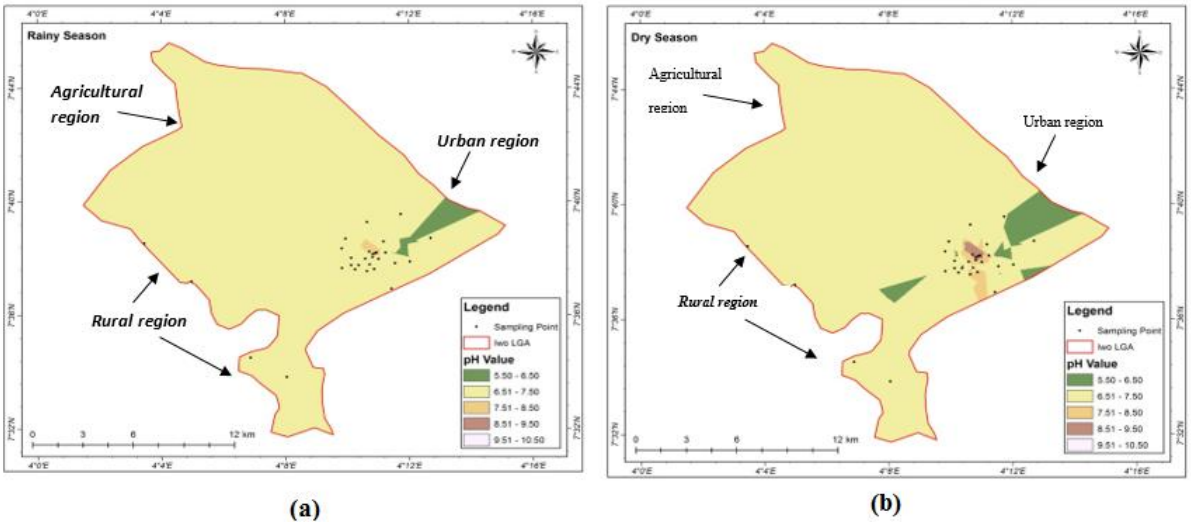
(LOOCV). Interpolation accuracy was evaluated using Root Mean Square Error (RMSE), Mean Absolute Error (MAE), and the coefficient of determination (R^2). The ArcGIS software automatically executed all of these mathematical steps in the background while using the Simple Kriging interpolation. The environmental maps prepared from the water quality test results gave the groundwater quality characteristics of the Iwo Local Government Area.

3. RESULTS AND DISCUSSION

The deployment of geostatistical simple kriging interpolation in Iwo mirrors recent findings by studies in the Ibadan Metropolis, where Kriging and factor analysis were integrated to model groundwater variability (Thomas, 2023). Simple kriging was used consistently for all parameter maps.

3.1 pH

The five colours denoting the spatial variation of hydrogen ion concentration (pH) during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 5.5 and 6.5, 6.51 and 7.5, 7.51 and 8.5, 8.51 and 9.5, and 9.51 and 10.5, respectively, as shown in Figure 2a and b.



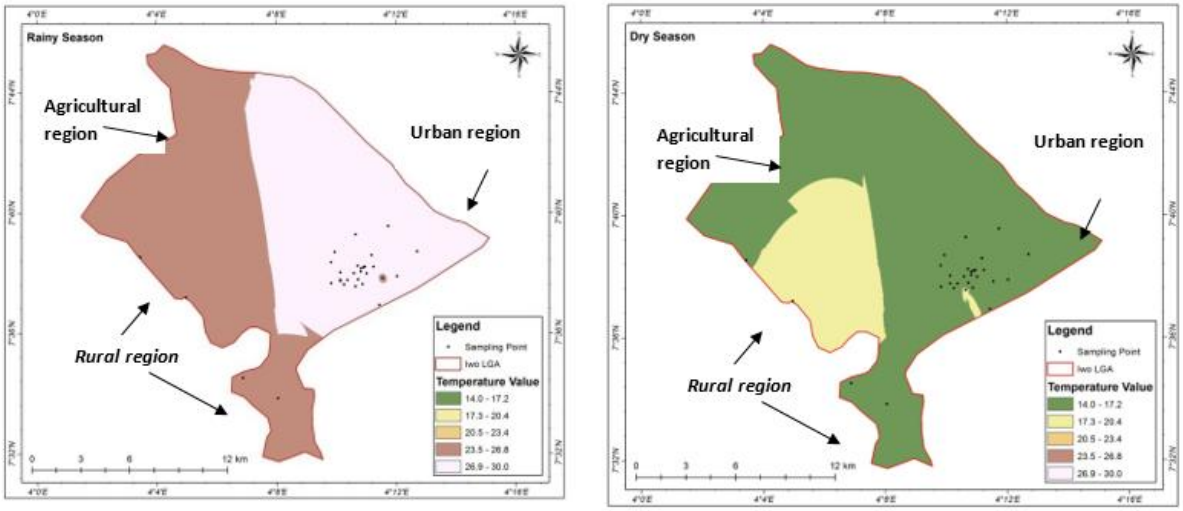


Figure 2: *Spatial Variation of Hydrogen Ion Concentration (a) Rainy Season (b) Dry Season*

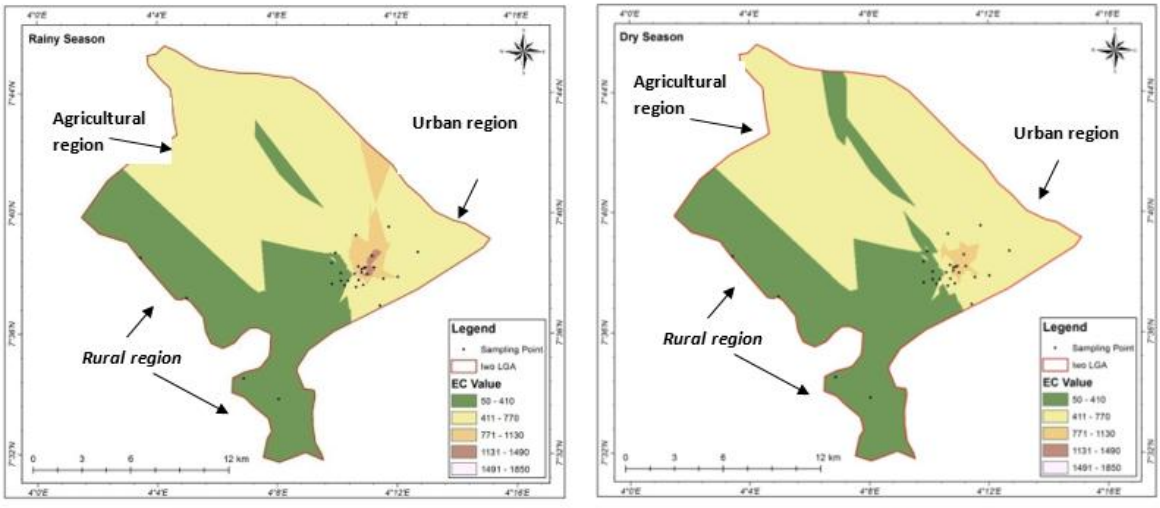
The yellow and orange colours of the spatial variation correlated with the pH range standard values of 6.5 and 8.5. In Figure 2a, the yellow colour occurred mainly. This denoted that the groundwater pH of the study area was acceptable. However, some north-eastern parts of the study area were acidic, having a pH value less than 6.5. In Figure 2b, the yellow colour occurred around the rural and agricultural regions of the study area. These rural and agricultural regions included the last two political wards of Oke Oba Ward 14 and Oke Oba Ward 15. This denoted that the hydrogen ion concentrations of these regions' groundwater were acceptable. However, it increased from the rainy season to the dry season primarily due to extended water-rock interaction times during the dry season (Zhang *et al.*, 2023; Subba Rao, 2005).

3.2 Temperature

The five colours denoting the spatial variation of temperature during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 14.0 ^{o}C and 17.2 ^{o}C, 17.3 ^{o}C and 20.4 ^{o}C, 20.5 ^{o}C and 23.4 ^{o}C, 23.5 ^{o}C and 26.8 ^{o}C, and 26.9 ^{o}C and 30.5 ^{o}C, respectively, as shown in Figure 3 a and b.



(a) **(b)**

Figure 3: *Spatial Variation of Temperature Concentration (a) Rainy Season (b) Dry Season*

The green, yellow, and orange colours of the spatial variation correlated with the temperature standard value (< 25 ^{o}C). In Figure 3a, the brown colour occurred mainly around the rural and agricultural region of the study area, which varied from 23.5 ^{o}C and 26.8 ^{o}C. This denoted that the groundwater temperatures of these regions were still acceptable, which is slightly above 25 ^{o}C.

3.3 Electrical Conductivity

The five colours denoting the spatial variation of electrical conductivity during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 50 µS/cm and 410 µS/cm, 411 µS/cm and 770 µS/cm, 771 µS/cm and 1130 µS/cm, 1131 µS/cm and 1490 µS/cm, and 1491 µS/cm and 1850 µS/cm, respectively, as shown in Figures 4a and b.

(a) **(b)**

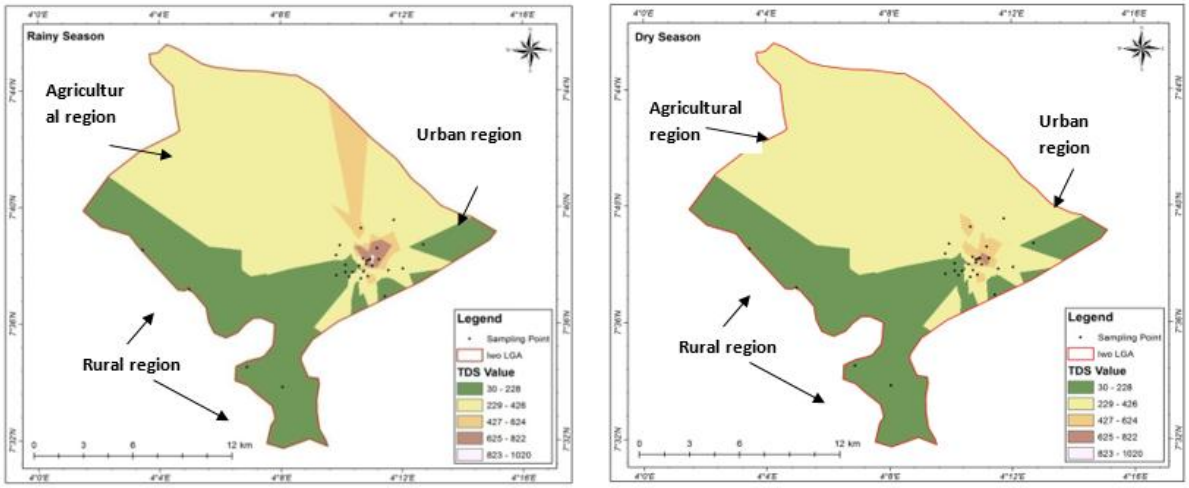


Figure 4: *Spatial Variation of Electrical Conductivity Concentration (a) Rainy Season (b) Dry Season*

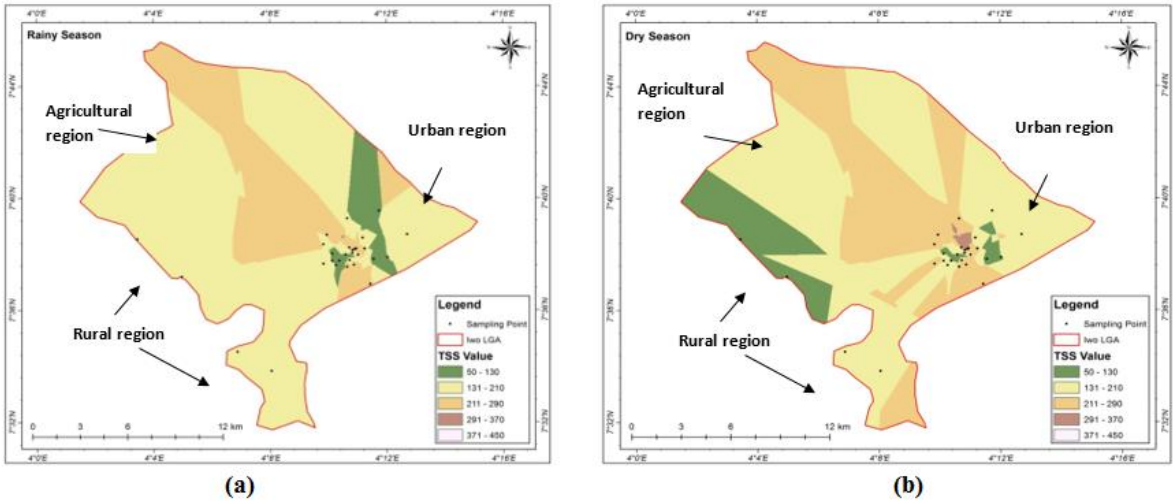
The green, yellow, and orange colours of the spatial variation correlated with the standard value of electrical conductivity, which was less than 1000 µS/cm. In Figure 4a, the green colour occurred mainly around the rural region and some parts of the agricultural and urban regions, which varied from 50 µS/cm and 410 µS/cm. The other urban region displayed yellow and orange colours. These denoted that the groundwater electrical conductivity of these regions was acceptable, which were majorly below 1000 µS/cm.

3.4 Total Dissolved Solids

The five colours denoting the spatial variation of total dissolved solids during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 30 mg/l and 228 mg/l, 229 mg/l and 426 mg/l, 427 mg/l and 624 mg/l, 625 mg/l and 822 mg/l, and 823 mg/l and 1020 mg/l, respectively as shown in Figure 5 a and b.

The spatial variations in green, yellow, and orange colours were within the permissible limit of total dissolved solids (500 mg/l). The green, yellow, and orange colours occurred mainly around the study area in both figures. This denoted that the total dissolved solids of the groundwater around these regions were acceptable, as they were mainly below 500 mg/l.

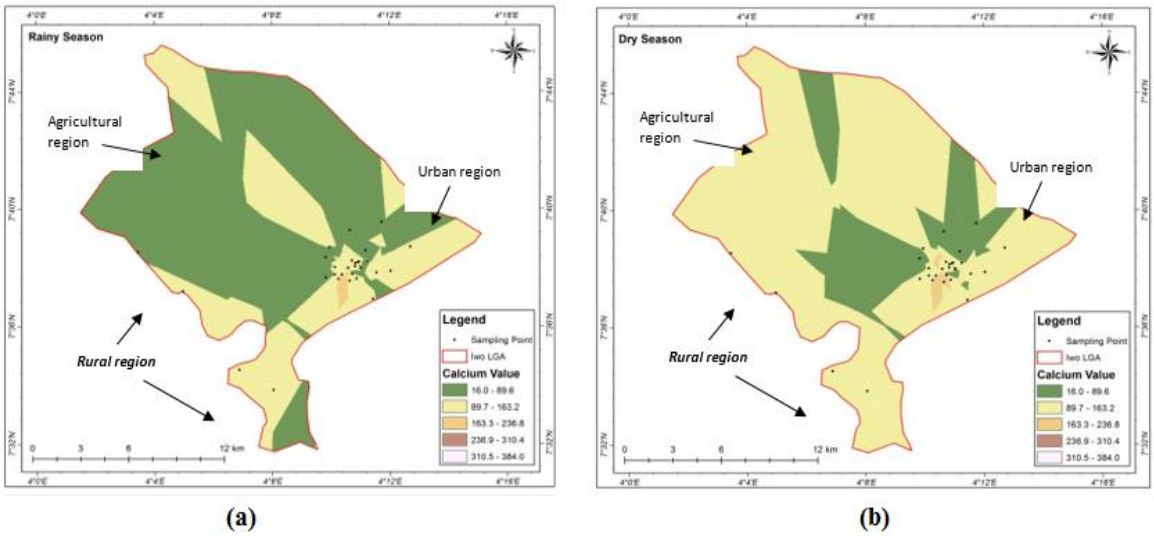


(a) (b)

Figure 5: *Spatial Variation of Total Dissolved Solids Concentration (a) Rainy Season (b) Dry Season*

3.5 Total Suspended Solids

The five colours denoting the spatial variation of total suspended solids during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 50 mg/l and 130 mg/l, 131 mg/l and 210 mg/l, 211 mg/l and 290 mg/l, 291 mg/l and 370 mg/l, and 371 mg/l and 450 mg/l, respectively as shown in Figure 6 a and b.



(a) (b)

Figure 6: *Spatial Variation of Total Suspended Solids Concentration (a) Rainy Season (b) Dry Season*

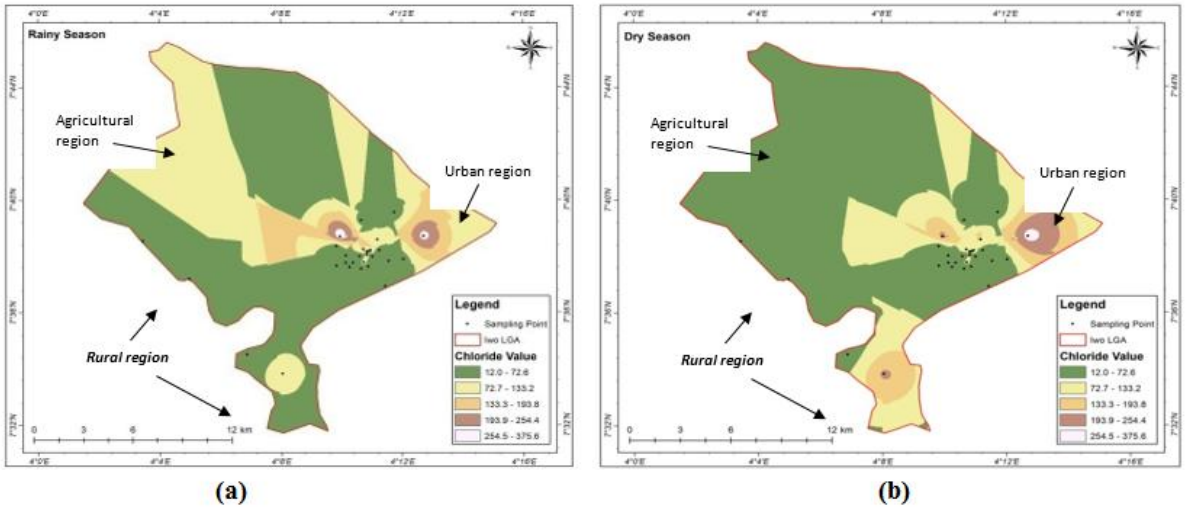
The green and yellow colours occurred mainly around the rural region for the rainy and dry seasons. This denoted that the groundwater's total suspended solids around this region were acceptable, which was mainly below 250 mg/l.

3.6 Calcium

The five colours denoting the spatial variation of calcium during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 16.0 mg/l and 89.6 mg/l, 89.7 mg/l and 163.2 mg/l, 163.3 mg/l and 236.8 mg/l, 236.9 mg/l and 310.4 mg/l, and 310.5 mg/l and 384.0 mg/l, respectively, as shown in Figure 7 a and b.

(a) **(b)**

Figure 7: *Spatial Variation of Calcium Concentration (a) Rainy Season (b) Dry Season*



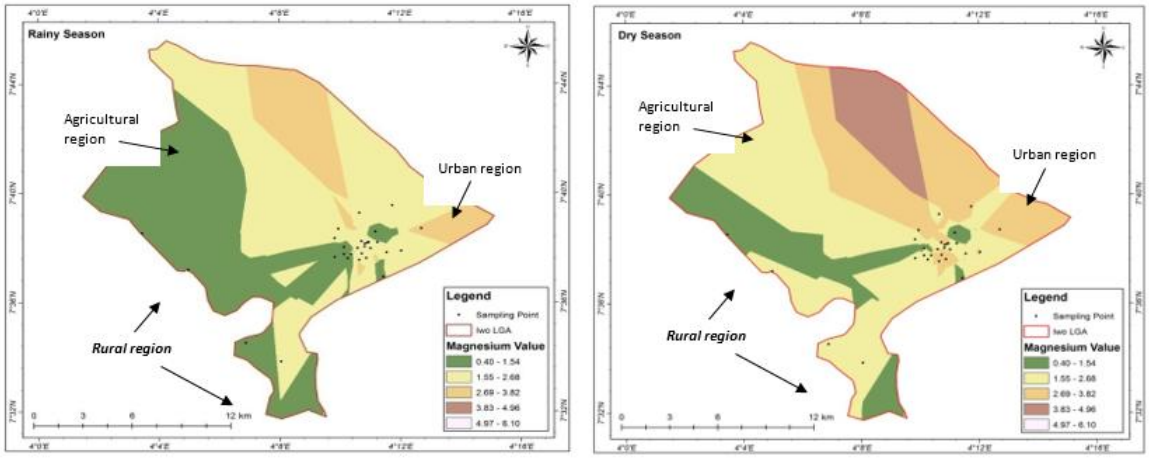
The green and yellow colours occurred mainly around the rural region for the rainy and dry seasons. This denoted that the groundwater calcium around this region was acceptable, which was mainly below 200 mg/l. The central part of the city displayed green, yellow, and orange colours, which indicated that its calcium ranged between 16 mg/l and 236.8 mg/l, which was unacceptably higher than 75 mg/l WHO standard.

3.7 Chloride

The five colours denoting the spatial variation of chloride during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 12.0 mg/l and 72.6 mg/l, 72.7 mg/l and 133.2 mg/l, 133.3 mg/l and 193.8 mg/l, 193.9 mg/l and 254.4 mg/l, and 254.5 mg/l and 375.6 mg/l, respectively as shown in Figure 8 a and b.

The green, yellow, orange, and brown colours of the spatial variation were within the permissible limit of chloride (250 mg/l). In Figure 8a, the green and yellow colours occurred mainly around the rural region and some parts of the urban area. This denoted that the chloride concentrations of the groundwater around these regions were acceptable, as they were below 250 mg/l. Two northern parts of the city displayed grey colours encircled by brown and orange colours. The grey colour ranged between 254.5 mg/l 375.6 mg/l, which was unacceptable.

In Figure 8b, the green, yellow, orange and brown colours occurred mainly around the study area for the dry season. The significant green colour in the agricultural and rural regions denoted that the chloride concentration of the groundwater in the study area was mainly acceptable. A groundwater source in the north-eastern part displayed a grey colour, which is encircled by brown and orange colours. This indicated that its chloride concentration ranged between 254.5 mg/l and 375.6 mg/l, which was unacceptable.



