2.6 ECONOMIC CONSIDERATIONS, LOCAL FABRICATION AND SCALE-UP POTENTIAL

The fabrication of the 5 BPSD catalytic reforming unit was performed keeping in mind the use of locally available engineering materials, shop facility and fabricating skills. Some of the major equipment fabricated were the surge drum, feed/product heat exchanger, three fixed bed catalytic reactors, three fired heaters and the phase separator. This helped reduce the need for imported proprietary pilot scale equipment and proved the practicability of transforming the process design to a functioning pilot plant by utilizing local engineering and fabrication skills.

Economically speaking, there are advantages associated with local fabrication of equipment for pilot-scale petroleum processing studies because it helps in designing and manufacturing the equipment according to the needs of the specific application and not purchasing as imported packages. It also helps in modifying, maintaining and replacing parts of the apparatus as well as upgrading the apparatus in accordance with further experimental requirements. But, the current study focused mainly on the technical design and fabrication of the unit and a detailed techno-economic study or a life cycle cost analysis of the items used was out of its scope. Hence, no general statement is made about the cost advantage of the fabricated unit over the imported commercial equipment.

The local fabrication technique also offers a way for future scaling up and commercialization of the system. The current 5 BPSD unit serves as a platform for generating operating data, performance of equipment and fabrication experience before proceeding onto building large units. Future scaling up must maintain the same process arrangement developed in the current study and include proper scaling changes in the size of equipment, heat transfer capabilities, sizing of reactors, instrumentation and control of processes as well as material used. It must also be accompanied by a detailed capital cost estimation, cost comparison of fabrication, energy consumption and economic feasibility study. Such studies will establish the commercial feasibility of locally made catalytic reforming systems and the identification of components that can be locally made and those that require special procurement.

3. RESULTS AND DISCUSSION

3.1 Equipment Fabrication

All the three (3) reactors are fabricated using stainless steel though mild steel was used in other units such heat exchanger and in phase separator as opposed to stainless steel specified by Aspen Hysys as the material of construction. The equipment was originally specified for fabrication from stainless steel; however, mild steel was used for selected components during fabrication because of cost and local material availability. The use of mild steel for appropriately selected refinery and process equipment is consistent with established industrial practice world wide, Accordingly, the use of mild steel in selected components of the pilot unit does not in itself constitute a process-design deficiency, although the material must remain compatible with the operating environment and be appropriately protected and monitored. The fabricated units are presented in Plate 1-4.

3.2 ASSEMBLY/ INSTALLATION OF CRU PLANT

This section presents the installation process for putting up the unit. This involves the installation of all fabricated units, piping, as well as installation of controls such as flow valves, pressure gauges and thermocouples. It also covers the installation of three burners for the fabricated fired heaters. All these are presented in Plate 5 and the model of the installed unit is depicted using SOLID WORKS 2016 in Figure 10 (a & b).

Plate 5: Cladding and Lagging

3.3 RON and MON of Fabricated CRU Processed Naphtha

The final experimental operation was conducted at a reactor temperature of between 460 – 480 °C and an operating pressure of approximately 3 bar and a feed rate was approximately 22.2 kg/h (0.5 L/min)**.** Although hydrogen addition was included in the design and simulation basis, no external hydrogen was introduced during the actual test run**.** These conditions differed from the original design simulation basis.

To actually have a basis for interpreting the experimental results, a comparison with the design parameters is presented in Table 6.

Table 6: Comparison of design/simulation and actual test-run operating conditions

Parameter	**Design/Simulation**	**Actual Test Run**
Reactor temperature	450 – 550 °C	460 – 480 °C
Operating pressure	6 bar	Approximately 3 bar
Feed rate	25.72 kg/h (0.58 L/min)	22.2 kg/h (0.50 L/min)
Hydrogen addition	0.10 kg/h	None

The actual operating conditions represent the conditions recorded during the experimental test run, whereas the design/simulation values represent the original process-design basis. The comparison presented in Table 6 shows that, although the experimental reactor temperature remained within the design temperature range, the unit was operated at a substantially lower pressure and feed rate than the design basis, and no external hydrogen was introduced. These differences are important when interpreting the experimentally obtained reformate quality because the test run did not reproduce all of the conditions used for the original design and simulation.