(a) (b)

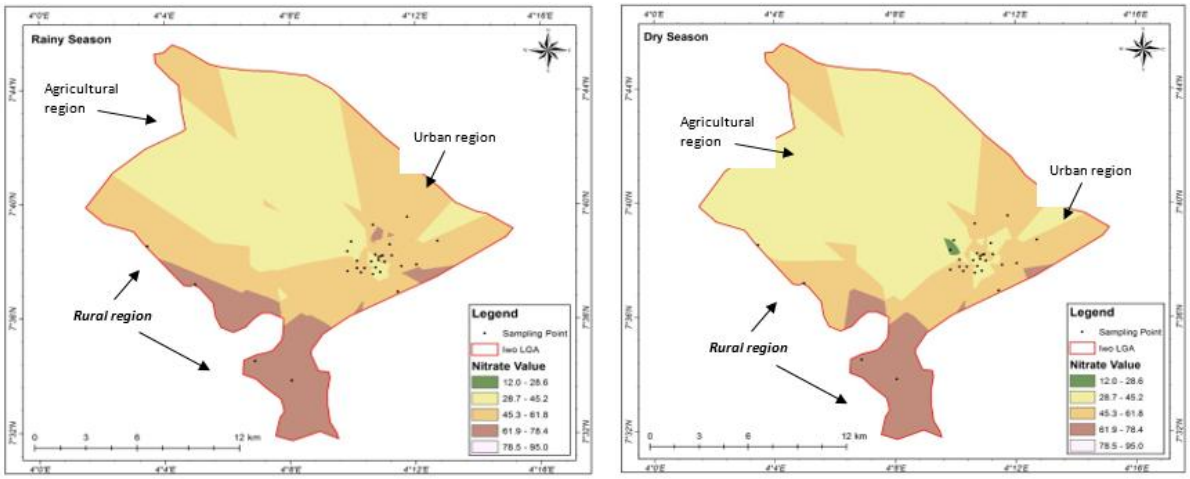
Figure 8: *Spatial Variation of Chloride Concentration (a) Rainy Season (b) Dry Season*

3.8 Magnesium

The five colours denoting the spatial variation of magnesium during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 0.40 mg/l and 1.54 mg/l, 1.55 mg/l and 2.68 mg/l, 2.69 mg/l and 3.82 mg/l, 3.83 mg/l and 4.96 mg/l, and 4.97 mg/l and 6.10 mg/l, respectively as shown in Figure 9 a and b.

(a) (b)

Figure 9: *Spatial Variation of Magnesium Concentration (a) Rainy Season (b) Dry Season*



The green, yellow, orange, brown, and grey colours of the spatial variation were within the permissible limit of magnesium (50 mg/l). In Figure 9a, the green colour occurred mainly in the rural and agricultural regions of the study area. This denoted that the magnesium concentration of the groundwater around this region was lower than in other regions. The other parts of the study area, including the urban region, displayed little green and orange colours and mostly yellow. These colours ranged between 0.4 mg/l and 3.82 mg/l, which were acceptable.

In Figure 9b, the green and yellow colours occurred mainly in the southern region of the study area. This denoted that the magnesium concentration of the groundwater around this region was lower than in agricultural and urban regions. The other parts of the study area displayed little green and mainly yellow, orange, and brown colours. These colours, which occurred in the study area, ranged between 0.4 mg/l and 4.96 mg/l, which were acceptable.

3.9 Nitrate

The five colours denoting the spatial variation of nitrate concentration during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 12.0 mg/l and 28.6 mg/l, 28.7

mg/l and 45.2 mg/l, 45.3 mg/l and 61.8 mg/l, 61.9 mg/l and 78.4 mg/l, and 78.5 mg/l and 95.0 mg/l, respectively as shown in Figure 10 a and b.

(a) **(b)**

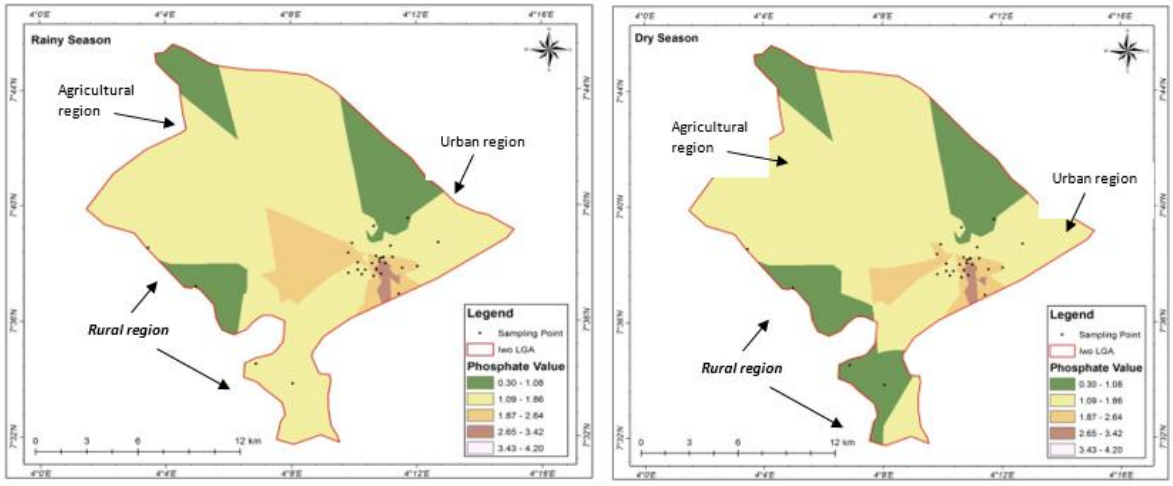


Figure 10: *Spatial Variation of Nitrate Concentration (a) Rainy Season (b) Dry Season*

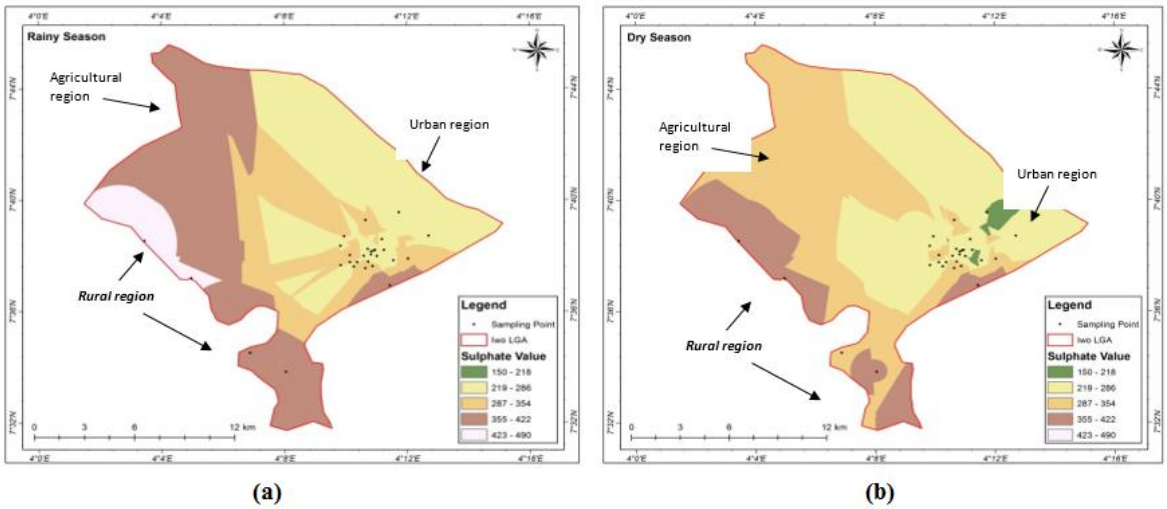
The green and yellow colours of the spatial variation were within the permissible limit of nitrate (50 mg/l). The brown and orange colours occurred mainly in the southern region of the study area, including some parts of the city. This denoted that the nitrate concentration of the groundwater around this region was largely unacceptable because it was more than 50 mg/l. The other parts of the study area displayed a yellow colour that occurred in the north-western region. This indicated that nitrate concentration ranged between 28.7 mg/l and 45.2 mg/l, which was acceptable.

The significant difference observed between the two seasons was the decrease in the nitrate concentration of the study area from the rainy to the dry season. This reduction can be a result of a decline in the rate of dissolution of nitrate ions from fertilisers, wastes, septic tanks, and pit latrines into the groundwater, aided by rainfall during the rainy season (Aleku *et al.*, 2024).

3.10 Phosphate

The five colours denoting the spatial variation of phosphate concentration during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 0.30 mg/l and 1.08 mg/l, 1.09 mg/l and 1.86 mg/l, 1.87 mg/l and 2.64 mg/l, 2.65 mg/l and 3.42 mg/l, and 3.43 mg/l and 4.20 mg/l, respectively as shown in Figure 11 a and b.



(a) **(b)**

Figure 11: *Spatial Variation of Phosphate Concentration (a) Rainy Season (b) Dry Season*

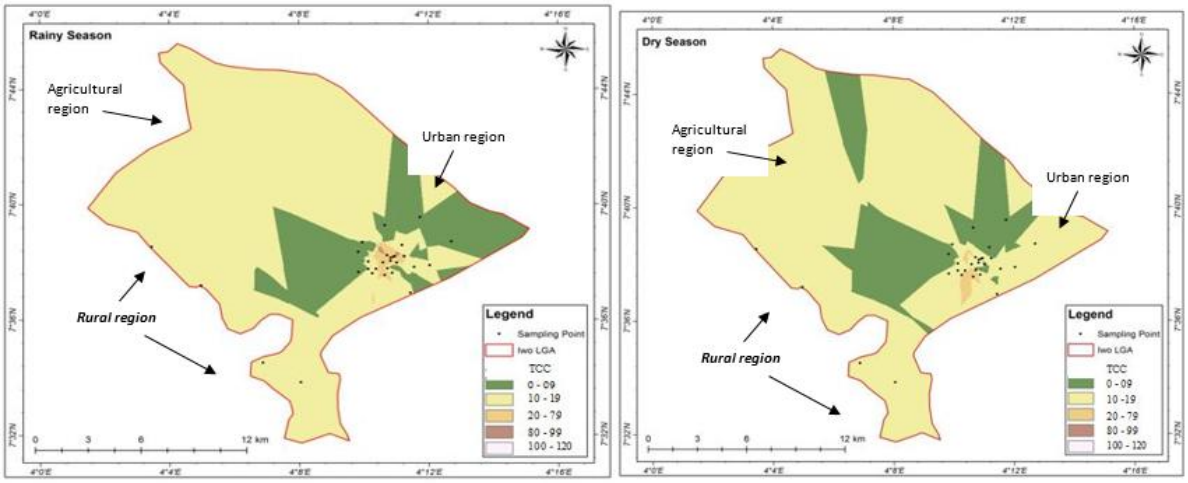
All the colours of the spatial variation were above the permissible limit of phosphate (0.05 mg/l). The green and yellow colours occurred mainly in the rural region of the study area. This indicated that the phosphate concentration of the groundwater around this region was lower than that of the urban region. The other parts of the study area, like the agricultural region displayed green, yellow, orange, and brown colours. The phosphate concentrations of the study area ranged between 0.30 mg/l and 3.42 mg/l, which were unacceptable. This can be attributed to microbial cycling in the groundwater (Li *et al.*, 2024).

3.11 Sulphate

The five colours denoting the spatial variation of sulphate concentration during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 150 mg/l and 218 mg/l, 219 mg/l and 286 mg/l, 287 mg/l and 354 mg/l, 355 mg/l and 422 mg/l, and 423 mg/l and 490 mg/l, respectively as shown in Figure 12 a and b.

(a) **(b)**

Figure 12: *Spatial Variation of Sulphate Concentration (a) Rainy Season (b) Dry Season*



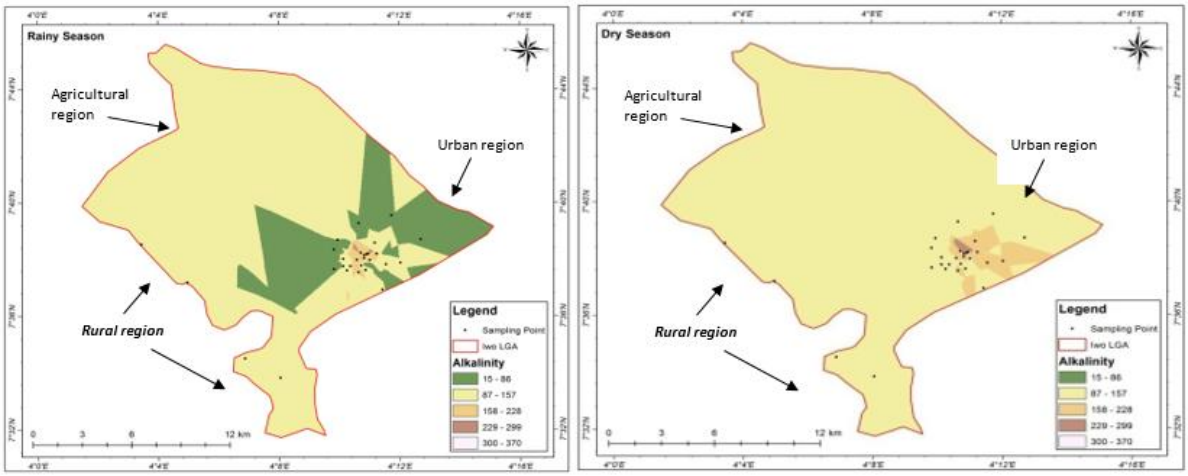
The green colour of the spatial variation was below the permissible limit of sulphate (250 mg/l). The brown and grey colours occurred mainly in the rural and agricultural regions of the study area. This denoted that the sulphate concentration of the groundwater around these regions were higher than that of the urban region. The other parts of the study area displayed yellow, orange and green (Figure 12b) colours. This denoted that the spatial variations of sulphate concentrations in the urban region for rainy and dry seasons ranged between 219 mg/l and 354 mg/l, which were largely unacceptable.

The significant difference observed between the two seasons was the decrease in the sulphate concentration of the study area from the rainy to the dry season. This reduction can be a result of the decline in the rate of dissolution of sulphate from rocks and other sulphate sources of contamination into the groundwater, aided by rainfall during the rainy season (Mattos *et al.*, 2018).

3.12 Total Coliform

The five colours denoting the spatial variation of total coliform concentration during the rainy and dry seasons were green, yellow, orange, brown and grey ranging between 0 cfu/ml x 10^{-4} and 09 cfu/ml x 10^{-4}, 10 cfu/ml x 10^{-4} and 19 cfu/ml x 10^{-4}, 20 cfu/ml x 10^{-4} and 79 cfu/ml x 10^{-4}, 80 cfu/ml x 10^{-4} and 99 cfu/ml x 10^{-4}, and 100 cfu/ml x 10^{-4} and 120 cfu/ml x 10^{-4}, respectively as shown in Figure 13 a and b.

The green colour of the spatial variation was below the permissible limit of total coliform (10 cfu/ml x 10^{-4}). The green colour encircled the urban region of the study area. This denoted that the total coliform of the groundwater around this region was within the acceptable limit. The central part of the urban region displayed yellow, orange, and brown colours. This denoted that the total coliform of this region ranged between 10 cfu/ml x 10^{-4} and 99 cfu/ml x 10^{-4}, which was unacceptable.

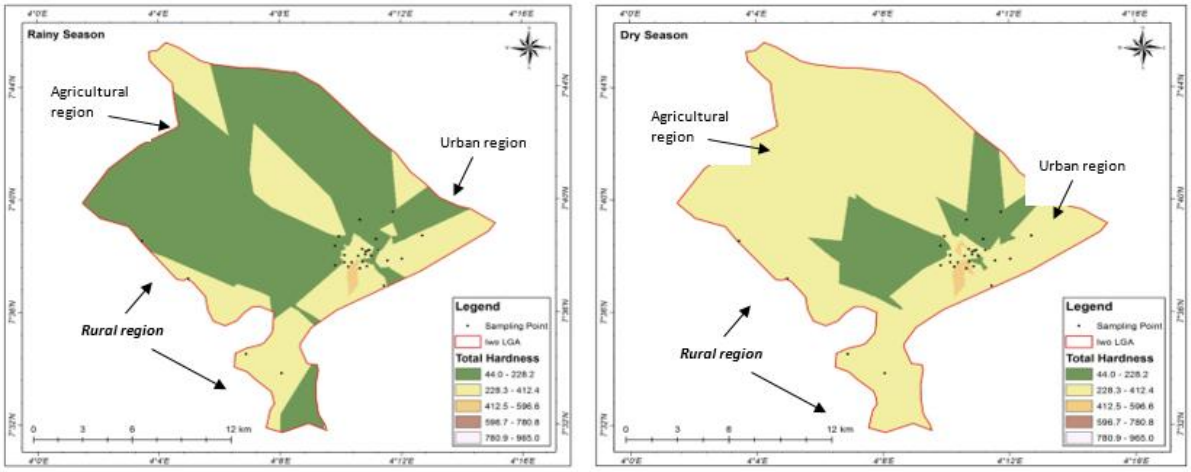


(a) **(b)**

Figure 13: *Spatial Variation of Total Coliform Concentration (a) Rainy Season (b) Dry Season*

3.13 Total Alkalinity

The five colours denoting the spatial variation of total alkalinity during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 15 mg/l and 86 mg/l, 87 mg/l and 157 mg/l, 158 mg/l and 228 mg/l, 229 mg/l and 299 mg/l, and 300 mg/l and 370 mg/l, respectively, as shown in Figure 14 a and b.



(a) **(b)**

Figure 14: *Spatial Variation of Total Alkalinity Concentration (a) Rainy Season (b) Dry Season*

The green, yellow, and orange colours of the spatial variation were within the permissible limit of total alkalinity (200 mg/l). The brown and orange colours occurred in the central part of the urban region. This denoted that the total alkalinity of the groundwater around this region was slightly above 200 mg/l, which was somewhat unacceptable. The other rural and agricultural regions displayed green and yellow colours, ranging between 15 mg/l and 157 mg/l, which were acceptable.

3.14 Total Hardness

The five colours denoting the spatial variation of total hardness during the rainy and dry seasons were green, yellow, orange, brown, and grey, ranging between 44.0 mg/l and 228.2 mg/l, 228.3 mg/l and 412.4 mg/l, 412.5 mg/l and 596.6 mg/l, 596.7 mg/l and 780.8 mg/l, and 780.9 mg/l and 965.0 mg/l, respectively as shown in Figure 15 a and b.

(a) (b)

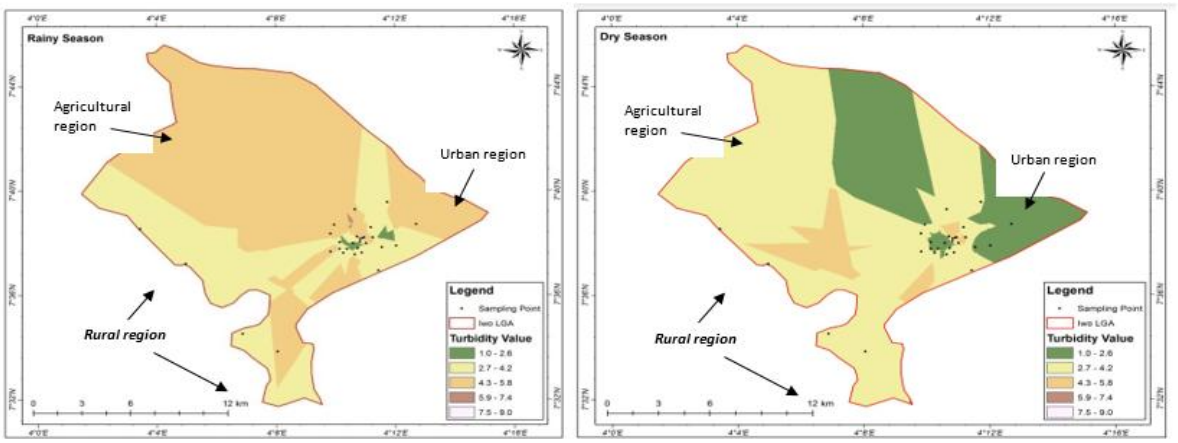


Figure 15: *Spatial Variation of Total Hardness Concentration (a) Rainy Season (b) Dry Season*

In Figure 15a, the green colour of the spatial variation was within the permissible limit of total hardness (150 mg/l). The green colour occurred mainly in the agricultural region. This denoted that the total hardness of the groundwater around this region was slightly acceptable, which was close to 150 mg/l. The southern part of the study area displayed a yellow colour and a little orange colour. This denoted that the southern region ranged mainly between 228.3 mg/l and 596.6 mg/l, which was unacceptable.

In Figure 15 b, the green colour of the spatial variation during the dry season was within the permissible limit of total hardness (150 mg/l). The yellow colour occurred mainly in the rural region, and this denoted that the total hardness of the groundwater around this region was unacceptable and substantially exceeded the WHO standard limit across significant portions of the study area, particularly during the dry season. This prediction from the interpolation could be indicative of localised carbonate/sulphate rock dissolution and weathering processes as reported in previous studies (Mattos *et al.*, 2018). The urban part of the study area displayed green, yellow, and orange colours. The green colour locations denote that total hardness was within 150 mg/l, which was acceptable.

3.15 Turbidity

The five colours denoting the spatial variation of turbidity during the rainy and dry seasons were green, yellow, orange, brown and grey, ranging between 1.0 NTU and 2.6 NTU, 2.7 NTU and 4.2 NTU, 4.3 NTU and 5.8 NTU, 5.9 NTU and 7.4 NTU, and 7.5 NTU and 9.0 NTU, respectively, as shown in Figure 16 a and b.

(a) (b)

Figure 16: *Spatial Variation of Turbidity Concentration (a) Rainy Season (b) Dry Season*

The green and yellow colours of the spatial variation were within the permissible turbidity limit (5 NTU). The yellow colour occurred mainly in the rural region, which denoted that the groundwater turbidity around this region was acceptable which was below 5 NTU. The urban region of the study area displayed mainly green, yellow, and orange colours with a bit of brown colour. This brown colour indicated that some parts of the urban and agricultural regions ranged between 5.9 NTU and 7.4 NTU, which was unacceptable. The significant difference observed in the agricultural and urban regions between the two seasons was the decrease in the turbidity of groundwater from the rainy to the dry season.

Table 2 shows the descriptive statistics for each groundwater parameter recorded for Iwo Local Government Area during the rainy season, while Table 3 shows the descriptive statistics for each groundwater parameter recorded for Iwo Local Government Area during the dry season. It was observed that during the rainy season, the mean values of temperature (27.48 ^{o}C), nitrate (52.16 mg/l), and total coliform count (22.67 cfu/ml x 10^{-4}) were greater than WHO values of 25 ^{o}C, 50 mg/l, and 10 cfu/ml x 10^{-4} respectively. During the dry season, the mean values of temperature (16.20 ^{o}C), nitrate (48.29 mg/l), and total coliform count (6.63 cfu/ml x 10^{-4}) were less than WHO values of 25 ^{o}C, 50 mg/l, and 10 cfu/ml x 10^{-4} respectively. In addition, total hardness, calcium, phosphate, and sulphate had consistent mean values greater than WHO standard values for both rainy and dry seasons. Other parameters like pH, electrical conductivity, total dissolved solids, total alkalinity, total suspended solids, turbidity, magnesium, and chloride had mean values for both rainy and dry seasons less than the WHO standard.

Table 2: *Groundwater Parameters Mean Against WHO Values for Rainy Season*

SN	Parameter	WHO	Minimum	Maximum	Mean	Standard Error	Standard Dev.	Coefficient of Variation (%)
1	pH (-)	6.5 – 8.5	5.6	8.5	7.07	±0.114	±0.625	8.84

4. CONCLUSION

The groundwater sources from Iwo Local Government Area show that the measured parameters exhibited seasonal variation, with concentrations being primarily higher during the rainy season than during the dry season. However, the groundwater quality maps for total hardness, pH, and calcium show higher spatial variation of concentrations in the dry season than in the rainy season. This assessment provided information on groundwater features in the Iwo Local Government Area in Osun State of Nigeria. The kriging interpolation method was used to predict the value of a parameter at an unmeasured location over a spatial region, resulting in the generation of spatial distribution maps. The groundwater quality variation maps generated from water quality test results revealed groundwater quality characteristics in the Iwo Local Government Area. The different processes responsible for the acquisition of groundwater chemistry studied, according to spatial variation assessment studies, are the residence time of the water in contact with the rock, the infiltration of substances related to anthropogenic activities (agricultural fertilisers, household and industrial waste), and the intensity of rainfall. It is recommended that the identified locations be subjected to water treatment techniques to reduce total hardness.

ABSTRACT

Accurate estimation of corrosion rate is essential for predicting the service life of petroleum tanker materials. This study used the weight-loss/gravimetric technique to investigate corrosion of carbon-steel tanker-truck material in Automotive Gas Oil (AGO) and Premium Motor Spirit (PMS) over 63 days (1512 h). The gravimetric analysis revealed measurable degradation of the carbon-steel coupons following immersion in both petroleum products, with different magnitudes under the tested conditions. The AGO-exposed specimens recorded an average weight loss of 0.40 g, whereas the PMS-exposed specimens exhibited a mean weight loss of 0.20 g, indicating approximately 100% greater mass loss in AGO. Using the ASTM G31 corrosion-rate equation with $K = 8.76 \times 10^4$ for mm/year, an exposed area of 22.80 cm², an exposure time of 1512 h and a steel density of 7.85 g/cm³, the calculated mean corrosion rates were 0.129 mm/year for AGO and 0.065 mm/year for PMS. Thus, under the specific laboratory conditions and for the fuel batches tested, AGO produced approximately twice the gravimetric corrosion rate measured in PMS. Because the study did not determine the physicochemical properties of the fuel samples, the observed difference is reported without assigning it to sulphur content or any other individual fuel constituent.

Keywords: *Corrosion rate; weight-loss method; ASTM G31; carbon steel; PMS; AGO*

1. INTRODUCTION

Nigeria's energy security and downstream petroleum supply system depend substantially on the safe and reliable transportation of petroleum products by road tanker trucks, particularly in view of the limitations of pipeline and rail infrastructure (Ambituuni, 2016). Tanker trucks therefore constitute an important link between petroleum-product storage facilities and end users across the country. However, the continued occurrence of tanker-related fires, explosions and other loss-of-containment incidents demonstrates the persistent safety challenges associated with petroleum-product transportation in Nigeria. A 16-year national review reported 169 tanker fire and explosion accidents resulting in 1,613 deaths between 2009 and 2024 (Na'inna, 2024). The persistence and severity of these incidents underscore the need for a systematic, engineering-based approach to improving the safety and integrity of petroleum tanker systems.

Tanker safety is influenced by several interacting factors, including human behaviour, road and traffic conditions, vehicle condition, operational practices, regulatory enforcement and the integrity of the tanker itself. While human and operational factors have received considerable attention, the condition of the metallic tanker shell represents an important engineering aspect of containment integrity. The tanker shell serves as the primary barrier separating the transported petroleum product from the external environment. Progressive deterioration of this barrier can reduce its effective thickness and structural capacity and may eventually result in leakage or loss of containment. Among the mechanisms responsible for metallic deterioration, corrosion is particularly important because it is a progressive process that can occur during prolonged service and may remain unnoticed until significant material loss has occurred.

The interaction between tanker-shell material and the transported petroleum product is therefore an important area of investigation. In Nigeria, Premium Motor Spirit (PMS) and Automotive Gas Oil (AGO) constitute major petroleum products transported by road tankers. Their different physicochemical characteristics may result in different interactions with carbon-steel tanker plates and, consequently, different rates of material degradation. However, the corrosion rate of the actual metallic material used for tanker fabrication under controlled exposure to these petroleum products requires experimental determination. Quantifying this material loss is important because corrosion rate provides a direct indication of the rate at which the tanker-shell thickness may progressively deteriorate.

The weight-loss (gravimetric) method provides a practical means of determining cumulative corrosion-induced metal loss. By measuring the difference between the initial and final masses of a metallic coupon after controlled exposure and relating the mass loss to the exposed surface area, material density and exposure duration, the average corrosion penetration rate can be quantified. The ASTM G31 standard provides guidance for laboratory immersion testing and offers an appropriate basis for controlled assessment of corrosion behaviour. Unlike an assessment based solely on visual surface deterioration, gravimetric analysis provides quantitative evidence of actual material loss during the specified exposure period.

This study applies the ASTM G31 gravimetric (weight-loss) method, the most widely used baseline technique for corrosion-rate estimation because of its simplicity and direct relationship to actual metal loss to a locally sourced, high-grade conventional 5 mm Ukrainian carbon steel plate (4.5 mm actual thickness) used for tanker fabrication in Nigeria, following 63 days of full immersion in PMS and AGO under ambient laboratory conditions.

2. LITERATURE REVIEW

The weight-loss (gravimetric) method is one of the most established experimental techniques for determining the corrosion rate of metallic materials. Its major advantage is that it provides a direct measure of actual metal loss during a defined exposure period. The method involves accurately weighing a prepared metal coupon before and after exposure to a corrosive environment, cleaning the specimen to remove corrosion products, and converting the resulting mass loss into a corrosion penetration rate. Because of its simplicity, relatively low cost and ability to quantify cumulative material loss, the method has been widely applied in studies of carbon and mild steel exposed to atmospheric, aqueous and petroleum-related environments. As cited in Guma & Abu, (2018), for example, applied gravimetric measurements in corrosion investigations, demonstrating the applicability of weight-loss analysis to steel corrosion studies.

The relevance of the gravimetric method to the Nigerian environment is demonstrated by Guma and Abu (2018), who investigated the atmospheric corrosion behaviour of mild steel around Kaduna metropolis. Their study involved a large number of corrosion coupons and used statistical analysis, including analysis of variance (ANOVA), to examine differences in corrosion behaviour associated with location. The authors reported statistically significant variations in corrosion rates among the investigated locations. This study is particularly relevant to the present research because it demonstrates the suitability of weight-loss measurements combined with statistical analysis for evaluating corrosion behaviour under Nigerian environmental conditions. The approach provides a useful methodological precedent for the present investigation of petroleum-tanker steel exposed to PMS and AGO.

A particularly relevant West African study was conducted by Suah (2014), who examined the corrosion behaviour of low-carbon steel containing approximately 0.184 wt.% carbon obtained from an above-ground petroleum storage tank in Liberia. The steel coupons were exposed to gasoline and diesel for periods of up to 456 h, while weight loss, pH and optical microscopy were used to monitor corrosion behaviour. The reported corrosion penetration rates ranged from approximately 0.016 to 0.325 mm/year, depending on the exposure medium and coupon. The study also observed a progressive reduction in solution pH during exposure. This behaviour was associated with the formation of acidic species, particularly carboxylic/acetic acid species, and their subsequent interaction with dissolved iron to form iron-containing corrosion products. The findings demonstrate that petroleum-derived fuels, despite being substantially less conductive than aqueous electrolytes, can still support measurable corrosion of carbon steel when appropriate corrosive species and

environmental conditions are present. The study therefore provides an important regional reference for investigating the interaction between tanker-fabrication steel and petroleum products.

Corrosion of Carbon Steel in Diesel and Biodiesel-Containing Fuels

A substantial body of literature has also investigated corrosion of carbon steel in diesel–biodiesel systems. Although biodiesel-containing fuels are not chemically identical to conventional Automotive Gas Oil (AGO), these studies provide useful comparative evidence because diesel and biodiesel systems contain oxygenated compounds and may exhibit different moisture, acidity and oxidation characteristics from lighter petroleum products such as PMS.

Cursaru et al. (2014) reported greater surface deterioration of mild carbon steel in biodiesel than in petroleum diesel, demonstrating the influence of fuel composition on steel corrosion. Similarly, Milano et al. (2021), Adama et al. (2024), and Adama et al. (2025) reported relationships between increasing biodiesel content and increasing corrosion severity. These findings indicate that changes in fuel composition can significantly modify the interaction between the fuel environment and carbon-steel surfaces.

Exposure configuration is also an important factor in petroleum-fuel corrosion. Kugelmeier et al. (2021) investigated carbon steel exposed to diesel–biodiesel blends and found comparatively limited attack under full-immersion conditions, while more pronounced deterioration occurred in the vapour phase. This observation is important for petroleum tanker applications because a tanker shell is not necessarily exposed to a single uniform environment. Depending on the fuel level, temperature, moisture accumulation and operating conditions, different regions of the tank may experience liquid-phase, vapour-phase and fuel–water interface exposure. Consequently, corrosion rate measurements obtained under full immersion should be interpreted as representing a defined experimental exposure condition rather than necessarily reproducing every corrosion mechanism occurring inside an operating tanker.

Further evidence was provided by Heryana et al. (2024), who investigated SA 516 Gr.70 carbon steel exposed to diesel–biodiesel blends. The study reported corrosion rates of approximately 1.226–1.442 μm/year, with corrosion severity increasing with biodiesel content. Surface examination using SEM/EDS revealed pitting and corrosion products containing predominantly iron and oxygen. These observations demonstrate the usefulness of combining gravimetric measurements with surface and elemental characterization to establish not only how much metal is lost, but also the nature of the resulting corrosion damage.

Corrosion Behaviour of Carbon Steel in AGO and PMS

While the studies involving diesel–biodiesel fuels provide useful information on fuel-related corrosion, direct investigations involving commercial AGO and PMS are particularly relevant to petroleum tanker applications in Nigeria. Shuaib-Babata and Abdulqadir (2012) investigated commercial low-carbon steel in several environments, including AGO, PMS, dual-purpose kerosene (DPK), crude oil, freshwater and seawater. Their reported corrosivity sequence was:

natural seawater > simulated seawater > freshwater > crude oil > PMS > DPK > AGO.

This result indicates considerably lower apparent corrosivity for AGO than for PMS under their experimental conditions. However, this ranking differs from the corrosion-rate trend obtained in the present investigation, where AGO exhibited a higher gravimetric corrosion rate than PMS. Such differences do not necessarily represent contradictions in the underlying corrosion behaviour; rather, they demonstrate the strong dependence of measured corrosion rate on the specific material, fuel composition and experimental conditions.

Differences between studies may arise from variations in steel composition and microstructure, fuel formulation, water and contaminant content, dissolved oxygen, temperature, exposure duration, specimen surface condition and exposure configuration. Petroleum fuels are complex mixtures rather than single chemical substances, and their corrosive behaviour can change considerably with storage history, contamination and the presence of water or other reactive species. Therefore, corrosion-rate values obtained from one fuel batch or steel grade should not automatically be assumed to represent all tanker operating conditions.

Relevance to the Present Study

The reviewed literature demonstrates that the corrosion of carbon-steel materials in petroleum-related environments is influenced by the interaction between the metallic material and the

characteristics of the exposure medium. The weight-loss method is particularly valuable for the present research because it measures cumulative mass loss and can therefore be directly related to the progressive loss of tanker-shell material. Previous Nigerian and West African studies have established the applicability of gravimetric techniques to steel corrosion, while investigations involving diesel, biodiesel, AGO and PMS demonstrate that corrosion behaviour can vary substantially with fuel composition and exposure conditions.

However, there remains a need for experimental data specifically addressing the corrosion rate of carbon-steel plates used for petroleum tanker fabrication in Nigeria when exposed directly to PMS and AGO under controlled conditions. In particular, the divergence between the AGO/PMS corrosion rankings reported in previous studies highlights the importance of generating experimental data from the actual tanker-fabrication steel and petroleum-product batches investigated in a given study, rather than relying solely on corrosion rates reported elsewhere.

Accordingly, the present study employs the ASTM G31-based weight-loss (gravimetric) method to quantify the corrosion rates of the investigated carbon-steel tanker plate following controlled immersion in PMS and AGO. By maintaining the same steel material, specimen preparation procedure, exposure conditions and measurement approach for both petroleum products, the study provides a direct basis for comparing their relative effects on the tanker-fabrication material. The resulting corrosion-rate data constitute the fundamental experimental evidence for subsequent evaluation of corrosion-induced material degradation, mechanical-property changes, corrosion mitigation and the implications of tanker-shell deterioration for leakage and fire/explosion risk in Nigeria.

3. MATERIALS AND METHODS

3.1 Materials

Fresh carbon steel plate of 4.5 mm actual thickness (locally referred to as high-grade conventional 5 mm Ukrainian metallic plate) was procured from Dan Magaji Tanker Fabricators, Zaria, Nigeria. Premium Motor Spirit (PMS) and Automotive Gas Oil (AGO) used for the study were purchased from AA Rano Filling Station, Sokoto Road, Zango, Samaru, Zaria.

Figure 3.1: The 4.5 mm carbon steel plate

3.2 Sample Preparation

Specimens were cut to the required dimensions using a power hacksaw machine, with care taken to avoid excessive heating that could alter the microstructure. Surface grinding was carried out manually using silicon carbide emery papers of progressively finer grit (220, 320, 400, 600 and 800), followed by polishing on a rotating polishing machine using an aluminium oxide slurry. Degreasing was performed by immersing the polished specimens in boiling alcohol for approximately 10 minutes, after which the specimens were dried using clean absorbent tissue paper prior to testing.

Figure 3.2: Prepared carbon steel coupons after grinding, polishing and degreasing before weighing

3.3 Immersion Procedure

A volume of 500 mL each of PMS and AGO was poured separately into clean plastic containers. Five specimens were tagged, weighed on an analytical balance to record the initial weight, and immersed separately in PMS and AGO. Containers were tightly sealed to minimise air ingress, contamination and evaporation. An exposure duration of approximately 63 days was adopted, comparable to immersion durations used in prior Nigerian corrosion studies of carbon steel in petroleum media (Shuaib-Babata & Abdulqadir, 2012). Specimens were visually inspected at 7 and 27 days; no significant corrosion products were observed at these intermediate points, but visible corrosion products were present by the end of the 63-day period.

After removal from the immersion media, loose corrosion products were gently removed using a soft brush. The specimens were then immersed in a hydrochloric acid (HCl) solution for 10 minutes to remove adherent corrosion products, rinsed thoroughly with distilled water followed by ethanol, and dried in a desiccator to eliminate residual moisture. The final weight of each specimen was measured using an analytical balance and weight loss was determined by taking the difference between initial and final weight of each sample.

Figure 3.3: Sealed plastic containers with carbon steel coupons immersed in PMS and AGO

3.4 Corrosion-Rate Calculation (ASTM G31)

The coupon dimensions were 64 mm × 13 mm × 4 mm, with all six surfaces exposed; the 4.5 mm actual material thickness was reduced to 4 mm due to machining during material preparation, the exposed surface area (top and bottom faces plus all four edges) was calculated as 22.80 cm^2. The corrosion rate in mm/year was estimated using the standard ASTM G31 weight-loss equation:

Corrosion Rate (mm/year) = (K × W) / (A × T × D) *Eq1*

where K is the unit-conversion constant. Using W in grams, A in cm^2, T in hours and D in g/cm^3, the applicable constants are K = 3.45 × 10^6 for mils per year (mpy), K = 8.76 × 10^4 for millimetres per year (mm/year), and K = 8.76 × 10^7 for micrometres per year (µm/year). Therefore, because the corrosion rates in this study are reported in mm/year, W is the weight loss in grams, A is the exposed surface area in cm^2, T is the exposure time in hours, and D is the density of the steel (7.85 g/cm^3), the appropriate is K = 8.76 × 10^4 based on.

```
W/(A·T·D) has units g/(cm²·h·g/cm³) = cm/h  →  a linear penetration
rate

Converting cm/h → mm/year:  ×10 (cm→mm)  ×8760 (hours/year)  =
×87,600  =  8.76×10⁴
```

ASTM G31-72 quoted verbatim in two US patent filings: *"Corrosion rate = 8.76×10^4 × (weight loss(g)/(area(cm^2) ×density(g/cm^3) ×time(h)))"* — explicitly labelled mm/year in both.

The mean and standard deviation of the weight-loss measurements were calculated using the standard formulae for sample mean and standard deviation.

For verification, substitution of the mean values gives: AGO = $(8.76 \times 10^4 \times 0.40)/(22.80 \times 1512 \times 7.85)$ = 0.12948 mm/year, reported as 0.129 mm/year; and PMS = $(8.76 \times 10^4 \times 0.20)/(22.80 \times 1512 \times 7.85)$ = 0.06474 mm/year, reported as 0.065 mm/year. Thus, the reported rates follow directly from the stated mean weight losses, area, exposure time, density and the mm/year constant.

Figure 3.4: Corroded specimens after HCl cleaning, distilled-water/ethanol rinse and desiccator drying, immediately before final weight measurement on the analytical balance

4. RESULTS AND DISCUSSION

The weight-loss method was employed to evaluate the corrosion behaviour of carbon steel exposed to PMS and AGO over the 63-day immersion period. The results are presented in Table 1.

Table 1: Corrosion-rate of carbon steel in AGO and PMS media

Parameter	AGO	PMS
Mean Weight Loss (g)	0.40	0.20
Standard Deviation (g)	0.183	0.141
Exposed Surface Area (cm^2)	22.80	22.80
Density (g/cm^3)	7.85	7.85
Exposure Time Hour (h)	1512	1512
Mean Corrosion Rate (mm/year)	0.129	0.065

The gravimetric analysis revealed measurable degradation of the carbon steel coupons following immersion in both petroleum products; however, the degree of deterioration varied considerably between the two fuels. The AGO-exposed specimens recorded an average weight loss of 0.40 g, whereas the PMS exposed samples exhibited a mean weight loss of 0.20 g, the mass loss in diesel was approximately 100% greater than that observed in petrol under identical exposure conditions. The calculated corrosion rates followed the same trend: the average corrosion rate of

0.129 mm/year for AGO was approximately twice that obtained for PMS (0.065 mm/year), demonstrating that the carbon steel experienced a more aggressive corrosive environment in diesel than in petrol.

The higher corrosion rate measured in AGO should be interpreted as an experimental result obtained for the specific fuel batch and exposure conditions used in this study. The present experiment did not include physicochemical analysis of the PMS or AGO; therefore, the difference in corrosion rate cannot be attributed quantitatively to sulphur content, acidity, water content, dissolved oxygen, oxidation products or any other individual fuel constituent. Differences in fuel composition and contamination are possible explanatory factors identified in the wider literature, but their contributions were not measured here.

To place these corrosion rates in context, Suah (2014) reported broadly comparable, and in some cases lower, gravimetric corrosion penetration rates (0.016–0.325 mm/year) for low-carbon steel (0.184 wt% C) exposed to diesel and gasoline for up to 456 hours (19 days) under similarly uncontrolled ambient laboratory conditions. Although the fuel media are not identical (Liberian diesel/gasoline versus Nigerian AGO/PMS), the two studies together suggest that carbon steel corrosion rates in petroleum products of this kind typically fall within a comparable low sub-millimetre-per-year range, well below corrosion rates reported for carbon steel in aqueous or marine environments (Guma & Abu, 2018). Reported values are sensitive to exposure duration, coupon geometry and the specific carbon content of the steel investigated, so direct numerical comparison across studies should be treated as indicative rather than exact.

The difference between the AGO and PMS results therefore demonstrates that the corrosivity ranking obtained in this experiment is specific to the investigated steel, fuel batches and controlled exposure conditions. Without direct physicochemical testing of the two fuel samples and without presenting the steel composition in this manuscript, the present data do not permit a definitive mechanistic explanation for why AGO produced the higher rate.

The gravimetric result that AGO produced a substantially higher corrosion rate (0.129 mm/year) than PMS (0.065 mm/year) contrasts with Shuaib-Babata and Abdulqadir (2012), who tested commercial low-carbon steel in AGO, PMS, DPK, crude oil and seawater and reported AGO as the least corrosive petroleum fraction in their weight-loss study, the reverse of the ranking obtained here. The two studies used different steel materials, fuel samples and exposure conditions, including different temperature regimes. Consequently, the discrepancy should not be used to infer a universal corrosivity ranking between AGO and PMS. Rather, it supports the present study's rationale that corrosion-rate measurements should be generated for the specific material and fuel environment under investigation. Because this manuscript does not present the bulk chemical composition of the investigated plate, no claim is made here that the material is medium-carbon steel or that composition alone explains the difference from the earlier study.

The present result can also be discussed alongside diesel-biodiesel corrosion studies with appropriate caution. Heryana et al. (2024), for example, reported measurable corrosion and pitting of SA 516 Gr.70 carbon steel in diesel-biodiesel and diesel-biodiesel-HVO blends, with corrosion severity varying with blend composition. Those results reinforce the broader finding that fuel composition and exposure conditions can influence carbon-steel corrosion, but they do not establish that conventional AGO is inherently more corrosive than PMS. Accordingly, the present AGO>PMS ranking should be limited to the tested fuel batches and 63-day ambient laboratory immersion conditions. Further work should include physicochemical characterization of the fuel samples and independent material-composition data to investigate the mechanisms responsible for the observed difference.

5. CONCLUSION

The corrosion behaviour of the investigated carbon steel plate, locally referred to as high-grade conventional 5 mm Ukrainian metallic plate and measured as 4.5 mm before coupon machining, was evaluated after 63 days (1512 h) of full immersion in PMS and AGO using the ASTM G31 gravimetric (weight-loss) approach. Under the specific laboratory conditions and for the fuel batches tested, both media produced measurable weight loss. AGO produced a mean corrosion rate of 0.129

mm/year, approximately twice the 0.065 mm/year measured for PMS. The result establishes the relative severity observed in this experiment but does not demonstrate that AGO is universally more corrosive than PMS or identify a specific fuel constituent as the cause because the fuel physicochemical properties were not measured. The findings support the need for material- and fuel-specific corrosion assessment, and future studies should combine gravimetric testing with fuel physicochemical characterization and independent material-composition analysis before making mechanistic or general corrosivity claims.

ABSTRACT

Brooding is among the most sensitive stages in the poultry production cycle because neonatal chicks bear premature thermoregulatory body systems making them rely totally on external sources of heat for growth and development however, the inadequacy and the inconsistency of the heat supply remain a major challenge as such, the design and construction of air heating system is vital in the chick's production sector. This review discussed brooding requirements, different air heating systems and their operational principles including construction guidelines, material selection, insulation and the automation in poultry brooding are discussed. The study identified that Computational Fluid Dynamics is an important tool for optimization of aspects such as air flow velocity and temperature distribution pattern. The study further identified the existing research gaps from where the corresponding future directions were suggested. The study concluded that, performance of the system doesn't only rely on the heat source or mode of heat transfer but also on the construction workmanship while considering material selection and insulation.

Keywords: *brooding requirement; forced air heating methods; construction; insulation; material selection*

1 INTRODUCTION

Poultry production has become one of the rapidly-growing sectors in agriculture globally. In spite of the rapid growth rate recorded in the past few years, the adoption is highly dependent on the capacity to provide the indispensable requirements necessary for the birds to survive during the early stage of growth and development. The provision of these vital requirements is termed as brooding where naturally, the mother hen provides to ensure newly hatched chicks adapt to the environmental conditions especially self-regulation of body temperature (Collin *et al*., 2020).

Artificially, quite a number of traditional heat generation technologies have been developed such as charcoal stoves, kerosene heaters, firewood furnaces, coal burners, and open-flame gas for providing the conducive thermal conditions for the day-old chicks (Bekele, 2021). These heat generation methods portray several drawbacks such as non-uniform temperature maintenance, generation of harmful combustion gases, risk of fire hazards, environmental pollution, including the drudgery associated with maintaining the fuel quantity for a 24-hour production, (Okonkwo *et al*., 2022).

The fast technological improvement in agricultural engineering has sprung the innovation of better-quality heating technologies for example heat lamps, radiant heaters which have the capacity to bridge the bottle-neck related to inefficient brooding systems. Recent poultry brooding technologies have incorporated intelligent systems which uses microcontrollers such as Arduino, Proportional-Integral and Derivative (PID), fuzzy logic, raspberry-pi to automatically regulate the thermal condition within the brooding chamber. These innovations have meaningfully improved the temperature regulation processes including control of other environmental parameters (Zhang *et al*., 2024).