Following the test run, samples of the naphtha feed and the resulting reformate were collected for octane number evaluation. The Research Octane Number (RON) and Motor Octane Number (MON) were measured using a hand-held Octanometer capable of measuring both RON and MON**.** The instrument used for the measurements is shown in Plate 7**.**

Plate 7: Hand-held Octanometer used for experimental determination of RON and MON of the naphtha feed and reformate.

The feed naphtha recorded 62 RON and 58 MON, whereas the reformate obtained from the fabricated catalytic reforming unit recorded 71 RON and 64 MON, respectively. Thus, the experimental process resulted in an increase of 9 RON points and 6 MON points relative to the feedstock. The experimental results are presented in Table 7.

Table 7: RON and MON of the feed and reformate

Parameter	Feed	Experimental Reformate	Predicted Reformate
RON	62	71	100
MON	58	64	84

The experimental results from Table 7 demonstrated that the fabricated reforming unit produced a measurable improvement in the octane quality of the heavy naphtha feed. However, the experimentally obtained RON of 71 and MON of 64 values were lower than the predicted reformate values (RON of 100 and MON of 84) and the higher octane values generally associated with commercial catalytic reforming. This difference is attributable to the disparity between the design simulation conditions and the actual test conditions as presented in Table 6. In particular, the experimental run was conducted at approximately 3 bar and without external hydrogen addition, while hydrogen addition was included in the design and simulation basis. The actual operating conditions, together with the use of manually operated controls and possible limitations in catalyst performance, may therefore have contributed to the lower experimental octane improvement.

The available experimental record contains single reported measurements for the feed and reformate. Replicate measurements and associated experimental uncertainty were not recorded during the original test campaign. Consequently, statistical uncertainty is not reported for the RON and MON values. Future experimental studies should include replicate measurements, documented instrument calibration and measurement uncertainty to improve the reproducibility and statistical reliability of the octane results.

Table 8: Comparison of the fabricated pilot-scale catalytic reforming unit with established industrial practice

Parameter	Fabricated pilot-scale unit	Established industrial practice
Capacity	5 BPSD	Published industrial catalytic reformers include 32,000 BPSD (Paulsboro); 40,000 BPSD (Chalmette); 35,000 BPSD (KNPC) reforming units.
Reactor configuration	3 fixed-bed reactors	3–4 reactors in series are used in conventional fixed-bed/semi-regenerative catalytic reforming configurations.
Catalyst	Pt–Re/Al_2O_3	Pt–Re/Al_2O_3 is an established catalyst formulation for naphtha reforming.
Reformate RON	71	Approximately 95–102, depending on feedstock and reforming severity.

Source: Present study; Yusuf et al. (2019); Mazzieri et al. (2005); U.S. Energy Information Administration (EIA) (2026), Kuwait National Petroleum Company (KNPC) (2025).

The 5 BPSD capacity of the fabricated plant is quite considerably smaller as compared to that of existing commercial industrial catalytic reforming plants (See Table 8). Existing operational commercial plants include 32,000 BPSD catalytic reforming plant of the Paulsboro refinery and 40,000 BPSD catalytic reforming plant of the Chalmette refinery. Moreover, there are two continuous catalytic reforming plants of capacity 35,000 BPD installed in Kuwait National Petroleum Company (KNPC) Clean Fuels Project. This is just an illustration of the difference in the capacity of the local fabricated pilot plant as opposed to commercial refinery reformers.