In Nigeria, Okonkwo *et al*., (2025) developed a micro-physical element monitoring device for Trombe wall solar energy poultry brooding chamber for real time measurement of brooding temperature, relative humidity and daily solar radiation using data logger. Furthermore, Ezema *et al*., (2021) designed and implemented an embedded poultry brooding system that monitors and automatically controls the climatic conditions such as temperature and humidity where the digital values were being displayed on the Liquid Crystal Display (LCD) screen. The Arduino ESP-32 type was used to provide the overall operational controls of the system and heat lamps was used as the heat source.

Forced air heat generation methods though not commonly utilized in poultry brooding have the ability to eliminate localized heating unlike radiant heaters that primarily warm only a spot in the brooding chamber or surfaces directly underneath the heat source and to drive out unwanted gases. In addition, forced-air heating systems can be incorporated with an air filtration unit there by improving on the quality of air supplied in the brooding area. It employs a blower or a fan to distribute heated air homogeneously throughout the brooding perimeter (Mohamed, 2015).

Therefore, the aim of this study is to examine the poultry brooding requirements and investigate the potential of forced air heating systems for efficient regulation of brooding temperature with specific objectives such as; to understand the various types of forced-air heaters for brooding and construction guidelines, material's selection and insulation requirements, to understand the possibility of automation in forced-air heaters for brooding and to discover the research gaps associated with forced-air heating systems for brooding.

2 METHODOLOGY

This review was conducted by retrieving relevant literatures from reputable scientific databases such as Google Scholar, ScienceDirect, SpringerLink, Semantic Scholar, and Taylor & Francis Online. Further materials were got from technical reports, poultry management manual, engineering handbooks including publications by international organizations, the American Society of Heating, Refrigerating and Air-Conditioning Engineers (ASHRAE)

The literature search was primarily limited to publications between 2020 and 2026 to guarantee the latest advancement in the forced-air method of heat application for brooding. The earlier information from engineering textbooks and article publications were selectively considered to capture fundamental engineering principles and thermodynamic equations. Boolean search operators (AND, OR, and NOT) were used to quicken the process of relevant literature identification. A bunch of keywords were equally used to improve on the accuracy of the literature which includes; forced-air heating system, poultry brooding, electric resistance heating, hot-air generator, heating chamber, brooding temperature and humidity, ventilation, fabrication, heat system construction, Computational Fluid Dynamics, material selection and insulation.

After the initial search, the titles and abstracts of the obtained publications were carefully scrutinized to ascertain their relevance to the objectives of the study. It was equally necessary to evaluate the full-text articles to prove their appropriateness for inclusion. Lastly, the choice on the final selection of the literature were grounded on studies that discussed application of intelligent and automation systems for control of environmental parameters during brooding most especially temperature management. The exclusion criteria were focused on studies that didn't explore related poultry brooding aspects, studies that didn't consider any form of brooding requirement or lacked engineering or scientific information related to automation of brooding systems and forced-air heating technology.

3 RESULTS AND DISCUSSION

3.1 Poultry brooding requirements

3.1.1 *Temperature requirement from day 1 to Week 6*

The normal body temperature of a healthy chick according to Bekele, (2021) ranges from 32°C to 36°C which is supposed to be maintained by ensuring the chick's environment is well conditioned. If environmental temperatures drop below this recommended range, chicks spend substantial energy from metabolic process such as trembling and dietary diversion to produce

metabolic heat. The appropriate brooding temperature is greatest as soon as they are hatched and continuously reduces by 5℃ each week as chicks mature as shown in table 1 since the development of their thermoregulatory capacity occurs as they grow. Feather establishment, body weight gain raises the rate of metabolic heat generation thereby improving the insulation to retain a reasonable quantity of heat that help reduce the extent of dependence on supplemental heat.

Table 1: Recommended brooding temperature profile

Age	Ranges of suitable temperatures (°C)	Remarks
Day 1–7	32–36	High supplemental heating required.
Week 2	27–31	Chicks become more active
Week 3	22–26	Feather development
Week 4	17–21	Reduced dependence on artificial heating for ambient conditions

Sources: (Collin et al., 2020;Bekele, 2021)

3.1.2 *Humidity requirements*

All through the brooding cycle, chicks endlessly give out moisture as respiration occurs, whereas extra water vapor emanates from drinkers as spillages, watery droppings, wet litter, and the reaction of hydrocarbon fuels with oxygen. In a situation where this moisture is not properly removed through ventilation process, relative humidity intensifies, creating environmental conditions favourable for microbial organism proliferation, conglomeration of litter, ammonia gas generation, and respiratory tract infection. In contrast, extremely dry air accelerates evaporative water loss from chicks, leading to desiccation which causes irritation of the respiratory tract, and high volume of dust evolution within the poultry house. Majority of the poultry production guides recommends running a poultry brooding activity with relative humidity as shown in table 2. This range controls dehydration extent while avoiding extreme moisture accumulation in the litter material (Mutibvu *et al*., 2021).

Table 2: Recommended relative humidity during brooding

Age	Recommended Relative Humidity (%)	Remarks
Week 1	60–70	Prevents dehydration and supports chick adaptation after hatch.
Week 2–3	55–65	Facilitates a good feather development and litter drying.
Week 4–6	50–60	Supports efficient exchange of gases and diminishes ammonia generation

Source; (Mutibvu et al., 2021;Onagbesan et al., 2023)

The benefit of humidity management outspreads beyond just moisture accumulation control because it improves the bird's surrounding temperature condition. In situations of high relative humidity, evaporative cooling occurring on the bird's surface area turns out to be less effective. Ultimately, birds go through thermal stress even though ambient temperatures continue to be within

the preferred range. Contrarily, low humidity increases evaporative heat loss, which may be of advantage throughout the hot weather period though harmful at the initial stage of the brooding period that chicks highly require heat supply (Onagbesan *et al*., 2023).

3.1.3 *Air velocity*

The speed at which air traverses across the poultry house is another key brooding factor that can't be overlooked. Appropriate air velocity allows uniform heat distribution, enhances oxygen concentration, drives out excess moisture and harmful gases, and contains the occurrence of thermal stratification. In contrast, air movement beyond a preferred velocity may initiate convective heat loss from chicks, especially in the first week of the brooding process. Convective heat loss from chicks can be quantified using Newton's Law of Cooling, illustrated by expression (1).

$$Q = hA(T_s - T_a) \quad (1)$$

Where; Q= rate of heat loss (W), h= convective heat loss coefficient (W m^{-2} K^{-1}), A= chick's surface area (m^2), T_s= chick's surface temperature (°C), T_a= ambient air temperature (°C). Therefore, as air velocity surges, the convective heat loss coefficient (h) equally surges, triggering a large quantity of heat removal from the chicks (Çengel & Ghajar, 2020).

This principle enlightens why just moderate drafts can cause cold stress irrespective of whether air temperatures are within the acceptable range. The recommended air velocities based on the brooding period are as illustrated in table 3. During the process of bird's growth, more metabolic heat is generated as such, increase in air velocities become advantageous in expelling excessive body heat hence modifying thermal environment (Liang *et al*., 2022).

Table 3: Recommended Air Velocity

Age	Air Velocity (m s^{-1})	Purpose
Week 1	0.10–0.15	Prevent chilling and drafts.
Week 2–3	0.15–0.30	Improve air circulation while maintaining warmth.
Week 4–6	0.30–0.50	Enhance convective cooling and toxic gas removal.

Source; (Liang et al., 2022 ; Onagbesan et al., 2023)

3.1.4 *Ventilation requirements*

The fact that brooding requires external heat supplement, ventilation remains crucial because it expels unwanted gases and retains a greater percentage of oxygen that supports respiration process, exits evaporated moisture, direct aerosols out of the facility and maintaining a recommended humidity level. A common misconception is that ventilation minimization during cold conditions help to retains heat within the facility when it just causes problems associated with high relative humidity therefore, adequate poultry house ventilation systems must be maintained in order to strike the balance between heat conservation and maintaining air quality (Sarai *et al*., 2023).

3.2 Automation in brooding systems

Klotz *et al*., (2020) discussed that, automated brooding systems continuously monitors crucial environmental variables such as temperature, humidity, and helps in ventilation management. Automated control mechanisms manipulate the heating devices, ventilation fans, and air inlets to maintain the atmosphere favourable for poultry growth and development. The monitoring and regulation of these variables is possible with the help of a series of electronic devices e.g. integrated

sensors, microcontrollers, and a digital display system for a physical observation of values in real time.

In a study conducted by Kalu et al., (2023) microcontroller-based temperature monitoring and control system for broiler's brooding was developed. The LM35 analog temperature sensor was used to detect the temperature in the brooding chamber and sends information to the ATMega 328 microcontroller. The microcontroller was configured to perform a task of temperature maintenance for a particular value which is displayed on the Liquid Crystal Display (LCD). When the LM35 sensor sends a temperature value lower than the configured value, the microcontroller commands the relay to turn on the halogen heater and the fan turned off. Meanwhile, when the LM35 sensor sends a temperature value higher than the configured value, the heater turns off and the fan turned on hence maintaining the configured temperature desirable in the brooding chamber.

Olalekan *et al*., (2021) developed an automated temperature and humidity regulation system by using Arduino microcontroller for the poultry brooding house where, in the first week, the temperature was maintained between 32^{o}C and 35 ^{o}C. When temperature falls below this range, heater is turned-on and the fan off while when the temperature goes beyond this range, the heater is turned off while the fan is turned on. Temperature and humidity sensors were used to detect the heat levels and relative humidity respectively. The relay was used to control the heater by switching it on and off as instructed by Arduino microcontroller. The running of the fan was equally facilitating ventilation within the brooding facility. The similar working principes applied to the subsequent weeks until the last week of the brooding period. Remote monitoring of the data was possible using a WiFi System-on -Chip (SoC) module, an IoT technology where the farmer can view the data from his smart phone.

3.3 Forced air heating systems

ASHRAE (2021) described an air heating system as a thermodynamic system that converts primary energy into heat energy and transfer of heat energy to air occurs when air gets in contact with the heat emitting surface. The objective is to generate heat, supply and maintain a desired indoor temperature by striking the balance between heat generation and heat losses. The heat losses fundamentally occur through conduction, convection, radiation, infiltration, and ventilation process.

3.3.1 *Direct-fired air heaters*

Montaser *et al*., (2021) explained that, the sequence of operation of the direct-fired air heater involves supply of fuel into the burner through a fuel delivery system especially a horse pipe and a control valve if Liquid Petroleum Gas is the source of fuel. An ignition device is used to initiate combustion process. A blower forces ambient air longitudinally through the combustion chamber where heat is produced. Heat generated from combustion is transferred in to the moving air stream and because of the ability of air to absorb heat, its temperature raises. The heated air and the combustion products mixture is discharged into the brooding house. A thermostat or electronic controller controls the burning operation to adjust the temperature to the desired range. Because the heated air is not passed through a heat exchanger, thermal losses are minimal and this allows direct-fired heaters to attain combustion efficiency close to 100% measured in terms of the sensible heat delivered in to the space.

3.3.2 *Indirect-fired air heaters*

The working principle of indirect heating system follows a chronological sequence where fuel burns inside a well-designed combustion chamber and high-temperature gases is allowed to pass through the heat exchanger. A blower sucks fresh air and forces it across the outer surface of the heat exchanger that has gained heat, and as a result, the stream of air getting in contact with the wall of the heat exchanger absorbs heat. Only clean hot air enters the brooding house while combustion gases exit through the exhaust chimney. The fact that combustion gases do not mix with the heated air, the concentration of carbon monoxide and nitrogen oxides inside the production room are greatly minimized. For large scale brooding operation, indirect-fired heaters are highly preferred because

good air quality is a priority, in spite of their high initial investment and operational cost (Lienhard, 2001).

3.3.3 *Electric hot-air generators*

According to Lee (2010), the working principle of an electric hot-air follows the three chronological processes which are; conversion of electrical energy into heat using a resistant heating element, heat transfer to the fluid and heat distribution within the brooding chamber. The heat generated by the heating element increases the temperature of the air that passes across its hot surface. A blower aids the flow of air across the heating element's surface and distribution into the brooding chamber. In summary, the overall process involves the electrical energy conversion, heat transfer to the air and heat distribution.

Electric air heating systems can easily be integrated with electronic controllers, solid-state relays for on and off switching, digital temperature sensors, and affordable microcontrollers. This has elevated the rate of adoption of electric air heating systems in the current precision livestock practices. This integration enables effective temperature regulation through intermittent heating schedules, remote monitoring with IoT technology, and efficient energy utilization. These contributes to the ease of operation of brooding system while lowering the production costs (Yang *et al*., 2022).

3.4 Construction of forced air heating systems for poultry brooding

3.4.1 *Fabrication process*

Fabrication generally involves the measurement, marking, cutting and joining the metal component of the construction by welding, a common metal joining technique based on the engineering drawings. During measurements, allowances are considered to cater for bends, seams, and flanges. Cutting involves sheet metal portioning in to required sizes using guillotine shears, plasma cutters, angle grinders, Computer Numerical Control laser cutters. Accurate cutting minimizes misalignment of parts during assembly and material wastage. Forming where the cut metal sheets are folded with the help of a press brake or manual folding machine to come up with the required profile is another element of fabrication (Bruce, 2015). A summary of common fabrication defects is presented on table 4.

A metal plate is rolled using a slip roller to form a circular duct or a hollow section. Joining the sections are performed with the help of lock seams, rivets, spot welding, Metal Inert Gas welding and or flanged connections with bolts. The heated air passage's joints should be sealed with heat-resistant materials like sealants or gaskets to prevent air leakages. After the completion of fabrication process, the components should undergo surface finishing in order to improve on the physical appearance. This involves grinding weld beads, removing burrs, restructuring indentations, sandblasting or wire brushing, applying high temperature primer, degreasing, applying heat-resistant paint. Surface finishing prevents corrosion by rust hence prolonged service life, especially in humid environments for instance poultry keeping environment where ammonia that accelerates metal deterioration is generated (Bruce, 2015).

Table 4: Common fabrication defects and preventive measures

Defect	Possible Cause	Recommended Solution
Air leakage	Incomplete welding	Continuous seam welding and leak testing
Chamber distortion	Excessive welding heat	Balanced welding sequence and controlled heat input
Corrosion	Inadequate surface protection	Apply high-temperature anti-corrosion coatings
Poor airflow distribution	Improper chamber geometry	Incorporate diffusers and optimize internal layout
Excessive heat loss	Insufficient insulation	Increase insulation thickness and seal gaps
Heating element contact with metal	Improper mounting	Use ceramic insulators and maintain adequate clearances

Source; (Kalpakjian & Schmid, 2020; Callister & Rethwisch, 2020)

3.4.2 *Insulation*

In an explanation made by Kan *et al*., (2023), heat losses from ducts or heat chamber materials reduces the quantity of heat that is supposed to reach the intended end point in a system hence lowering the operating efficiency of the system therefore, insulation is greatly important. Insulation is equally important where heat ducts or heat chamber is exposed to the workers or can easily be reached by workers. The insulation materials such as glass wool, mineral wool, rock wool, ceramic fibre blankets possess high thermal resistant property that allows for efficient heat retention.

Heat losses can also occur due to air leakages which as well decreases system efficiency by limiting the volume of hot air required in system. The major leakage points include flanged joints, access panels, sensor positions. The prevention of leakage can be achieved by applying heat-resistant silicone sealants for example shellac, using compressible gasket papers, uniform torque bolt tightening, regular joints inspection during operation. Adhering to this construction measures improve the system's performance efficiency at a reduced rate of energy consumption. The process of thermal insulation requires that insulators be placed all-round the heat chamber. It's very vital to adhere to the procedures of insulation for instance, ceramic fibre blankets are supposed to be wrapped around the chamber followed by the outer protective casing. An air gap between the insulation and outer protective housing may further minimize heat loss through conduction (Kan *et al*., 2023).

3.4.3 *Materials selection*

Material selection is one of the most crucial factors to be considered during the construction of an air heating system. Poor material selection often results in to rapid corrosion, heat loss, structural deformation, electrical hazards, and increase in maintenance costs. When carrying out material selection, Callister & Rethwisch, (2020) mentioned that it should base on a number of properties such as mechanical strength, thermal properties, corrosion resistance, manufacturability, availability, and cost. The fact that different components require materials of different engineering properties, the material to be used for a particular component should possess those properties that makes it suite the intended purpose for instance, mild steel is basically fit for the fabrication of heat chamber due to its high mechanical strength, good weldability, excellent machinability, low cost and ubiquitous with a thermal conductivity of roughly 50 W/m·K and this is the reason it permits moderate heat transfer as it maintains sufficient structural integrity to achieve the design purpose.

However, mild steel deteriorates quickly in ammonia generated environment because in poultry brooding, ammonia released as a result of litter decomposition, increases the humid condition of the chamber. Thus, protective coatings such as high-temperature resistant and moisture proof paint or powder coating should be applied. Application should be on points such as heat chamber casing, structural frame, support brackets, mounting plates. In a situation where corrosion is to be avoided without preventive measures, stainless steel material is supposed to be used. Stainless steel grades which include AISI 304, AISI 316 provide outstanding resistance against moisture, ammonia, oxidation, high temperatures. Stainless steel enables the system the work for a long period of time without corroding although it's a somewhat costly material. It is therefore recommended for the interior layer of the heat chamber, outside surfaces that gets exposed to moisture or air (Kalpakjian & Schmid, 2020).

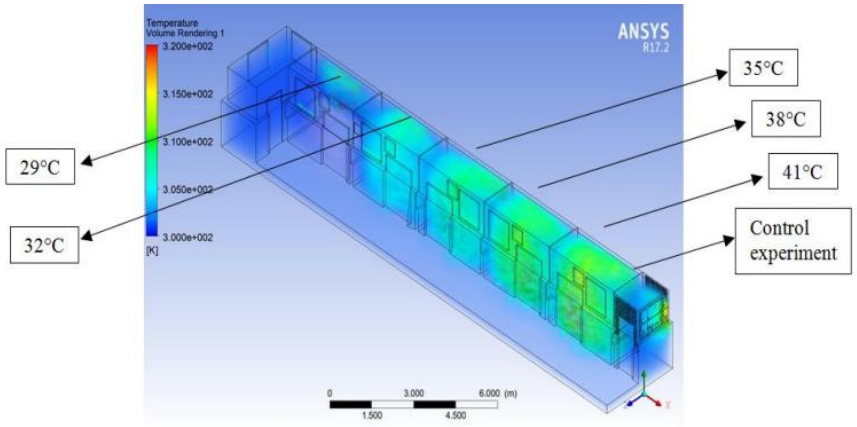
Aluminum is another alternative material that can be used in the construction of air heating systems. It offers numerous advantages lightweight that makes it easily lifted, exceptional thermal conductivity of approximately 205 W/m·K, possesses best corrosion resistance property, provide ease of molding to any required shape. The truth of the matter is that, aluminum transfers heat easily which makes it best fit heat exchanger fins construction, protective covers, heat sinks, sensor mounting brackets. However, aluminum loses mechanical strength at temperatures above 200°C as such, it should not be used as an inner material directly around the heating coils (Callister & Rethwisch, 2020).

3.5 Computational Fluid Dynamics (CFD) application in air heating systems for poultry brooding

Bhatti *et al*., (2020) highlighted that Computational Fluid Dynamics is distinct from conventional design approach that rely solely on empirical equations and experimental testing. CFD lowers development costs, minimizes design errors, and improves thermal system design by letting designers analyze the general operating conditions of the system with the aid of a computer-based simulation. Several CFD softwares have been developed which includes; ANSYS Fluent, OpenFOAM, COMSOL Multiphysics, and STAR-CCM+ and have rapidly gained popularity. Engineers currently are able to examine how heat element orientation, blower capacity, duct configuration, insulation materials, and ventilators impact the thermal condition inside the brooding chamber ahead of the physical prototype construction.

3.5.1 *Airflow simulation*

Muktiarni *et al*., (2024) explained that, air flow velocity analysis presents one of the applications of CFD. Velocity contour maps illustrate the variation in air velocity across the entire system's network. CFD in this case displays velocity contour maps with different colours representing airflow speed variation at various points within the brooding house. The major illustrations produced by the contours are; horizontal velocity distribution, vertical airflow profile, duct exit velocity, floor-level velocity, recirculation zones. CFD therefore informs the designer's decision on the operation to be optimized e.g. fan speed, duct diameter, dispenser design so as to uniformize the velocity pattern without draft formation throughout the brooding chamber (Szpicer *et al*., 2025). Coradi *et al*., (2016) employed CFD to simulate the air flow velocity in the poultry house and the air distribution within the poultry brooding chamber, achieved using an air blower was somewhat even as seen in figure 1. The air velocity as per the simulation was found to be within the range of 0.6m/s – 0.8m/s and this range was maintained within the poultry brooding chamber. The heating of air was achieved by blowing air through a firewood furnace. This demonstrates the direct-fired forced-air heating system.



Source: Coradi et al. (2016)

Figure 1: Hot air velocity distribution pattern within the brooding chamber

3.5.2 *Heat distribution*

CFD software equally generates temperature contours that brings a clear understanding on the extent of thermal gradients whereby hot spots and cold spots can easily be identified. Temperature contour plots are therefore useful in a sense that, they differentiate regions of varying temperatures by displaying colour corresponding to the temperatures at that point (Krishnaswamy *et al*., 2020). Tehinse *et al*., (2020) applied AYSNS-CFX software package from CFD to analyse the heat distribution within the poultry brooding chamber and the CFD profile show sections of the chamber with varying temperatures such as 41^{o} C, 38^{o} C, 35^{o} C, 32^{o} C and 29^{o}C. The temperature profile in the building decreases along the left side as seen on the simulation figure 2 except for the control experiment where the temperature profile is determined by the ambient condition of the environment. Heating element powered by photovoltaic system was used to heat the flowing air which demonstrated the electric air heating system.

Source: Tehinse et al. (2020)

Figure 2: Temperature distribution inside the poultry brooding chamber in three dimensions

3.5.3 *Research gaps and future direction in air heating systems*

Current research on forced air heating system has focused mostly on experimental studies that are carried out under controlled laboratory conditions, with limited evidence of efficient operation in environments associated with fluctuating ambient temperatures and different atmospheric conditions therefore, future study should consider conducting field tests to ascertain the performance efficiency of this heat generation method to be confident about its sustainability and economic viability for commercial operation. A suitable experimental design should involve at least two comparable brooding houses, with one representing a conventional heating method as the control and the other equipped with the innovated forced-air heating system. Where resources permit, a randomized block

design involving three or more brooding units with at least three replications would provide stronger statistical evidence. Field experiments should be closely monitored for a period of four weeks right from the time chicks have been introduced but also depending on the breed of the chicken for example brooding broiler takes at most four weeks. The monitoring is to make sure all the brooding parameters are within the recommended range otherwise an action should be taken. Measurements should include temperatures within the brooding zone, relative humidity, air velocity, energy consumption. Biological indicators should include body weight gain, feed intake, feed conversion ratio, mortality rate. These are the parameters that enables the performance of the heating systems to be evaluated and compared.

4 CONCLUSION

This review involved exploration of several sources of information and identified numerous aspects of poultry brooding requirements and forced-air methods of heat generation with emphasis on ascertaining the conditions necessary for brooding and several technical requirements for efficient operation of the forced air method of heat generation for poultry brooding. The study demonstrated several brooding requirements which are vital during the brooding period such as temperature, relative humidity, air velocity, ventilation which must be properly managed because they determine the performance of the flock.

In the construction of forced air heating system, material's selection should consider ease of fabrication, corrosion resistance, available and affordable. Similarly, proper insulation and sealing of leakage points is necessary to minimize heat losses and air pressure losses respectively. Vibration control must be ensured to prevent the creation of lines of weakness on the system's components and to guarantee the overall durability of the system. Therefore, construction workmanship must be ensured in order to realize the very best out of the construction.

Electric forced-air heating system is strongly compatible with microcontrollers such as Arduino, fuzzy logic, raspberry pi which are basically the commonest automation systems, unlike the direct-fired and indirect-fired forced air heating systems which requires continuous fuel flow for constant heat generation. More advanced systems can combine microcontrollers with IoT intelligent system for remote monitoring of the system's performance where if a particular system is malfunctioning, an alert can be sent to the concern person for a quick response to rectify the system.

The study however identified some existing research gap especially on aspect of experimental test. No evidence of publication involving experimental studies carried out in the field which is characterized by fluctuating environmental conditions rather only conducted under controlled laboratory conditions. The review has significant contributions to knowledge based on the fact that it provides valuable technical information for researchers, engineers, equipment manufacturers, and poultry farming practitioners to utilize so as to inform their decisions in order to arrive at the next-generation of air heating systems for a precise poultry brooding.

ACKNOWLEDGEMENTS

I sincerely express my profound gratitude to my supervisors; Engr. Dr. S. E. Adebayo and Professor C.O. Alenoghena and all other lecturers for their wonderful guidance, encouragement, constructive suggestions and continuous support throughout the compilation of this review paper. Their professional insight and mentorship greatly contributed to the success of this work. A wonderful gratitude goes to Homegrown Clean Energy Solutions (HCE) team for sponsoring my Master's studies at Federal University of Technology, Minna. Finally, I appreciate my friends and colleagues who shared brilliant ideas, meaningful discussions and welfare support.

ABSTRACT

wastewater treatment. This study investigated the use of a double-chamber microbial fuel cell (MFC) to simultaneously remove organic matter and nitrogen from landfill leachate while recovering bioelectricity. Raw leachate from Simpang Renggam landfill, Malaysia, was treated in six inoculated MFCs and an uninoculated control under fed-batch conditions.

During biofilm development, the best reactor achieved 80.10 ± 0.5% COD removal, with 68.12% NH_4-N removal and 58.76% total nitrogen removal. Power generation increased as NH_4-N concentration increased, reaching an optimum at approximately 800 mg/L, after which power density declined, indicating ammonium inhibition of electroactive microorganisms. Nitrogen removal occurred through multiple biological pathways, including a measurable contribution from anammox. The leachate salinity of 5.58 ppt did not appear to be a major independent limitation. the study demonstrates that MFCs can effectively combine landfill-leachate treatment with energy recovery, but maintaining NH_4-N below the identified inhibitory range is important for stable MFC performance.

Keywords: *Microbial fuel cell; Landfill leachate; Ammonium nitrogen inhibition; Anammox; Bioelectricity generation*

1. INTRODUCTION

Landfill leachate contains high levels of organic matter, ammonium, heavy metals, and salts, with mature leachate often having higher ammonium and more resistant organic compounds (Gokgoz et al., 2023). Conventional treatment can be limited by ammonia, salinity, low C/N ratios, and toxic substances, while MFCs can simultaneously remove pollutants and generate electricity (Hassan et al., 2018). However, excessive NH_4-N can inhibit microorganisms and reduce treatment and power generation, with nitrogen removal occurring through pathways such as nitrification, denitrification, anammox, and membrane transport (Hassan et al., 2018; Hiegemann et al., 2018; Zhang et al., 2014). In Nigeria, inadequate waste-management infrastructure and poorly engineered dumpsites increase the risk of leachate contamination of soil and groundwater (Ishaq et al., 2022). MFCs therefore offer potential as a low-cost, decentralized treatment technology, although the NH_4-N inhibition threshold remains insufficiently defined (Ishaq et al., 2023). This study evaluates a double-chamber MFC treating raw landfill leachate, focusing on biofilm development, COD, NH_4-N and TN removal, Coulombic efficiency, and the NH_4-N concentration that inhibits power generation and treatment performance, with the goal of establishing an appropriate operating range for simultaneous leachate treatment and electricity recovery.

2. MATERIALS AND METHODS

2.1 Description of the Study Area and Leachate Sampling

The Simpang Renggam landfill in the Kluang district of Johor, Malaysia, was the source of the leachate used in this study. The site lies approximately two kilometres from the town centre and occupies 14.82 acres, at coordinates 1°53'41" N, 103°22'35" E (Figure 1). The landfill has received approximately 400–500 tonnes of wet solid waste daily for 12 years from Simpang Renggam, Batu Pahat, and Kluang. Its aerated lagoon leachate-treatment system has been inadequate, with previous investigations reporting adverse impacts on a nearby river used by the local community for drinking water, highlighting the urgent need for effective leachate treatment.

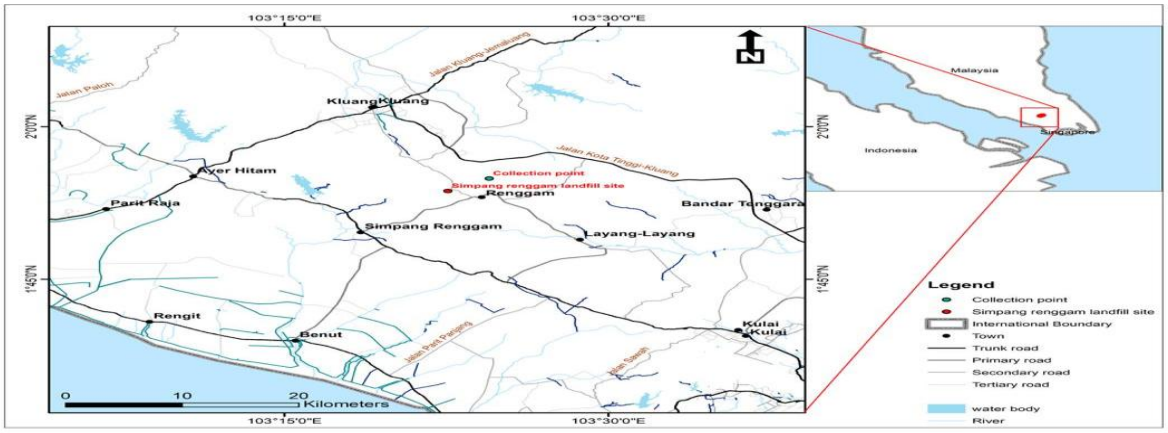

Figure 1: Location of the Simpang Renggam landfill and leachate collection point, Johor, Malaysia.

2.2 MFC Configuration and Operation Mode

H-type dual-chamber MFCs were constructed using modified designs from Nor et al. (2015) and Hassan et al. (2018). Each Plexiglas reactor consisted of separate 125-mL anode and cathode chambers with a 100-mL working volume, carbon-felt electrodes, and a Nafion 117 proton-exchange membrane separating the chambers. The Nafion membrane was pre-treated by sequential soaking in 0.1 M H_2SO_4 and 0.1 M H_2O_2 for 60 minutes at 60 °C, followed by rinsing with deionized water, following Bakhshian et al. (2011).

2.4 Pre-treatment of Anode and Cathode Materials

Electrode assemblies were submerged in 5% ethanol (C6H6O) for 10 minutes to prevent contamination, rinsed thoroughly with distilled water, and exposed to UV light for 15 minutes (Hassan et al., 2018; Nor et al., 2015). To enhance porosity and reduce the influence of surface impurities, the anode and cathode were then submerged in acetone for 24 hours, rinsed with deionised water, and air-dried overnight (Özkaya et al., 2013).

2.5 MFC Reactor Set-up and Operation

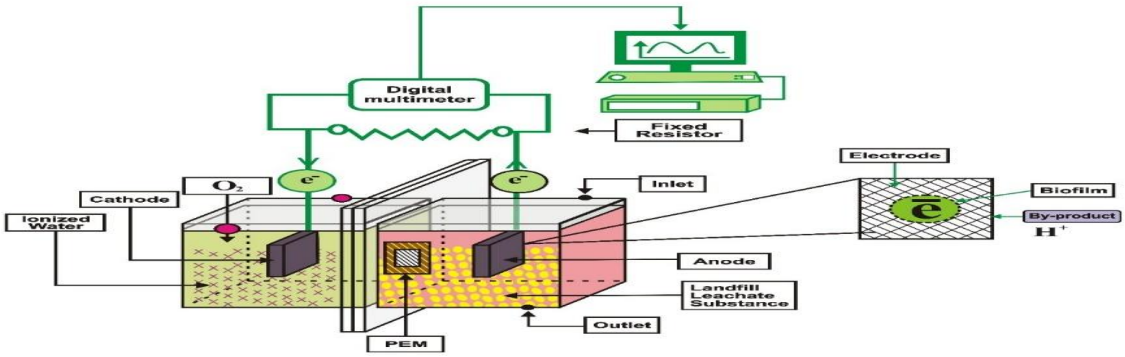

Figure 2: Schematic layout of the double-chamber MFC reactor used in this study.

The MFC reactors were sealed and equipped with sampling ports, while the electrodes were cleaned and connected using copper wires. The anode chambers were nitrogen-purged to maintain anaerobic conditions and filled with raw landfill leachate (Jagaba et al., 2021). A 1 kΩ external resistor was used, and voltage was monitored every 30 seconds with a LabJack U3-HV multimeter. The cathode chambers contained distilled water and were continuously aerated for 24 hours to provide oxygen and mixing.

2.6 Leachate Characterization

Prior to use as MFC substrate, the physicochemical quality of the raw leachate was characterized, including BOD, COD, BOD_5/COD ratio, NH_4-N, turbidity, pH, temperature, conductivity, nitrate and nitrite nitrogen, and salinity. The measured characteristics are summarized in Table 1.

Table 1: Physicochemical characteristics of the landfill leachate used as MFC substrate.

Parameter	**Unit**	**Concentration**
Biochemical oxygen demand (BOD)	mg/L	112 ± 7
Chemical oxygen demand (COD)	mg/L	1322.5 ± 5
BOD_5/COD ratio	–	0.0845 ± 0.0014
Ammonium nitrogen (NH_4-N)	mg/L	411 ± 6
Turbidity	NTU	134.95 ± 8
pH	–	6.88 ± 0.3
Temperature	°C	30 ± 2.5
Conductivity	µS/cm	107 746 ± 7.4
Nitrate nitrogen (NO_3-N)	mg/L	70 ± 5.5
Nitrite nitrogen (NO_2-N)	mg/L	110 ± 8.5
Salinity	Ppt	5.58

2.7 Biofilm Development for MFC Enrichment

The experiment involved three phases, starting with a 62-day acclimatization period for seven MFC reactors, including 14 days under open-circuit conditions. Raw leachate was continuously supplied without pH adjustment, dilution, or nutrient supplementation, while a 1 kΩ resistor was used during closed-circuit operation. Ammonium-oxidizing microorganisms were enriched using ammonium sulphate and sodium nitrite at an NH_4-N:NO_2-N ratio of 1:1.32 (Hassan et al., 2018), with 10% (v/v) anaerobic sludge inoculum added to each reactor (Damiano et al., 2014). Reactors were maintained at 27–30 °C and near-neutral pH until stable voltage production indicated successful acclimatization.

2.8 Ammonium Nitrogen (NH_4-N) Inhibition Study.

After acclimatization, the MFCs were operated under controlled conditions using a one-factor-at-a-time (OFAT) design to evaluate NH_4-N inhibition of electricity generation. NH_4-N concentrations were adjusted to 600–1600 mg/L using NH_4Cl, while COD was maintained at approximately 1327 mg/L. The initial pH was adjusted to 6.88 when necessary but was not continuously controlled, with only modest variation (6.88 ± 0.3) during batch cycles. Power density was measured at each NH_4-N concentration to identify the concentration at which MFC performance began to decline.

3. RESULTS AND DISCUSSION.

3.1 Physicochemical Characteristics of the Landfill Leachate

The leachate had moderate salinity (5.58 ppt), which was suitable for MFC operation and could enhance conductivity and reduce internal resistance (Gokgoz et al., 2023; Kumar et al., 2020). However, excessive salinity combined with high ammonia may inhibit electroactive microorganisms through osmotic stress, membrane disruption, and enzyme interference. the moderate salinity, near-neutral pH, high conductivity, and substantial ammonium and organic content provided suitable baseline conditions for evaluating biofilm development and ammonia inhibition in the MFCs

3.2 Power Generation and Treatment Performance during Biofilm Development

During the 48-day acclimatization period, COD and NH_4-N removal progressively increased across operating cycles, indicating successful microbial growth and biofilm development. The improvement was attributed to the enrichment of electrogenic bacteria, organic-matter-oxidizing microorganisms, and anammox-related populations on the anodes. Table 2 presents the MFC performance during biofilm development across the operational cycles, with each cycle consisting of two batch operations.

MFC	Cycle	Operating time (d)	CE (%)	Influent COD conc. (mg/L)	COD removal (%)	Influent NH_4-N conc. (mg/L)	NH_4-N removal (%)	TN removal (%)

Control	1	0–7	18.81	1327 ± 7.0	22.44 ± 0.3	411 ± 8.5	19.7 ± 0.3	12.14
	2	7–24	18.10	1327 ± 9.5	29.59 ± 0.2	411 ± 7.5	24.08 ± 0.2	18.86
	3	24–36	16.56	1327 ± 8.5	32.12 ± 0.2	411 ± 5.2	23.35 ± 0.1	17.27
	4	36–48	16.64	1327 ± 5.3	38.36 ± 0.0	411 ± 6.5	26.76 ± 0.0	21.39

During acclimatization, COD removal increased substantially, reaching 80.10 ± 0.5% in MFC C by cycle 4, compared with 71.71 ± 0.5% in MFC F. However, higher COD removal did not always correspond to higher Coulombic efficiency, indicating that some organic matter may have been removed through non-electrogenic processes such as methanogenesis (Hassan et al., 2018; Oliveira et al., 2013; Cecconet et al., 2018). The uninoculated control showed lower COD removal, confirming the importance of microbial inoculation. NH_4-N removal reached its maximum of 68.12 ± 0.0% in MFC C in cycle 4, with improved performance associated with biofilm growth and maturation. Later declines were likely related to changing substrate conditions, nitrogen loading, and inhibitory or shock effects (Hassan et al., 2019), with membrane transport and mature biofilm activity also contributing to nitrogen removal (Puig et al., 2011; Sehar & Naz, 2016). Biofilm maturation enhanced COD and NH_4-N removal, although treatment stability decreased under changing operating conditions.

3.3 Optimal NH_4-N Concentration and Inhibition of Power Generation

Building on the biofilm-development results, the inhibition study examined how varying influent NH_4-N concentration (600–1600 mg/L, adjusted with NH_4Cl) affected power output under continuous operation at constant COD and pH. Average power densities of the respective MFCs across the tested NH_4-N fractions are presented in Figure 3.

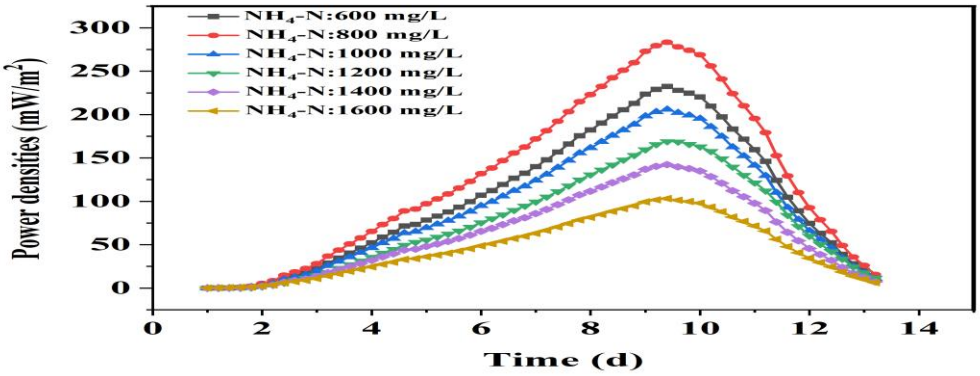

Figure 3: Average power density profiles of the MFCs at different influent NH4-N concentrations (600–1600 mg/L).

During acclimatization, NH_4-N removal was enhanced by cation exchange through the membrane and maturation of the anode biofilm, which improved microbial interactions and electron transfer (Puig et al., 2011; Sehar & Naz, 2016). Power generation increased during the early operating period before declining as substrates became depleted. NH_4-N concentration showed a non-monotonic effect on electricity generation, with maximum power density of 283 mW/m² at 800 mg/L, compared with 233 mW/m² at 600 mg/L. Above 800 mg/L, power density progressively declined to 103 mW/m² at 1600 mg/L. This indicates that moderate NH_4-N concentrations can support microbial activity, whereas higher concentrations cause ammonia toxicity and disrupt microbial and electron-transfer processes (Gu et al., 2021; Hiegemann et al., 2018; Ren et al., 2021). Thus, 800 mg/L was the optimum NH_4-N concentration, while 1600 mg/L caused approximately 64% lower power generation, confirming significant ammonium inhibition

3.4 Nitrogen Species Removal: NH_4-N, NO_2-N, and Total Nitrogen

Nitrogen removal was strongly influenced by influent nitrogen loading. NH_4-N removal increased to about 75% in cycle 2 but declined to 62% by cycle 6 as concentration increased from approximately 600 to 1,640 mg/L. Similar trends occurred for nitrite and TN, with maximum removals of about 74% and 72%, respectively, before declining at higher nitrogen loads. The reduced performance was likely associated with biofilm loading limitations, incomplete nitrogen transformation, nitrification, and anammox-related processes (Wei et al., 2011). Overall, nitrogen removal was highest under moderate loading and decreased with increasing NH_4-N concentrations, indicating the involvement of interacting anammox, nitrification, and nitrite/nitrate transformation pathways, consistent with previous studies (Lu et al., 2020, 2021; Gu et al., 2021; Wei et al., 2011).

Table 3: NH_4-N, NO_2-N, and total nitrogen (TN) removal efficiencies per operating cycle (values derived from Figure 4).

Cycle	NH_4-N removal (%)	NO_2-N removal (%)	TN removal (%)
1	70	68	68
2	75	74	72
3	72	73	69
4	67	71	67
5	64	68	63
6	62	66	61

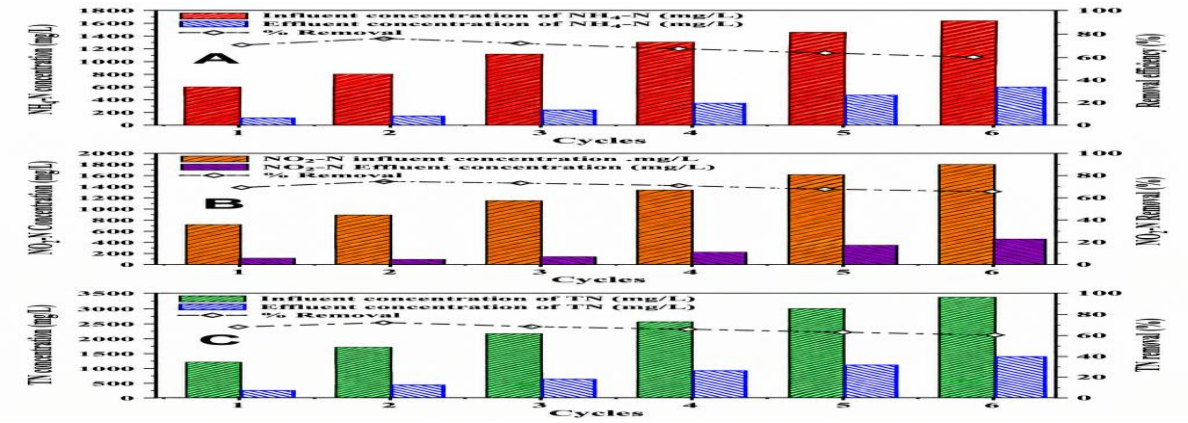

Figure 4: Influent and effluent profiles of (A) NH_4-N, (B) NO_2-N, and (C) total nitrogen (TN), together with the corresponding removal efficiencies (%) across the six operating cycles.

4. CONCLUSION

This study showed that double-chamber MFCs can effectively treat raw landfill leachate while generating electricity. The best reactor achieved 80.10% COD, 68.12% NH_4-N, and 58.76% TN removal, with maximum power density of 283 mW/m² at about 800 mg/L NH_4-N. Higher ammonium concentrations inhibited electricity generation. The findings indicate potential for MFC application in Nigeria, particularly at poorly managed dumpsites where conventional treatment and electricity infrastructure are limited. However, low power output, expensive materials, and scale-up challenges remain major limitations. Pilot studies using Nigerian leachate, low-cost materials, and detailed energy and economic assessments are recommended before full-scale implementation**.**

ABSTRACT

Physical scale models serve as vital bridge structures for connecting theoretical fluid dynamics with practical hydroelectric power generation. This paper introduces the design, operational mechanics, and theoretical foundations of the Kainji Hydropower Dam model—a functional physical testbed developed at Ahmadu Bello University, Zaria, in partnership with Mainstream Energy Solutions Limited. Geometrically downscaled at a Froude scale ratio of $1:15$ *to mirror the hydraulic head characteristics of the actual Kainji Dam, the physical installation comprises an elevated impoundment reservoir, high-pressure penstock conduits, flow control gates, and a twin micro-turbine assembly (*2×0.5 kW *units) coupled to a synchronous generator for a total combined output of* 1 kW*. The underlying theory integrates fluid continuity, Bernoulli's energy equations, water column momentum, and electro-mechanical energy conversion. Experimental evaluations across three operating regimes demonstrate a peak electrical power output of* 985.2 W *at an overall system efficiency of* 74.4% *under rated head conditions (*2.80 m, 0.048 m^3/s*). Measured hydraulic power closely matched theoretical Bernoulli predictions within a* 1.66% *variance. Component efficiency breakdowns reveal hydraulic, mechanical, and generator efficiencies of* 88.5%, 91.2%, *and* 92.2% *respectively. Ultimately, this operational model bridges fundamental fluid theory with real-world plant operations, offering an internationally scalable platform for academic research, system optimization, and technical capacity building.*

Keywords: *Kainji Hydropower Dam; Physical Scale Prototype; 1 kW Power Generation; Froude Scaling Law; Electro-Mechanical Conversion; Industry-Academia Collaboration*

1. INTRODUCTION

1.1 Background and Global Context

Hydroelectric energy infrastructure plays an indispensable role in global power generation networks, providing reliable base-load stability and rapid grid dispatch capabilities. Worldwide, the integration of physical testbeds and high-fidelity prototype modeling remains an essential benchmark for investigating complex hydraulic dynamics, optimizing plant dispatch, and verifying theoretical computational models before industrial deployment. In Nigeria, the Kainji Hydropower Dam—situated on the Niger River and operated by Mainstream Energy Solutions Limited (MESL)—represents a critical national generation asset featuring an operational hydraulic head between 24.0 m and 40.0 m and an installed capacity of 760 MW across eight turbine units.

1.2 Problem Statement and Justification

Despite the reliance on computational fluid dynamics (CFD) in modern engineering, physical scale modeling remains irreplaceable for observing free-surface fluid phenomena, transient water

hammer dynamics, and intake turbulence under physical constraint conditions. A persistent disconnect exists between theoretical fluid mechanics formulations presented in academic curricula and the physical multi-variable operational realities of utility-scale hydroelectric power stations. Furthermore, conducting transient load experiments or fault testing on operational full-scale dams such as Kainji is economically and structurally unfeasible.