4. CONCLUSIONS AND RECOMMENDATIONS

4.1 Conclusions

i. This study successfully achieved the design, fabrication, installation and test-run of a 5 BPSD pilot-scale semi-regenerative catalytic naphtha reforming unit for the processing of straight-run heavy naphtha. The study commenced with characterization of the Escravos heavy hydrotreated naphtha used as the design feedstock and establishment of the process design basis. The selected semi-regenerative configuration comprised three fixed-bed catalytic reactors arranged in series, with interstage heating, consistent with the requirements of catalytic naphtha reforming.

ii. The process material balance established a design feed rate of 25.72 kg/h to the reforming section. The component balances demonstrated progressive conversion of paraffins and naphthenes to aromatics through the three reactor stages, accompanied by hydrogen generation. The paraffin content decreased from 8.57 kg/h in the feed to 0.55 kg/h at the outlet of R-03, while naphthenes decreased from 10.54 to 2.52 kg/h. In contrast, aromatics increased from 6.51 to 14.53 kg/h and hydrogen increased from 0.10 to 8.12 kg/h. The final separator further divided the reactor effluent into an H_2-rich gas stream and liquid reformate, demonstrating the intended material-separation function of the process.

iii. The energy-balance calculations provided the thermal design basis for the process equipment. The calculated heat-transfer duty for EX-01 was 74.62 MJ/h, while the fired-heater duties for H-01, H-02 and H-03 were 201.58, 1088.55 and 11,800.65 MJ/h, respectively. The corresponding calculated endothermic heat requirements of R-01, R-02 and R-03 were 8,289.82, 11,787.37 and 11,797.63 MJ/h, respectively. These calculations, together with the material balances, provided the basis for sizing and specifying the principal equipment of the pilot plant, including the surge drum, heat exchanger, fired heaters, fixed-bed reactors and phase separator.

iv. The resulting equipment was successfully fabricated and assembled into an operational pilot-scale reforming unit. The fabricated system comprised surge drum D-01, feed/product heat exchanger EX-01, phase separator D-02, three fired heaters (H-01, H-02 and H-03) and three fixed-bed

reactors (R-01, R-02 and R-03). The successful installation and test run demonstrate the practical feasibility of translating the process design and equipment calculations into an indigenous pilot-scale catalytic reforming facility.

v. Experimental evaluation of the produced reformate gave a RON of 71 and MON of 64, compared with feed values of 62 and 58, respectively. Thus, the reforming operation produced an improvement in both measured octane indices, although the resulting reformate quality remained below the commercial gasoline quality values considered in this study. The relatively modest octane improvement is interpreted in the context of the actual pilot-plant operating conditions, including the relatively low operating pressure, operation at approximately 460–480 °C, absence of hydrogen addition during the test run and manual process control. Other process variables may also have contributed to the observed product quality. The available experimental results do not permit the effect of any single factor to be isolated.

vi. The study demonstrates the feasibility of designing and fabricating an indigenous 5 BPSD catalytic naphtha reforming pilot unit and provides a practical platform for further investigation of catalyst performance, process optimization, reformate quality and hydrogen production. The fabricated unit also provides an experimental bridge between process-design calculations and practical refinery-process operation and can support subsequent studies aimed at optimizing the operating conditions and improving the performance of locally developed refining technology.

4.2 Recommendations

The following recommendations can be made based on the limitations and results obtained from this study:

i. Operating conditions should be optimized in the fabricated pilot-scale catalytic reforming unit with particular emphasis being put on reactor temperature, operating pressure, hydrogen to hydrocarbon ratio and feed rate to enhance the severity of the reforming process and improve the quality of octane in the produced reformate.

ii. Hydrogen circulation or hydrogen to hydrocarbon ratio should be applied in future experiments in order to investigate its effect on catalyst stability, reforming performance and quality of RON and MON in the produced reformate.

iii. The pilot plant should be installed with better instruments and process-control system for improved and better controlled reforming process with respect to reactor temperature, pressure, feed rate and other operating conditions.

iv. Further experiments on the fabricated pilot unit should be done at different operating conditions for establishment of process variables versus reformate octane quality and identification of optimum operating conditions for the unit.