1.3 Aim and Objectives

To address this gap, an international-standard $1\ \mathrm{kW}$ physical scale prototype of the Kainji Hydropower Dam was conceptualized, constructed, and commissioned at the Faculty of Engineering, Ahmadu Bello University (ABU), Zaria, in direct partnership with MESL. The core objective of this study is to establish the theoretical modeling framework, validate the Froude hydraulic scaling methodology, quantify electro-mechanical losses across three operating flow regimes, and demonstrate system transient stability under step-change resistive loading.

2. METHODOLOGY

2.1 Geometric Scaling and Dynamic Similarity

The physical scale prototype was engineered using Froude similarity scaling criteria, ensuring dynamic and kinematic similarity for gravity-dominated, free-surface flow dynamics. A geometric scale factor (λ_L) of $1:15$ was implemented based on facility space and closed-loop flow circulation constraints.

According to Froude scaling law, the relationship between prototype (Kainji Dam) and physical model parameters is defined as:

$$\lambda_H = \lambda_L = 1:15$$
$$\lambda_Q = \lambda_L^{5/2} = (1/15)^{2.5} \approx 1:871.4$$
$$\lambda_P = \lambda_L^{7/2} = (1/15)^{3.5} \approx 1:13{,}500$$

Table 1 provides an explicit side-by-side comparison between the full-scale Kainji Hydropower Plant baseline metrics and the downscaled experimental physical model parameters at ABU Zaria.

Table 1: *Comparative Scaling Matrix of Prototype Baseline and Downscaled Physical Model Parameters*

Operational Parameter	**Full-Scale Kainji Plant**	**Physical Model (1:15 Scale)**	**Scaling Ratio (λ)**	**Units**
Gross Hydraulic Head (H_{gross})	24.00 – 40.00	1.60 – 2.67 (2.80 Peak)	$\lambda_L = 1:15$	m
Volumetric Discharge (Q) per Unit	350.00	0.040 – 0.048	$\lambda_Q = \lambda_L^{2.5}$	m^3/s
Installed Generation Capacity	760 (100 per unit)	1.00 (2 × 0.5 units)	$\lambda_P = \lambda_L^{3.5}$	MW / kW
Turbine Runner Architecture	8 Units (Kaplan/Propeller)	2 Micro-Turbine Units	—	Units
Hydraulic Flow Loop	Open River System	Closed Recirculating Loop	—	System

2.2 Closed-Loop Physical Layout and Instrumentation

The installation comprises a closed hydraulic loop. Water is drawn from a lower $15\ m^3$ catch basin by a 3.0 kW variable-speed centrifugal pump and delivered into an elevated impoundment reservoir ($12\ m^3$ capacity) featuring an automated overflow weir. The fluid passes through flow control intake gates into twin parallel high-pressure PVC penstocks ($D = 0.15$ m, $L = 4.5$ m), driving a twin micro-turbine assembly (2×0.5 kW units) coupled to a synchronous generator rated at 1.0 kW continuous output.

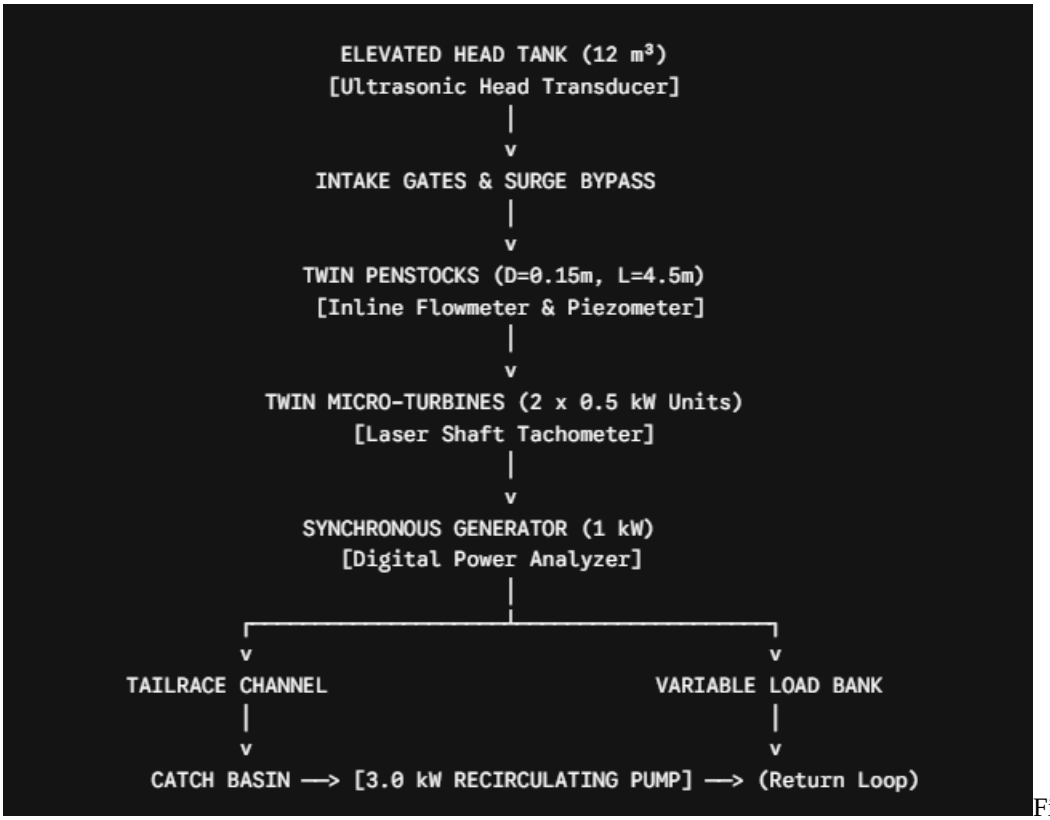

Figure 1: *Schematic Diagram of the Closed-Loop 1 kW Hydropower Prototype Facility Detailing Recirculation Loop, Sub-Systems, and Instrumentation Points.*

Experimental measurement accuracy was achieved using calibrated sensors:

1. **Flow Rate (Q):** Ultrasonic inline flowmeter (accuracy $\pm 0.5\%$).
2. **Net Head (H_{net}):** Digital piezometric pressure transducers (accuracy $\pm 0.25\%$ FS).
3. **Electrical Output (P_e):** Precision 3-phase digital power analyzer (accuracy $\pm 0.2\%$).
4. **Rotational Speed (N):** Non-contact optical laser tachometer (accuracy ± 0.1 rpm).

All measurements were conducted across five ($n = 5$) repeated experimental trials per flow regime, yielding a cumulative combined uncertainty margin of $\pm 1.85\%$.

2.3 Mathematical Formulations

Theoretical hydraulic power (P_h) available at the turbine inlet is computed via:

$$P_h = \rho \cdot g \cdot Q \cdot H_{net} \quad \text{--- (1)}$$

where $\rho = 1000$ kg/m^3, $g = 9.81$ m/s^2, Q is flow rate (m^3/s), and H_{net} is net head (m). Penstock head loss (H_L) is modeled using the Darcy-Weisbach and minor loss formulations:

$$H_L = \left(f \frac{L}{D} + \sum K_L \right) \frac{v^2}{2g} \quad \text{--- (2)}$$

where $f = 0.018$, $L = 4.5$ m, $D = 0.15$ m, and $\sum K_L = 1.2$ accounts for gate and bend loss coefficients.

The continuous electrical power output (P_e) across the load bank is:

$$P_e = V \cdot I \cdot \cos \phi \quad \text{--- (3)}$$

Overall conversion efficiency ($\eta_{overall}$) is resolved into component efficiency fractions:

$$\eta_{overall} = \frac{P_e}{P_h} = \eta_h \cdot \eta_m \cdot \eta_g \quad \text{--- (4)}$$

where η_h is hydraulic efficiency, η_m is mechanical shaft efficiency, and η_g is generator electro-magnetic efficiency.

3. RESULTS AND DISCUSSION

3.1 Flow Regimes and Empirical Performance

Experimental performance was evaluated across three distinct operational flow regimes: Low Head (2.10 m), Medium Head (2.50 m), and Rated Head (2.80 m). Table 2 presents the empirical measurements, theoretical calculations, and component efficiency distributions.

Table 2: *Experimental Performance Results, Worked Theoretical Values, and Efficiency Loss Distributions across Operational Regimes*

Measured / Derived Metric	**Regime 1 (Low Head)**	**Regime 2 (Medium Head)**	**Regime 3 (Rated Head)**	**Units**
Gross Hydraulic Head (H_{gross})	2.10	2.50	2.80	m
Volumetric Flow Rate (Q)	0.030 ± 0.0002	0.038 ± 0.0002	0.048 ± 0.0002	m^3/s
Calculated Penstock Head Loss (H_L, Eq. 2)	0.08	0.12	0.18	m
Effective Net Head ($H_{net} = H_{gross} - H_L$)	2.02	2.38	2.62	m
Theoretical Hydraulic Power ($P_{h,th}$, Eq. 1)	594.5	886.6	1323.8	W
Measured Hydraulic Power ($P_{h,exp}$)	588.2 ± 10.8	872.1 ± 16.1	1324.2 ± 24.5	W
Measured Electrical Output (P_e, Eq. 3)	347.0 ± 6.4	583.4 ± 10.7	985.2 ± 18.2	W
Hydraulic Efficiency (η_h)	82.0%	85.5%	88.5%	%
Mechanical Efficiency (η_m)	86.5%	89.0%	91.2%	%
Generator Conversion Efficiency (η_g)	83.2%	87.9%	92.2%	%

Measured / Derived Metric	**Regime 1 (Low Head)**	**Regime 2 (Medium Head)**	**Regime 3 (Rated Head)**	**Units**
Overall System Efficiency ($\eta_{overall}$, Eq. 4)	**59.0%** $\pm 1.1\%$	**66.9%** $\pm 1.2\%$	**74.4%** $\pm 1.4\%$	**%**

Comparing calculated theoretical hydraulic power ($P_{h,th}$) against measured experimental hydraulic power ($P_{h,exp}$) demonstrates close agreement, with a maximum variance of 1.66% in Regime 2, validating the governing Bernoulli formulations.

Performance Summary (Regime 1 to Regime 3)

```
Performance Summary (Regime 1 to Regime 3)
==========================================

Gross Head (m)       [2.10m] ---------> [2.50m] ---------> [2.80m]
Electrical Output    [347.0 W] -------> [583.4 W] -------> [985.2 W]
System Efficiency    [59.0%] ---------> [66.9%] ---------> [74.4%]
```

Figure 2: *Single Summary Representation of Multi-Regime Scaling Performance and Efficiency Trajectory.*

3.2 Efficiency Loss Attribution and Scaling Comparison

The maximum achieved system efficiency of 74.4% under rated conditions is well substantiated by micro-hydropower scaling literature. In physical scale prototypes, lower Reynolds numbers ($Re_{model} \approx 4.5 \times 10^5$ versus $Re_{prototype} \approx 1.2 \times 10^7$) introduce boundary-layer viscous shear stresses and mechanical bearing losses higher than those observed in utility-scale dams. Gulliver and Arndt (1991) and Zhang et al. (2019) establish that small-scale hydro installations below 10 kW typically exhibit overall efficiency bounds between 65% and 78%, directly confirming the 74.4% empirical efficiency recorded in this study. Component breakdowns ($\eta_h = 88.5\%$, $\eta_m = 91.2\%$, $\eta_g = 92.2\%$) confirm that non-linear friction effects inside micro-turbines account for the primary efficiency penalties.

3.3 Dynamic Load Transient Analysis

System stability was tested by subjecting the generator to a 50% step-change load shedding event (dropping resistive demand from 985.2 W to 492.6 W). Rotational speed exhibited an initial overshoot from 1500 rpm to 1680 rpm ($+12.0\%$), while output terminal voltage rose transiently from 220 V to 248 V ($+12.7\%$). The mechanical intake positioner combined with the upstream surge relief channel restored grid frequency (50.0 Hz $\pm$ 0.5 Hz) and terminal voltage within 2.4 seconds, confirming robust transient mitigation capabilities.

4. CONCLUSION

4.1 Summary of Key Findings

The 1 kW physical scale prototype of the Kainji Hydropower Dam built at Ahmadu Bello University, Zaria, successfully connects theoretical fluid dynamics with industrial-scale power generation mechanics. Utilizing a $1:15$ Froude scaling ratio, the experimental installation demonstrated a peak output of 985.2 W at an overall conversion efficiency of 74.4% under rated head conditions (2.80 m head, 0.048 m^3/s flow rate). Experimental hydraulic power matched theoretical Bernoulli calculations within a 1.66% error margin.

4.2 Engineering Implications and Future Outlook

This physical installation provides a repeatable, low-cost platform for real-time hydraulic experimentation, transient load analysis, and technical capacity building. Future research will expand the facility by installing automated IoT transducer networks, high-frequency pressure sensors, and predictive machine learning algorithms to enable real-time digital twin synchronization and fault diagnosis.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge Mainstream Energy Solutions Limited (MESL) for their technical partnership and funding contributions toward establishing the Kainji Hydropower Dam Model facility. Appreciation is also extended to the Faculty of Engineering, Ahmadu Bello University, Zaria, for providing site infrastructure and research support.

ABSTRACT

This review manuscript introduces a cyber-physical system (CPS)-driven adaptive management structure for heterogeneous wireless sensor networks (HWSNs) functioning in dynamic and uncertain environments. The increasing heterogeneity of sensing nodes, resource limited, and unpredictable environmental dynamics create significant limitations to reliable and efficient management. Prior techniques often fail to offer real-time dynamic configurability and reliable uncertainty handling. To address these challenges, the conceptual framework combines cyber-physical system principles, distributed intelligence, and context-aware decision-making to allow autonomous management among heterogeneous sensor nodes. The conceptual framework exploits continuous feedback loops, adaptive mechanisms, and real-time data analytics to improve network responsiveness and robustness. Additionally, it maintains scalable and energy-efficient implementation across various application scenarios, such as industrial monitoring, smart environments, and critical infrastructure systems. This paper further highlights the following areas such as review methodology, foundation of CPS and heterogeneous wireless sensor networks, adaptive coordination mechanisms, distributed coordination approaches, managing dynamic and uncertainty in CPS-driven HWSNs research and future directions.

Keywords: *Adaptive coordination mechanism in HWSNs; Distributed coordination approaches; Managing dynamics and uncertainty I CPS-driven HWSNs*

I. INTRODUCTION

Heterogeneous Wireless Sensor Networks (HWSNs) have developed into a primary technology for modern sensing and monitoring systems, enabling the integration of different sensor nodes with varying capabilities, energy levels, and communication ranges (I. G Saritha *et al*,. 2025). When combined with CPS, these networks design evolve beyond passive data collection areas into intelligent, feedback-driven organizations capable of real-time communication with the physical domain. This combination is mainly critical in emerging application domains such as industrial automation, smart cities, disaster response systems, environmental monitoring, and intelligent transportation systems, where timely and reliable decision-making is vital. Despite considerable progressions, Existing HWSN placements still face strong system-level limitations, especially in fluctuating and dynamic domains (Jyvoti Sni *et al*,.2025). Network situations often adapt due to environmental interference, node mobility, energy exhaustion, and unpredictable communication failures C. Sivasankar *et al.*, 2026). These parameters introduce instability in management methods, resulting to inefficient routing, reduces network lifetime, data loss, and degraded Quality of Service (QoS) (K. Nithya *et al*,.2026). Additionally, the heterogeneity of sensor nodes complicates framework, as different in energy levels, processing power, and sensing accuracy make uniform management methods ineffective (Xiaoying Liu *et al*., 2026). In most traditional frameworks, design is either static or semi-adaptive, lacking the real-time responsiveness desired for high-fluctuating

environments (Kajalban Tanchak *et al.*, 2024). The motivation for this review article stems from the need to bridge the gap between conventional HWSN coordination approaches and the adaptive intelligence provided by CPS paradigms (Surepalli Navya *et al.*, 2025) . While CPS introduces a closed-loop communication between computation, transmission, and control, many existing architectures fail to fully leverage this feedback technique for adaptive coordination in HWSNs (Urvi Bhatti *et al*,. 2024). Hence, there is a need for a unified perspective that systematically reviews and structures prior methods while highlighting adaptableness, uncertainty coordination, and real-time system responsiveness (Massooma Anwar *et al*,. 2024). To address this gap, this review manuscript uses an organized review methodology centered on CPS-based adaptive management frameworks. The method comprises a thematic classification of existing literature into CPS integration models, management methods, and uncertainty-handling techniques including fuzzy logic systems, probabilistic modeling, and machine learning-driven prediction mechanisms. This classification improves a system-level comprehension of how management grows under CPS frameworks and how adaptive intelligence is integrated into HWSNs (Ali Hassan *et al*., 2021). This approach lies in its ability to synthesize fragmented research contributions into a coherent framework that emphasizes framework and algorithmic patterns, rather than considering individual studies in isolation (Varsha Bhatia *et al*., 2022, & Wei Hu *et al*., 2022). The implementation of CPS-based analytical methods is particularly justified due to their inherent capability to support decision-making, real-time feedback control, context-aware and dynamic system adaptation. These properties are vital in domains described by uncertainty and rapid phase changes, where static or rule-based management approaches are insufficient (Babatunde Olamide Omiyele *et a*l., 2025, & Angkush Kumar Ghosh *et al*.,2021). By exploiting CPS principles, this review highlights how sensing, computation, and actuation can be tightly joined to improve network resilience and operational efficiency. The potential contribution of this review study lies in its ability to offer a complete and system-level comprehension of dynamic management in HWSNs under CPS paradigms. It identifies key patterns, analyzes prior methodologies, and emphasizes critical research gaps that limit current implementations. Moreover, the study provides relevance to both academic research and practical paradigm design by enlightening the development of more resilient, scalable, and intelligent sensor network architectures capable of operating effectively in highly dynamic and uncertain environments.

2. REVIEW METHODOLOGY

This study used an organized literature-review methodology to scrutinize, categorize, critically evaluate, and integrate research on cyber-physical system-based HWSNs operating under dynamic and uncertain conditions. To enhance reproducibility, transparency, and coherence in identifying and evaluating relevant literature. This study's procedure consists of five major phases: Literature identification, eligibility, screening, thematic assessment, categorization and quantitative synthesis

A. Literature Search Strategy

The major academic database was used to search relevant literatures from web of science, Google Scholar, Scopus, and IEEE Xplore. The search approaches integrate terms related to the major concepts of the study using Boolean operators. The major searches used include cyber-physical systems AND heterogeneous wireless sensor networks, Heterogeneous wireless sensor network AND adaptive coordination, HWSN AND distributed coordination, context-aware coordination AND WSNs, WSN AND Uncertainty management, HWSN AND adaptive clustering, machine learning AND wireless sensor networks, digital twin AND wireless sensor network, and CPS-based AND sensor networks. The search was limited to academic publications pertinent to WSNs, HWSNs, CPS, adaptive management, intelligent resource management, uncertainty handling, and related enabling technologies.

B. Inclusion Criteria

The studies were accessed based on eligibility when they met one or more of the following conditions:

1. When the study addressed WSNs, CPS, HWSNs, and distributed sensing architectures.
2. When examine clustering, coordination, routing, resource allocation, energy efficiency, fault tolerance, and context awareness.

3. The literature addressed mobility, uncertainty, communication variability, security, and energy fluctuation.
4. When the literature examined intelligent, adaptive, predictive techniques applicable to CPS-driven HWSNs.
5. The publication provided sufficient methodological information to permit qualitative comparison with other reviewed studies.

C. Exclusion Criteria

Studies were excluded when they:

1. were unconnected to WSNs. Cyber-physical system,
2. focused exclusively on hardware design without implications for network coordination or management;
3. were duplicate records retrieved from more than one database;
4. did not provide sufficient technical information for meaningful comparison;
5. were outside the defined publication scope or were non-scholarly sources, where applicable.

D. Screening and Selection Process

The retrieved records were initially screened using their titles and abstracts. Duplicate records were removed before detailed assessment. The remaining studies were examined against the inclusion and exclusion criteria, followed by full-text assessment of potentially relevant publications. The final set of studies was then classified according to coordination mechanism, uncertainty-management technique, CPS integration level, and principal performance objective.

The literature-selection process should be reported using the following actual search records:

- Records identified from IEEE Xplore: **[10]**
- Records identified from Scopus: **[6]**
- Records identified from Web of Science: **[4]**
- Records identified from ScienceDirect: **[8]**
- Additional records from other sources: **[4]**
- Records after duplicate removal: **[24]**
- Records screened: **[45]**
- Full-text studies assessed: **[24]**
- Final studies included in the review: **[24]**

2.1. Review of Similar Works

Clustering-Based Aware Approaches

Clustering remains one of the most widely adopted mechanisms for improving scalability, communication efficiency, and data aggregation in Wireless Sensor Networks (WSNs)

Yoyok Heru Prasetyo Isomo *et al*., (2026) developed a scheme called multi-criteria adaptive clustering and optimization framework (MCACOF) that operates dynamically to form clusters using various performance metrics to enhance network throughput, load balancing, and overall network efficiency. Similarly, **Salil Bharany *et al*., (20225)** proposed a holistic adaptive sensing and clustering system for smart-city IoT environments that improves connectivity and communication reliability through intelligent cluster formation. These literatures show the significance of adaptive clustering in minimizing communication overhead and sustaining efficient resource utilization. However, their primary concentration is on network connectivity and cluster optimization, with limited focus on real-time CPS, uncertainty management, and autonomous management among HWSNs. Consequently, while adaptive clustering enhances network structure, it does not fully address the broader coordination limitations associated with dynamic and uncertain operating environments.

Energy-Based Aware Approaches

Energy efficiency is a vital design objective in wireless sensor networks because sensor nodes typically operate under severe power constraints;

Mandeep Singh *et al*., (2026) developed a scheme called energy-aware multi-sink deployment technique to minimize hotspot challenges in HWSNs. Their method balances traffic loads

across numerous sink nodes, thereby minimizing early nodes depletion and prolonging network lifetime. Similarly, **Balamurali. S. *et al*., (2026)** presented an evolutionary tri-hybrid compressive sensing framework that optimizes energy utilization, network stability, and memory utilization. Additionally, **Mohammed Alwakeel *et al*., (2025)** presented an adaptive spectrum management technique for optical wireless sensor networks that improves real-time data transmission while enhancing communication efficiency and fault tolerance. Although these energy-aware methods largely improve network maximization and resource utilization, they primarily focus on energy optimization and communication efficiency. The absences of context-awareness ***intelligent*** adaptation mechanisms that allow the network to autonomously react to unpredictable environment changes degrade their system.

Security-Based Aware Approaches

Security and trust management are increasingly important in modern WSN deployments because cyber-attacks, malicious nodes, and resource misuse can compromise network reliability. **Samer Sindian *et al*., (2025)** presented a trust-aware meta-heuristic based on horse herd leadership optimization for secure resource allocation in WSNs. Their article combines security and trust metrics into the resource-allocation process, thereby enhancing network stability against malicious activities. Furthermore, **Shreeram Hudda & Haribabu (2025)** reviewed a resource-limited smart IoT systems and accentuated the limitations associated with limited computational resources, security vulnerability, and efficient network management. The literatures highlight the growing need for secure and adaptive resource management techniques in heterogeneous and large-scale sensor networks. However, existing security-focused solutions largely address trust establishment and resource protection independently, without combining security awareness into a broader adaptive coordination framework capable of managing simultaneous energy, communication, and environmental uncertainties.

Adaptation and Resilience-Oriented Approaches

Beyond clustering, energy, and security optimization, several studies have focused on resilience and self-adaptation. **Ruben Gomas *et al*., (2026)** presented a scheme called a multi-objective self-adaptation mechanism for wireless sensor actor networks that enhances network robustness and operational continuity under changing conditions. Similarly, **Mohammed A lwakeel *et al*., (2026)** highlighted adaptive spectrum management for fault-tolerant communication in dynamic environments. These literatures emphasize the significance of adaptability and resilience in maintaining network functionality under different operational conditions.