ABSTRACT

This study presents comparative optimization and predictive modeling of the flexural properties (deflection and failure load) of bamboo- and steel-reinforced concrete beams at a target grade of 25 MPa. Using Optimal Custom Design (OCD) in Response Surface Methodology (RSM), the effects of curing age (7–28 days) and reinforcement areas (145–580 mm² for bamboo; 50.3–201.2 mm² for steel) were analyzed. Sequential model sum of squares recommended third-order cubic polynomial models, while analysis of variance (ANOVA) validated their significance at a 99.99% confidence level. Residual diagnostics indicated approximately normally distributed experimental errors. The fit summaries showed high predictive power, with adjusted R^2 values of 0.9984–0.9992, predicted values agreeing within 0.2, and adequate precision ratios ranging from 175.18–242.13, exceeding the threshold of 4. Multi-response optimization minimized deflection and maximized failure load. For bamboo-reinforced concrete, the optimum was 9.588 days curing age and 580.000 mm² bamboo area, producing 4.692 mm deflection, 9.471 kN failure load, and 0.785 desirability. For steel-reinforced concrete, the optimum was 9.926 days and 201.200 mm² steel area, producing 6.229 mm deflection and 13.865 kN failure load. Approximately 10 days curing age was optimal for both. Steel-reinforced concrete was 24.67% more ductile and sustained 31.70% more load than bamboo-reinforced concrete. Desirability values were 0.785 and 0.782, respectively. The findings demonstrate bamboo's potential as a substitute for steel reinforcement in low-cost housing.

1. INTRODUCTION

Steel-reinforced concrete remains one of the most important developments in structural engineering since its introduction in the nineteenth century. Its widespread application is largely attributable to the favourable properties of concrete, including high compressive strength, durability, relatively low maintenance demand, and the ability to be moulded into different forms (McCormac & Brown, 2014). Steel complements concrete by addressing its principal limitation, namely, its relatively poor tensile capacity. The continued success of steel-concrete composite action is also associated with the comparatively low cost of steel among metallic materials. Iron, which constitutes the principal component of steel, is described as the least expensive and most extensively used metal (USGS, 2019). Fibre Reinforced Polymers (FRP) offer mechanical characteristics comparable to, and durability greater than, those of steel; however, their substantially higher cost limits their economic attractiveness (Burgoyne & Balafas, 2007).

A comparison based on volume is more appropriate when steel is evaluated against bamboo because the strength contribution of a reinforcing material depends on its cross-sectional area rather than simply on its mass. Steel is also considerably denser than bamboo, with reported densities of approximately 7.6 ton/m3 and 0.65 ton/m3, respectively. Although establishing an exact market price for bamboo may be difficult, available evidence indicates that bamboo is substantially less costly than steel. Its prevalence in developing countries further enhances its potential as a locally accessible reinforcement material, particularly in locations where steel may be difficult to obtain (Ghavami, 1995; Sharma, 1990).

The search for alternatives to steel has consequently been encouraged by the need for reinforcement materials that are economical and readily obtainable, particularly within developing economies. The concept of using bamboo to reinforce concrete is also longstanding. Chow (1914) conducted an early investigation at MIT into bamboo reinforcement, motivated by bamboo's high tensile strength and widespread availability in China. Since then, reduction in construction expenditure has remained a major justification for considering bamboo as reinforcement. At the same time, population growth continues to increase demand for construction materials, contributing to rising material costs and greater environmental pressure. The need for economical and environmentally sustainable construction materials is particularly significant because the construction sector accounts for about 50% of global raw-material consumption (Pacheco-Torgal & Labrincha, 2013).

Response Surface Methodology (RSM) comprises mathematical and statistical procedures for examining and optimizing processes in which several independent variables influence a measurable response. Its application enables the researcher to establish relationships between process variables and the response and to determine factor combinations capable of producing a desirable outcome. RSM is also applicable to product development, formulation, design improvement, and process enhancement (Montgomery, 2020).