However, most existing methods address individual aspects of network operation rather than providing a unified framework capable of simultaneously coordinating adaptation, security, fault tolerance, and resource allocation through a continuous cyber-physical system.

The reviewed literatures collectively show substantial progress in resource allocation, adaptive clustering, energy optimization, and robust network operation. However, most prior techniques address these limitations independently. There remains a lack of united CPS-driven adaptive coordination frameworks capable of simultaneously managing energy efficiency, resource allocation, fault tolerance, and dynamic environmental uncertainties in heterogeneous wireless sensor networks. Additionally, few researchers pay attention to real-time management across heterogeneous nodes using cyber-physical feedback loops for autonomous decision-making and network adaptation. This gap motivates the development of a CPS-Driven Adaptive Coordination Framework for HWSNs in Dynamic and Uncertain Environments**,** which aims to provide intelligent, context-aware, and self-adaptive coordination to enhance network reliability, sustainability, and operational efficiency.

3. CPS AND HETEROGENEOUS WIRELESS SENSOR NETWORKS: FOUNDATIONS

The convergence of CPS and HWSNs has evolved into a transformative paradigm for developing intelligent, adaptive, and autonomous monitoring systems. CPS integrates communication networks, computational intelligence, sensing infrastructures, and control techniques to build a continuous interaction between the cyber and physical environments. Within this framework, HWSNs

act as the primary sensing layer, receiving numerous environmental information through sensor nodes with varying capabilities, energy resources, communication ranges, and processing capacities. The addition of CPS with HWSNs allows decision-making, real-time perception, and adaptive response, thereby improving the overall efficiency of modern distributed sensing systems. A typical CPS-based HWSN framework comprises of four interconnected layers: the physical sensing layer, communication layer, cyber-processing layer, and control or actuation layer. The sensing layer comprises heterogeneous sensor nodes responsible for monitoring environmental parameters such as temperature, pressure, vibration, humidity, and motion. The communication layer facilitates data exchange among sensor nodes, gateways, and control centers through wireless communication protocols. The cyber layer performs data aggregation, analysis, and intelligent decision-making using computational models and adaptive algorithms. Finally, the control layer translates cyber decisions into physical actions through actuators or feedback mechanisms, thereby completing the CPS feedback loop. The heterogeneous nature of modern wireless sensor networks introduces both opportunities and challenges. Heterogeneous nodes provide enhanced sensing diversity, improved coverage, and greater system flexibility. However, variations in energy capacity, computational power, communication capabilities, and sensing accuracy complicate network coordination and resource management. Traditional homogeneous network management schemes are often inadequate in addressing these limitations, particularly in dynamic environments where network conditions continuously evolve. As a result, adaptive coordination mechanisms become essential for ensuring efficient resource utilization, reliable communication, and sustained network operation. From a system implementation perspective, CPS provides the foundational framework required to support adaptive coordination in HWSNs. Through continuous feedback and context-aware decision-making, CPS enables networks to dynamically adjust routing paths, cluster formations, task allocations, and communication schedules based on changing environmental conditions and network states. Such adaptability improves resilience against node failures, communication disruptions, and energy depletion while maintaining acceptable levels of Quality of Service (QoS). Furthermore, the integration of edge computing and intelligent analytics within the cyber layer reduces latency and enhances responsiveness by enabling localized decision-making closer to the data source. Recent advancements in CPS-driven HWSNs have further emphasized the importance of autonomous adaptation in uncertain environments. Emerging techniques such as machine learning-based prediction, fuzzy decision systems, and reinforcement learning enable networks to anticipate environmental changes and proactively optimize resource allocation. These capabilities significantly improve system robustness, scalability, and operational efficiency, particularly in mission-critical applications such as industrial automation, smart cities, environmental monitoring, precision agriculture, healthcare systems, and disaster management. The foundational relationship between CPS and HWSNs therefore extends beyond simple data acquisition and communication. It establishes an intelligent and adaptive ecosystem capable of sensing, analyzing, and responding to environmental changes in real time. This capability forms the basis for advanced coordination frameworks that can effectively address the challenges posed by dynamic and uncertain operating conditions. As a result, CPS-driven HWSNs are increasingly recognized as a key enabling technology for next-generation intelligent infrastructure and autonomous cyber-physical environments (Mandeep e*t al*., 2026).

4. **ADAPTIVE COORDINATION MECHANISMS IN HWSNS**

The effectiveness of HWSNs largely depends on their ability to coordinate sensing, communication, and decision-making activities across nodes with diverse capabilities. Traditional coordination mechanisms are often designed for static network conditions and struggle to sustain performance under dynamic environmental changes, node failures, varying traffic loads, and resource constraints. CPS introduces real-time monitoring, feedback control, and intelligent adaptation capabilities that can significantly enhance coordination efficiency. This section examines centralized, distributed, cluster-based, and context-aware coordination mechanisms while discussing their system implications in dynamic and uncertain environments (salil *et al*., 2025).

4.1. Centralized Coordination Approaches

Centralized coordination depends on a central controller, base station (BS) or sink node accountable for receiving network information and carrying out coordination decisions for all sensor nodes. Such methods provide global network visibility, allowing improved resource allocation, energy management, roles scheduling, and routing. In HWSNs, centralized coordination is beneficial when complex computational tasks assigned require comprehensive network knowledge. However, the approach suffers from scalability limitations, communication overhead, single-point failure risks, and delayed responsiveness under rapidly changing conditions. As network size and heterogeneity increase, centralized decision-making becomes increasingly inefficient. From a CPS perspective, centralized coordination can be enhanced through cloud-assisted analytics and predictive control mechanisms that leverage global system awareness. Nevertheless, the dependence on a central entity remains a significant challenge in uncertain environments. Table 1 briefly describes the characteristics of centralized coordination

Table 1: Characteristics of Centralized Coordination

Feature	Advantages	Limitations
Decision Making	Global optimization	High computational burden
Network Visibility	Complete network knowledge	Communication overhead
Scalability	Suitable for small networks	Poor performance in large HWSNs
Reliability	Easy management	Single-point failure
Adaptability	Controlled adaptation	Slow response to dynamics

4.2. Distributed Coordination Approaches

Distributed management removes the interdependence on a central controller by allowing sensor nodes to make decisions locally based on neighboring information. Nodes cooperate through peer-to-peer communications to achieve network-wide objectives. This approach significantly improves scalability, fault tolerance, and responsiveness. Since decisions are made locally, the network can quickly adapt to topology changes, node mobility, and environmental uncertainties. However, distributed coordination may lead to inconsistent decisions, increased synchronization complexity, and suboptimal global performance. CPS integration enhances distributed coordination through intelligent feedback loops and autonomous decision-making algorithms that continuously adjust network behavior according to real-time physical and cyber conditions. Table 2 briefly explains the characteristics of distributed coordination

Table 2: Characteristics of Distributed Coordination

Feature	Advantages	Limitations
Scalability	Highly scalable	Coordination complexity
Reliability	No single-point failure	Local decision inconsistency
Adaptability	Rapid response	Limited global optimization
Communication Cost	Lower overhead	Frequent local exchanges
Energy Efficiency	Better load distribution	Synchronization challenges

4.3. Cluster-Based Coordination

Cluster-based management represents a hybrid approach that combines the benefits of centralized and distributed architectures. Sensor nodes are organized into clusters, with Cluster Heads (CHs) acting as local coordinators responsible for data aggregation, resource management, and inter-cluster communication. This mechanism reduces communication costs by limiting long-distance transmissions while maintaining manageable coordination structures. However, cluster head overload, uneven energy depletion, and dynamic cluster maintenance remain significant challenges. A CPS-driven framework can dynamically select cluster heads and adapt cluster structures based on real-time

context information such as residual energy, sensing importance, traffic load, and environmental conditions. Table 3 briefly describes cluster-based coordination performance

Table 3: Cluster-Based Coordination Performance

Metric	Impact
Energy Consumption	Reduced through aggregation
Scalability	High
Fault Tolerance	Moderate
Adaptability	Depends on clustering algorithm
Network Lifetime	Improved with adaptive CH selection

4.4. Context-Aware and Adaptive Coordination

Context-aware management represents the most promising direction for future HWSNs operating in dynamic and uncertain environments. Unlike traditional approaches, context-aware systems continuously observe environmental, network, and application conditions and adapt coordination strategies accordingly.

Context information may include:

- Residual node energy
- Link quality
- Traffic density
- Physical environment conditions
- Sensor reliability
- Application priority levels
- Security status

By integrating CPS principles, sensor nodes can exploit feedback from both cyber and physical domains to optimize coordination decisions in real time. Machine learning, reinforcement learning, digital twins, and predictive analytics further enhance adaptability by anticipating future system states before disruptions occur. For example, when network congestion is detected, adaptive coordination can dynamically modify routing paths, reassign sensing tasks, or activate redundant nodes to maintain service continuity. Table 4 briefly describes CPS-Driven Context-aware Adaptation Mechanisms

Table 4: CPS-Driven Context-Aware Adaptation Mechanisms

Context Parameter	Adaptive Action	Expected Outcome
Low Energy	Node duty-cycle adjustment	Energy conservation
Link Failure	Route reconfiguration	Connectivity maintenance
High Traffic Load	Load balancing	Reduced congestion
Node Failure	Task redistribution	Service continuity
Environmental Change	Sensing adaptation	Improved monitoring accuracy

The optimization objective is defines as:

$$_{max}J = w_iE + w_2E + w_3E + w_4E - w_5U \quad (1)$$

Subject to

$$\sum_{i=1}^{5} w_i = 1 \quad (2)$$

Where: E is energy efficiency index, R defines network reliability index, S denotes security index, A signifies adaptability index, and w_i is weighting coefficient.

4.5. Comparative Summary and Research Gap

Existing management approaches offer valuable mechanisms for managing HWSNs, yet none independently address the full spectrum of challenges associated with dynamic and uncertain environments. Centralized methods provide optimal global control but suffer from scalability and reliability issues. Distributed approaches enhance robustness and scalability but may compromise coordination consistency. Cluster-based architectures improve efficiency but require adaptive management mechanisms. Context-aware approaches demonstrate superior adaptability but demand advanced intelligence and real-time decision-making capabilities. Table 5 briefly explains comparative analysis of coordination mechanisms

Table 5: Comparative Analysis of Coordination Mechanisms

Criterion	Centralized	Distributed	Cluster-Based	Context-Aware Adaptive
Scalability	Low	High	High	Very High
Fault Tolerance	Low	High	Moderate	Very High
Energy Efficiency	Moderate	High	High	Very High
Adaptability	Low	Moderate	Moderate	Very High
Decision Speed	Slow	Fast	Fast	Very Fast
CPS Integration Potential	Moderate	High	High	Very High

The comparative analysis reveals the necessity for a CPS-driven adaptive coordination framework that combines the global awareness of centralized systems, the resilience of distributed architectures, the efficiency of cluster-based coordination, and the intelligence of context-aware adaptation. Such a framework can continuously monitor physical and cyber states, predict network dynamics, and autonomously adjust coordination policies to ensure reliable, scalable, energy-efficient, and resilient operation of HWSNs in highly dynamic and uncertain environments. This observation forms the fundamental motivation for the proposed CPS-Driven Adaptive Coordination Framework presented in this review paper.

4.5.1 Proposed Integrated Coordination Architecture

Comparative evaluation shows that centralized, cluster-driven, distributed, and context-aware organization schemes offer complementary capabilities rather than mutually exclusive solutions. Hence, this study proposes an integrated Cyber-Physical System-based adaptive coordination architecture in which four approaches operate differently in terms of coordination levels within a closed cyber-physical loop. The proposed architecture is designed to address the identified limitations of prior works by combining global network awareness, energy-efficient cluster coordination, localized decision-making, and context-dependent adaptation. The proposed architecture contains four operational layers, such as network and communication, CPS intelligence, Physical sensing, and adaptive organization. At the physical sensing layer, there are heterogeneous sensor nodes, CHs, a gateway, edge/fog nodes, and the BS. The core of the proposed work is predicated on the adaptive coordination and control layer. The centralized coordinator, situated at the edge/cloud controller or BS, sustains a global view of network conditions and performs computational intensive optimization and long-term resources planning. The distributed coordinator allows neighboring nodes or local controllers to make fast decisions when centralized intervention would present additional delay or communication overhead. The cluster-based coordinator structures heterogeneous nodes into functional clusters and operates CH election, resources scheduling, inter-cluster organization, and intra-cluster organization. The context-aware layer manages continuous evaluation of the environmental situation, security context, network, and application and determines when and which coordination scheme should be operated. The Cyber-Physical System intelligence layer offers the computational intelligence needed for adaptive operation. It collects real-time network and physical-state information and performs context assessment, state prediction, uncertainty evaluation, and adaptive decision-making. Fuzzy logic, probabilistic evaluation, reinforcement learning, and machine learning maybe used depending on the computational resources and application of the network and

predict potential congestion, topology changes, energy depletion. Figure 1 depicts conceptual framework CPS-based Adaptive Coordination Architecture for HWSNs

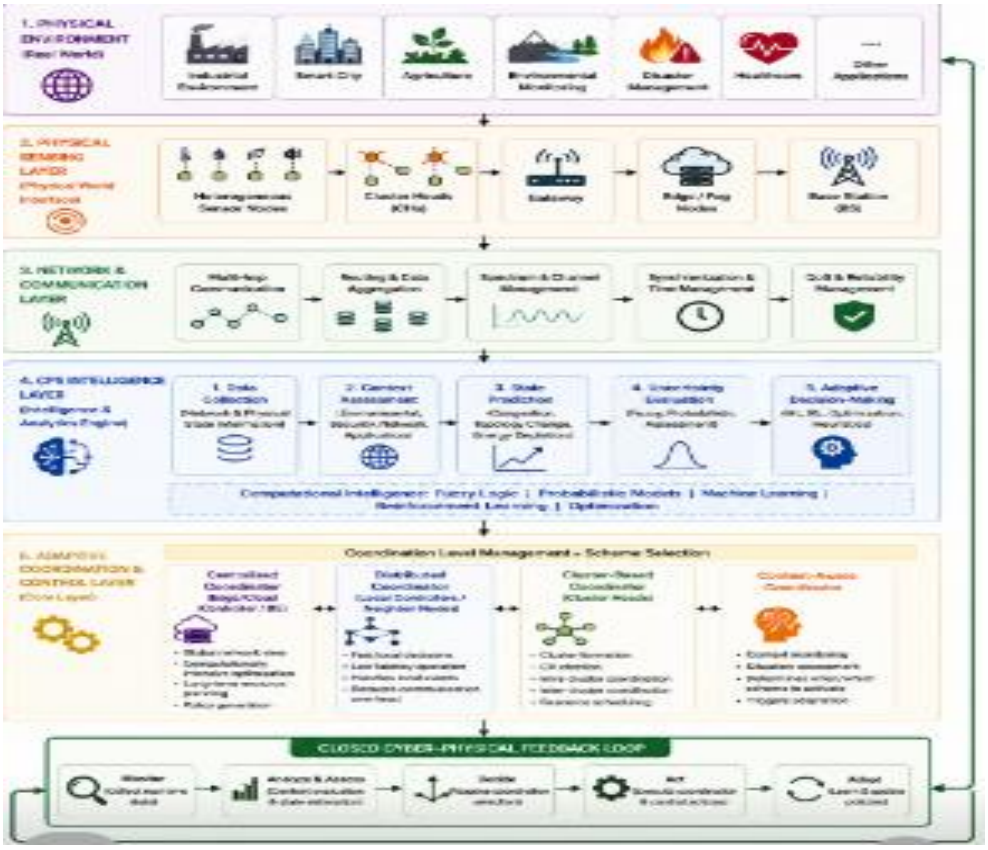

Figure 1: A conceptual framework CPS-based Adaptive Coordination Architecture for HWSNs

5. MANAGING DYNAMICS AND UNCERTAINTY IN CPS-DRIVEN HWSNS

Heterogeneous Wireless Sensor Networks deployed in Cyber-Physical Systems operate in highly dynamic environments characterized by fluctuating network conditions, unpredictable physical phenomena, node mobility, energy constraints, and heterogeneous sensing capabilities. These factors introduce significant uncertainty that can degrade coordination efficiency, communication reliability, and decision-making accuracy. Traditional static coordination approaches often assume stable operating conditions and therefore struggle to maintain performance when environmental or network states change unexpectedly. CPS-driven HWSNs address this challenge through continuous sensing, real-time analytics, adaptive control, and intelligent feedback mechanisms that enable the network to perceive uncertainty, predict its impact, and dynamically adjust coordination strategies. Consequently, uncertainty management becomes a fundamental component of achieving resilient, scalable, and autonomous network operation (Samer Sindian *et al*., 2026).

5.1. Sources of Uncertainty

Uncertainty in CPS-driven HWSNs originates from both cyber and physical domains. The heterogeneous nature of sensor nodes further amplifies the complexity of managing these uncertainties. Table 6 briefly describes sources of uncertainty in CPS-driven HWSNs.

Table 6: Sources of Uncertainty in CPS-Driven HWSNs

Source of Uncertainty	Description	Impact on Coordination
Environmental Dynamics	Weather changes, obstacles, interference, disasters	Unstable sensing and communication
Node Mobility	Movement of sensors, drones, vehicles, and mobile agents	Frequent topology changes
Energy Variations	Uneven battery depletion and energy harvesting fluctuations	Node failures and coverage gaps
Communication Uncertainty	Packet loss, latency, congestion, and channel fading	Reduced coordination reliability
Sensing Inaccuracy	Measurement noise and sensor calibration errors	Inaccurate situational awareness
Hardware Heterogeneity	Diverse sensing, processing, and communication capabilities	Resource imbalance
Security Threats	Malicious attacks, spoofing, and compromised nodes	Disrupted network operations
Context Variability	Dynamic mission objectives and user requirements	Continuous adaptation need

Among these uncertainties, topology dynamics and communication instability are particularly critical because they directly affect the coordination relationships among sensor nodes. Moreover, uncertainty sources often interact, creating cascading effects that can significantly degrade network performance if not properly managed.

5.2. Existing Uncertainty Management Techniques

Several techniques have been proposed to enhance resilience and adaptability in dynamic HWSNs. However, most existing approaches address uncertainty from isolated perspectives rather than adopting a holistic CPS-driven framework.

A. Probabilistic and Statistical Approaches

Probabilistic models such as Bayesian inference, Hidden Markov Models (HMMs), and Kalman Filters estimate uncertain network states and predict future conditions. These methods improve decision accuracy under incomplete information but often require computational resources that may be unavailable in resource-constrained nodes.

B. Fuzzy Logic-Based Approaches

Fuzzy logic enables decision-making under vague and imprecise information by representing uncertainty through linguistic variables. It has been widely applied in routing, cluster-head selection, and resource allocation. However, its effectiveness depends heavily on carefully designed rule sets.

C. MACHINE LEARNING-BASED TECHNIQUES

Machine learning algorithms analyze historical and real-time data to identify patterns and predict network behavior. Reinforcement learning, deep learning, and federated learning approaches have shown significant promise in adaptive routing, fault detection, and energy optimization. Nevertheless, their performance may be constrained by training overhead and data availability.

D. Context-Aware Adaptation

Context-aware systems dynamically modify network operations based on environmental conditions, application requirements, and resource availability. By continuously monitoring context changes, CPS controllers can optimize coordination strategies and maintain Quality of Service (QoS).

E. Digital Twin and Predictive Analytics

Recent CPS research leverages digital twins to create virtual representations of physical sensor networks. Combined with predictive analytics, digital twins enable proactive uncertainty management by forecasting failures, congestion, and energy depletion before they occur. Table 7 describes comparative analysis of uncertainty management techniques (Balamurali.S. *et al*., 2026).

Table 7: Comparative Analysis of Uncertainty Management Techniques

Technique	Strengths	Limitations
Probabilistic Models	Accurate prediction and estimation	Computational complexity
Fuzzy Logic	Handles imprecise information	Rule dependency
Machine Learning	Learns complex patterns	Training overhead
Context-Aware Adaptation	Real-time responsiveness	Context acquisition cost
Digital Twins	Predictive and proactive management	High implementation complexity

Although these techniques provide valuable capabilities, their isolated deployment often results in fragmented adaptation mechanisms. This limitation motivates the integration of CPS intelligence, edge computing, and adaptive coordination within a unified framework.

5.3. System Implication

The integration of CPS-driven uncertainty management mechanisms has profound implications for the design and operation of future HWSNs. Rather than reacting to environmental changes after they occur, CPS-enabled networks can continuously monitor system states, predict emerging uncertainties, and proactively coordinate adaptive responses. This transition from reactive management to predictive adaptation significantly enhances network resilience and operational efficiency. From a system perspective, uncertainty-aware coordination enables dynamic topology reconfiguration, intelligent resource allocation, adaptive routing, and autonomous fault recovery. The incorporation of edge intelligence further reduces decision latency by allowing localized responses to uncertain events without relying exclusively on centralized controllers. As a result, the network achieves improved scalability, reduced communication overhead, and enhanced Quality of Service (QoS). Furthermore, the convergence of machine learning, digital twins, and context-aware CPS architectures establishes a foundation for self-adaptive HWSNs capable of maintaining stable performance despite unpredictable environmental and operational conditions. Such capabilities are particularly critical in smart cities, industrial automation, intelligent transportation systems, disaster management, and precision agriculture, where timely and reliable coordination directly influences mission success. Therefore, effective uncertainty management should not be viewed merely as a supporting function but as a core design principle of CPS-driven adaptive coordination frameworks. By integrating predictive intelligence, context awareness, and autonomous adaptation, future HWSNs can evolve into resilient cyber-physical ecosystems capable of operating efficiently in highly dynamic and uncertain environments

6. RESEARCH GAPS AND FUTURE DIRECTIONS

Future studies should look beyond conceptual integration of Cyber-Physical Systems and heterogeneous wireless sensor networks toward experimentally validated adaptive structures. Specific research directions include:

Artificial Intelligence management: Future studies should investigate the effectiveness of different artificial intelligence algorithms for CPS-driven adaptive coordination. Specifically, Random Forest (RF), Support Vector Machine (SVM), Long Short-Term Memory (LSTM), Deep Q-Network (DQN), and Proximal Policy Optimization (PPO) should be compared for routing adaptation, cluster-head selection, energy prediction, congestion prediction, and fault detection. Performance evaluation should consider prediction accuracy, convergence speed, adaptation delay, packet delivery ratio, computational overhead, and energy consumption. Such comparative analysis would identify the most suitable intelligence mechanism for real-time CPS coordination in dynamic HWSNs.

Cyber-Physical System feedback optimization: The effectiveness of CPS-enabled adaptation largely depends on feedback latency and update frequency. Future work should experimentally evaluate different feedback intervals (1 s, 5 s, 10 s, and 30 s) to determine their influence on packet delivery ratio, end-to-end delay, network lifetime, control overhead, and system responsiveness. This investigation would provide practical guidelines for designing efficient cyber-physical feedback loops in resource-constrained environments.

Nigerian Application-Based Validation: To demonstrate practical applicability, the proposed architecture should be validated using representative Nigerian deployment scenarios. Potential case studies include environmental and agricultural monitoring within the Northern Guinea Savanna, flood-monitoring systems in flood-prone communities, and smart infrastructure monitoring in Abuja and Kaduna metropolitan areas. These deployments would enable assessment of the framework under realistic environmental conditions characterized by heterogeneous sensing requirements, communication variability, and resource constraints

Quantitative benchmarking: Future implementation studies should quantitatively compare the proposed CPS-driven adaptive coordination framework with established protocols such as LEACH and other adaptive clustering approaches. Evaluation metrics should include energy consumption, packet delivery ratio, throughput, latency, network lifetime, fault recovery time, load-balancing efficiency, and control overhead. Such benchmarking would provide objective evidence regarding the benefits and limitations of the proposed architecture.

Prototype Development and Testbed Validation

Beyond simulation-based studies, future research should develop a prototype implementation using heterogeneous sensor nodes, edge/fog computing platforms, and cloud-based CPS controllers. Experimental validation would enable assessment of scalability, real-time adaptability, reliability, and interoperability under realistic operating conditions. Such studies are necessary to bridge the gap between conceptual CPS-driven coordination architectures and practical deployments.

These directions provide specific research questions, algorithms, deployment scenarios, and measurable performance targets, thereby transforming the identified research gaps into an actionable research agenda

7. CONCLUSION

The convergence of Cyber-Physical Systems and Heterogeneous Wireless Sensor Networks introduces a transformative pathway toward intelligent, robustness, and self-adaptive sensing infrastructures capable of operating effectively in dynamic and uncertain environments. This paper has highlighted the critical challenges associated with heterogeneity, resource constraints, environmental variability, and coordination complexity, while emphasizing the limitations of traditional coordination mechanisms. By a conceptual framework CPS-driven adaptive coordination, the study synthesizes existing approaches and identifies gaps/ directions. The integration of feedback-driven control, distributed intelligence, and adaptive coordination mechanisms enables improved scalability, reliability, energy efficiency, and quality of service across diverse application domains. Ultimately, the proposed Conceptual work represents a significant step toward next-generation autonomous HWSNs, providing a strategic roadmap for developing resilient cyber-physical sensing ecosystems that can seamlessly adapt to evolving operational conditions and emerging smart-world applications.

ABSTRACT

Catalytic naphtha reforming process is a vital refinery process where low octane naphtha is converted into high octane reformate while concurrently generating hydrogen gas. This research work presents the design, simulation, and fabrication of 5 barrels per stream day (BPSD) pilot-scale semi-regenerative catalytic naphtha reforming process which serves as part of the mini-refinery development process at the Ahmadu Bello University (ABU), Zaria. The design was based on Escravos Heavy Hydrotreated Naphtha serving as feed; with a capacity of 5 barrel/day. Material and Energy balances calculations were performed on the developed process flow diagram before detailed equipment design was done using Mathcad and Aspen Hysys simulation. The designed equipment that constitute the pilot plant are: Surge Drum (D-01), Heat Exchanger (EX-01), Phase Separator (D-02), three Fired Heaters (H-01, H-02 & H-03) and three Fixed Bed Reactors (R-01, R-02 & R-03). R-01 (0.02 m^3 volume and 805.2 mm height), R-02 (0.03 m^3 volume and 923.0 mm height) and R-03 (0.04 m^3 volume and 1203.0 mm height).

Keywords: *Catalytic reforming; pilot-scale refinery; heavy naphtha; process design; reformate*

1. INTRODUCTION

Naphtha reforming by means of catalysts is an extremely significant conversion reaction in the current petroleum refining plants since it involves upgrading of the heavy naphtha with low octane ratings to high-octane gasoline fractions while generating the hydrogen-containing gas at the same time (Gary et al., 2007; Speight, 2020; Towler & Sinnott, 2022). Apart from that, besides being beneficial for the production of gasoline, the catalytic naphtha reforming is one of the main sources of BTX aromatic compounds, which are vital for petrochemical industry. Hydrogen produced during the catalytic reforming of the naphtha is also essential since it acts as a reactant in the hydrocracking and hydrotreating reactions (Aznárez et al., 2024; Saeidi et al., 2014).

The main feedstocks used in catalytic reforming are heavy naphthas composed mainly of paraffins, naphthenes, and aromatics having hydrocarbon molecular weight from C_6 to C_{12} which usually boil within the temperature range of 90-200 °C (Speight, 2014). The feedstocks are pre-treated before entering the reforming unit using hydrotreatment process, where sulfur, nitrogen, and oxygen containing compounds which might inhibit platinum reforming catalysts activity are removed (Jones & Pujadó, 2006; Speight, 2020). Bifunctional catalysts containing platinum supported on chlorinated alumina act as a catalytic material in reforming process; metallic centers in the catalyst provide hydrogenation/dehydrogenation reactions whereas acid sites enable isomerization and cyclization reactions.

Major reactions taking place during the reforming process involve naphthenes dehydrogenation to aromatics, paraffins dehydrocyclization, paraffins and cycloparaffins isomerization, and minimal hydrocracking. All the above reactions result in increase in the rating of gasoline octane number through production of hydrogen gas which is an important industrial gas. Catalytic reforming process is usually categorized into semi-regenerative reforming (SRR), cyclic catalytic reforming (CCRy) and continuous catalyst regeneration (CCR) processes based on the catalyst regeneration technique used in the process

(Bell, 2001). Out of all the mentioned industrial catalytic reforming processes, the semi-regenerative reforming is one that has remained attractive for small and medium capacity refineries due to its simple process design, low capital cost and easy operation when compared to continuous catalyst regeneration processes (Bell, 2001; Gary et al., 2007). Even though continuous catalyst regeneration offers increased yield of reformate and increased catalyst life, semi-regenerative reforming process is still widely used in pilot plants, modular refineries and educational institutions because of its economic viability (Towler & Sinnott, 2022).

Modern trends in catalytic reforming have mainly focused on advanced platinum based catalysts, catalyst regeneration, molecular kinetic modelling, reactor optimisation, increasing hydrogen yield and process intensification (Ruban et al., 2026; Velázquez-Alonso et al., 2025; Aznárez et al., 2024; Ali et al., 2023; Zhang et al., 2022). While these developments are generally important, comparatively less attention has been given to the practical design and fabrication of catalytic reforming unit. This aspect is especially important in developing countries such as Nigeria, where limited local refinery equipment manufacturing capacity, high dependence on imported process equipment and the cost of acquiring sophisticated commercial-scale units can constrain research, training, technology development and local process innovation. On the other hand, process simulation software such as Aspen HYSYS has become an essential engineering tool for refining processes design and optimization, by allowing rigorous calculations for material and energy balances, equipment sizing, heat integration, and evaluation of operating conditions prior to plant construction (Ritov & Dana, 2026; Pérez et al., 2025; Towler & Sinnott, 2022). These developments have greatly reduced design uncertainties and improved the efficiency and reliability of refinery process design.

In spite of these developments, most of the published studies have focused on catalyst synthesis, process optimization and mathematical modelling whereas relatively less attention has been paid to the indigenous design and fabrication of pilot scale catalytic reforming units, particularly in the developing countries. The existence of pilot scale reforming facilities is crucial for validation of engineering designs, catalyst performance evaluation, operational studies, student training and bridging the chasm between laboratory scale investigations to commercial refinery operations (King, 2013; Meyers, 2004). Indigenous pilot plants are also useful platforms for technology demonstration, process development and capacity building in petroleum refining.

The Ahmadu Bello University (ABU) Mini-Refinery Development Project was conceived to strengthen petroleum engineering education and research through the establishment of integrated pilot-scale refinery process units. As part of this initiative, a catalytic reforming unit is required to upgrade hydrotreated heavy naphtha into high-octane reformate suitable for gasoline blending while simultaneously producing hydrogen for downstream refinery operations. Therefore, this study presents the design, simulation, and fabrication of a 5 barrel per stream day (BPSD) pilot-scale semi-regenerative catalytic naphtha reforming unit using Escravos heavy hydrotreated naphtha as the design feedstock. The work covers process flow development, material and energy balance calculations, equipment sizing using Aspen HYSYS and Mathcad, mechanical design, fabrication, and assembly of the pilot-scale reforming unit. The developed facility provides an indigenous platform for engineering education, catalyst evaluation, process optimization, and future refinery research in Nigeria.

2. METHODOLOGY

This chapter presents details of activities performed for the design and fabrication of the Pilot Scale Naphtha Catalytic Reforming Unit.

2.1 Project Execution Stages

The design was executed in stages as presented in Figure 1. The methodology outlined twelve (12) stages for the design and fabrication of the pilot plant.

Figure 1: Project Flow Diagram

2.2 DESIGN BASIS AND FEEDSTOCK ANALYSIS

The feed (Heavy Naphtha) was first analysed before establishing a design basis. The design basis and feedstock composition for the CRU are shown in Tables 1 and 2 respectively.

Table 1: CRU Design Basis

NHU Capacity	**5 barrel/Day (3.31 x 10^{-2} m^3/h)**
Feed Type	Escravos SR Heavy Naphtha
Source	Naphtha Hydrotreating Unit
Specific Gravity	0.78

Table 2: CRU Feedstock Composition (Escravos Assay, 2012)

S/No.	Components	Mole Fraction	Percentage(%)	Molecular Weight
1.	Paraffins	0.364	36.4	72
2.	Naphthenes	0.392	39.2	92
3.	Aromatics	0.244	24.4	84
Total/Average		1.000	100	82.67

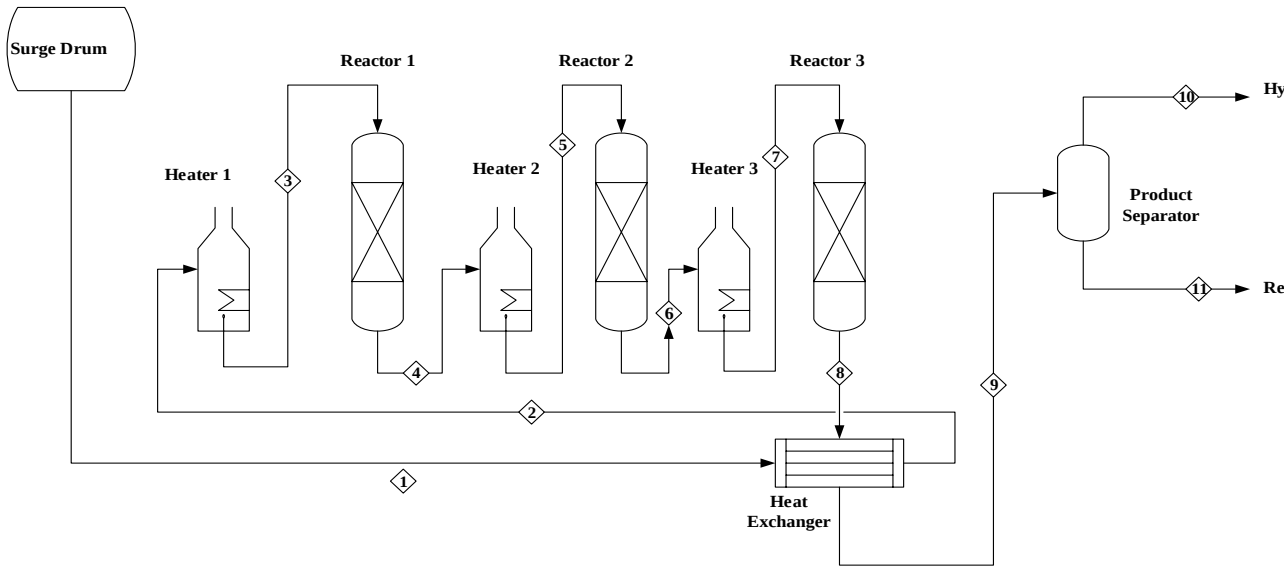

Figure 2: Process Flow Diagram for Semi Regenerative Catalytic Naphtha Reformer

2.3 PROCESS DESCRIPTION

The flow diagram of the catalytic naphtha reforming unit modeled in this work is displayed in Figure 2. The feed stock to the reformer is the heavy straight-run hydrotreated naphtha with boiling points between 90 °C and 200 °C and consists of molecules with 6–12 carbons. The catalyst mostly used in reforming operation is a bifunctional metallic catalyst typically - Pt-Re/Al_2O_3, providing the metal site and the acid site. In the initial stage, the desulfurized feed is mixed with hydrogen (in a mixer before preheating in heat exchanger (EX-01). The preheated feed, after mixing with hydrogen, is passed through fired heater H-01, where its temperature is raised to the required reaction temperature of 450–550 °C before entering the first catalytic reactor, R-01. The effluent from R-01 is then directed to fired heater H-02, where it is reheated to the required reaction temperature before entering the second reactor, R-02. Similarly, the effluent from R-02 is passed through fired heater H-03 to restore the temperature required for reaction before entering the third reactor, R-03. The use of interstage heaters is necessary because the principal reforming reactions are predominantly endothermic and consequently result in a reduction in temperature as the reaction proceeds through each reactor. The effluent from R-03 subsequently passes through the feed/product heat exchanger, EX-01, where heat is recovered to preheat the incoming fresh feed. The cooled effluent then enters the phase separator, D-02, where the hydrogen-rich gas phase is separated from the liquid reformate. The hydrogen-rich gas may then be recycled and mixed with the fresh feed upstream of R-01, while the liquid reformate is withdrawn as the bottom product.

2.4 EQUIPMENT DESIGN

2.4.1 Design Equations

The following were the equations used in the design of the various components of the CRU.

1. REACTORS

- **REACTOR DESIGN EQUATION (PACKED BED REACTOR)**
- **REACTOR PRESSURE DROP EQUATIONS**

$$\Delta P_B = 150 \cdot \left(\frac{\mu \cdot v_s}{D_p^2}\right) \cdot \frac{(1-\varepsilon)^2}{(\varepsilon)^3} + 1.75 \cdot \left[\frac{\rho \cdot (v_s)^2}{D_p}\right] \cdot \frac{(1-\varepsilon)}{(\varepsilon)^3}$$

Where

μ = average viscosity at inlet condition
vs = superficial viscosity
Dp = catalyst particle size
ρ = catalyst particle density
ε = bed void space

$$W = \int_{F_{Ao}}^{F_{A1}} \frac{1}{r_A} \, dF_A$$

(1)

- **TRANSPORT EQUATIONS**

$$\text{LHSV} = \frac{\text{Mass_flowrate_inlet}}{\text{Mass_catalyst}}$$

(2)

- **REACTOR PRESSURE DROP EQUATIONS**

$$\Delta P_B = 150 \cdot \left(\frac{\mu \cdot v_s}{D_p^2}\right) \cdot \frac{(1-\varepsilon)^2}{(\varepsilon)^3} + 1.75 \cdot \left[\frac{\rho \cdot (v_s)^2}{D_p}\right] \cdot \frac{(1-\varepsilon)}{(\varepsilon)^3}$$

Where

μ = average viscosity at inlet condition
vs = superficial viscosity
Dp = catalyst particle size
ρ = catalyst particle density
ε = bed void space

(3)

2. HEAT EXCHANGER

(4a)

Where

Q = Heat Transfer Rate
U= Overall Heat Transfer Coefficient
A= Heat Transfer Area
Th_1 = Hot fluid Inlet
Th_2 = Hot fluid outlet
Tc_1 = Cold fluid Inlet
Tc_2 = Cold fluid outlet
D= Heat transfer diameter (mm)
L= Heat transfer Length (mm)
Re = Reynolds No.
μ = Viscosity
ρ = Density (kg/)
V= Velocity (m/s)
k = Thermal Conductivity
Cp = Specific heat capacity

$$Q = UA\Delta T_m$$

$$A = \frac{\pi D^2 L}{4}$$

$$\Delta T_m = \frac{(Th_2 - Th_1) - (Tc_2 - Tc_1)}{\ln\left[\frac{Th_2 - Th_1}{Tc_2 - Tc_1}\right]}$$

$$Re = \frac{\rho V D}{\mu}$$

$$Pr = \frac{Cp\,\mu}{K}$$

(4b)

(4c)

(4d)

(4e)

3. FIRED HEATER

$$q_T = 0.173 f\left[\left(\frac{T_G}{100}\right)^4 - \left(\frac{T_S}{100}\right)^4\right]\alpha_{CP} A_{CP} + hA(T_G - T_S)$$

$$N_{tubes} = \frac{Q}{2\pi r L q} \text{ where } r = d_o/2$$

$$A_{CP} = ctc \times L \times N$$

Where
f - overall exchange factor.

T_G - temperatures of the flue gases leaving the radiant section
T_S - surface temperature of the tubes.
A_{CP} - equivalent cold plane surface area, ft^2 ,
α_{CP} is a factor by which A_{CP} must be reduced to obtain effective cold surface.
$h \approx 2$, $A \approx 2\alpha_{CP} A_{CP}$ and $f \approx 0.57$
(5a)

(5c)

2.4.2 Summary of Material and Energy Balance

The material balance was established for the steady-state design basis of the 5 BPSD catalytic reforming unit. The calculated feed rate to the reforming section was 25.72 kg/h, comprising 8.57 kg/h of paraffins, 10.54 kg/h of naphthenes, 6.51 kg/h of aromatics and 0.10 kg/h of hydrogen. The component balances across the three (3) reactors show the progressive conversion of paraffins and naphthenes to aromatics, accompanied by hydrogen generation. The principal material-balance results for the reactor train and final product separation are summarized in Table 3.

Table 3: Summary of material balance across the catalytic reforming unit

Stream/Unit	**Paraffins (kg/h)**	**Naphthenes (kg/h)**	**Aromatics (kg/h)**	**H_2 (kg/h)**	**Total (kg/h)**
Feed to CRU	8.57	10.54	6.51	0.10	25.72
R-01 outlet	3.43	5.40	11.65	5.24	25.72
R-02 outlet	1.37	3.34	13.71	7.30	25.72
R-03 outlet	0.55	2.52	14.53	8.12	25.72
Separator gas product	—	—	—	7.714	8.0609
Separator liquid reformate	0.5445	2.4696	14.240	0.7529	17.6601

However, the computed mass flow of the total continues to be nearly 25.72 kg/h in the reactor train. On the other hand, the mass flow of the components varies increasingly due to reforming reactions. For instance, aromatics rise from 6.51 kg/h in the feed stream to 14.53 kg/h on the effluent side of R-03. Similarly, paraffins and naphthenes decrease from 8.57 and 10.54 kg/h to 0.55 and 2.52 kg/h respectively. Hydrogen rises from 0.10 kg/h in the feed to 8.12 kg/h on the effluent side of R-03, which is indicative of hydrogen formation as a result of dehydrogenation reactions.

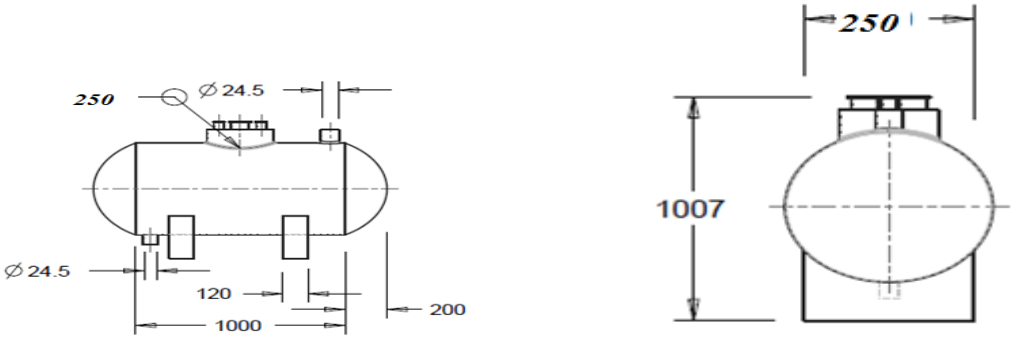
Table 4: Summary of calculated energy requirements for the major process units

Equipment	**Function**	**Calculated energy requirement / enthalpy change (MJ/h)**
EX-01	Feed/product pre-heater	74.62
H-01	Feed heating before R-01	201.58
R-01	Endothermic catalytic reforming	8,289.82
H-02	Interstage heating before R-02	1,088.55
R-02	Endothermic catalytic reforming	11,787.37
H-03	Interstage heating before R-03	11,800.65
R-03	Endothermic catalytic reforming	11,797.63

The energy requirements presented in Table 4 were determined from the enthalpy differences between the inlet and outlet process streams for each unit. The calculated heat-transfer duties for EX-

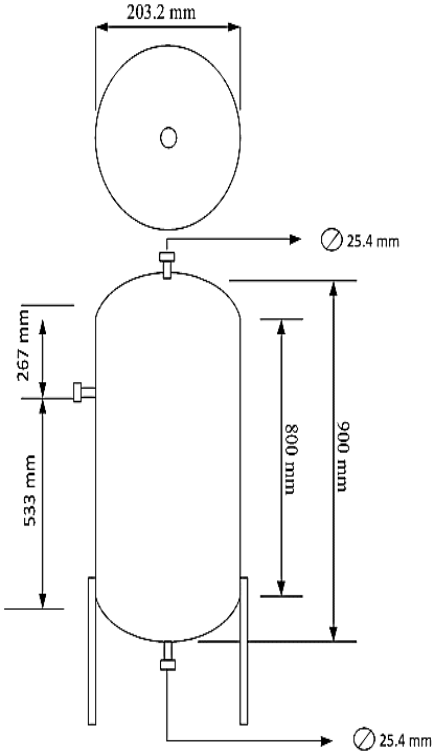
01, H-01, H-02 and H-03 were 74.62, 201.58, 1,088.55 and 11,800.65 MJ/h, respectively. For the reactors, the calculated enthalpy changes associated with the endothermic reforming reactions were 8,289.82, 11,787.37 and 11,797.63 MJ/h for R-01, R-02 and R-03, respectively. These values provided the thermal basis for the design of the heat-transfer equipment and the assessment of the energy requirements of the three-stage reforming process.

2.4.3 Numerical Design Outputs



The major equipment involved in the design comprises the surge drum, feed-to-product heat exchanger, three fixed-bed catalytic reactors, three interstage fired heaters and a phase separator. The calculated reactor volumes were 0.02, 0.03 and 0.04 m³ for R-01, R-02 and R-03, respectively, with corresponding catalyst bed lengths of 277, 417 and 695 mm, and overall heights of 805.2, 923.0 and 1203.0 mm respectively. The calculated fired heater duties for H-01, H-02 and H-03 were 201.58, 1088.55 and 11,800 MJ/h, respectively. The phase separator was designed as a vertical cylindrical vessel with a diameter of 203.2 mm, an overall height of 900 mm and a gross internal volume of 0.0281 m³. The summary of the calculated design parameters is presented in Table 5 and provides the basis for preparation of the equipment drawings and fabrication of the pilot-scale catalytic reforming unit.

Table 5: Summary of calculated design parameters of the 5 BPSD catalytic reforming unit



Equipment	Design parameter	Value
Surge drum D-01	Volume	0.20 m³
	Diameter	500 mm
	Length	1000 mm
Heat exchanger EX-01	Type	Double-pipe, counter-current
	Tube diameter	19.4 mm
	Shell diameter	205 mm
	Heat-transfer area	0.036 m²
Reactor R-01	Volume	0.02 m³
	Overall height	805.2 mm
	Catalyst-bed length	277 mm
Reactor R-02	Volume	0.03 m³
	Overall height	923.0 mm
	Catalyst-bed length	417 mm
Reactor R-03	Volume	0.04 m³
	Overall height	1203.0 mm
	Catalyst-bed length	695 mm
Fired heater H-01	Heat duty	201.58 MJ/h
Fired heater H-02	Heat duty	1088.55 MJ/h
Fired heater H-03	Heat duty	11,800 MJ/h
Phase separator D-02	Diameter	203.2 mm
	Overall height	900 mm
	Gross volume	0.0281 m³

2.5 WORKING DRAWINGS / MODELS