Where experimental resources are inadequate for determining the absolute optimum response, RSM can still provide useful information about the behaviour of the system. If a known deterministic relationship exists between the response and experimental factors, suitable factor levels may be established mathematically. However, practical systems frequently exhibit complicated or poorly understood relationships. In such cases, empirical modelling provides a suitable means of representing the response and identifying favourable operating conditions (Khuri & Cornel, 1996).

Central Composite Design (CCD) is a commonly applied RSM technique for developing second-order mathematical models. It combines a two-level factorial arrangement with centre and axial points and is particularly useful for studying quadratic relationships. Box and Wilson introduced the design as an alternative to conventional three-level factorial arrangements (Box & Wilson, 1951). The principal components of a CCD are the factorial portion, centre points, and axial points. The factorial component may be a complete or fractional (2^k) arrangement, with factor levels normally represented by −1 and +1. Centre points are located at the middle of the experimental region, whereas axial points are positioned along the factor axes at predetermined distances from the centre. Together, these components provide information for estimating main, interaction, and quadratic effects (Montgomery, 2020; Khuri & Cornel, 1996).

Box–Behnken Design, developed by Box and Behnken (1960), is another experimental strategy used in Response Surface Methodology. Its construction combines two-level factorial arrangements with balanced incomplete block designs (BIBD), producing a systematic distribution of experimental points within the factor space. A major benefit of BBD is its efficiency in terms of experimental runs. It can provide adequate information for response-surface modelling without requiring as many experimental observations as some alternative designs. Consequently, it is useful where experimental materials, time, labour, or financial resources are limited (Montgomery, 2020; Myers et al., 2016).

Conventional RSM designs such as CCD and BBD may become unsuitable when an experiment involves complex restrictions. Although individual factors may have defined upper and lower limits, these limits may not adequately represent the actual feasible experimental region. Consequently, conventional designs can generate experimental points in areas that are impractical, unsafe, or impossible to investigate.

Computer-generated optimal designs address this limitation by using algorithms to select experimental points according to the objectives and restrictions of a particular investigation. Their application is especially valuable where standard RSM designs cannot accommodate complicated constraints (Anderson & Whitcomb, 2017; 2007).

Such designs are also applicable where the required predictive model is more complex than a conventional quadratic model. For example, prior process knowledge may indicate the need for cubic terms, for which CCD or BBD may not provide sufficient information. Optimal designs can additionally accommodate categorical factors, such as different catalyst types or configurations, alongside quantitative process variables (Anderson & Whitcomb, 2007).

Response Surface Methodology has been applied to concrete and cement-based materials for optimizing compositions and predicting engineering performance. Sridhar et al. (2022) used RSM

within a Design of Experiment framework to optimize the flexural moment of ferrocement composites containing galvanized square welded mesh and steel slag. A Central Composite Design was employed to determine suitable combinations of the investigated variables. Analysis of variance showed that the developed model was statistically significant, with a reported p-value below 0.05. The prediction-related errors were also reported to be below 20%, while the predicted responses corresponded satisfactorily with the experimental observations. The volume fraction of galvanized square welded mesh was identified as an important variable affecting flexural moment. Surface-response plots, Pareto analysis, and regression results further established its substantial influence on the flexural behaviour of the composites (Sridhar et al., 2022).

Kostić et al. (2016) applied RSM together with Monte Carlo simulation to develop a robust procedure for estimating concrete strength. Their model expressed concrete strength in relation to unit mass, water-to-cement ratio, age, and superplasticizer content. The resulting model demonstrated satisfactory accuracy during calibration and verification. Importantly, the verification stage used observations that were excluded from model development, thereby providing an independent evaluation of model performance. The residual analysis indicated normality during both stages, while uncertainty in the estimated coefficients had no statistically significant influence on concrete strength. The researchers also found that laboratory measurement variations had limited effects on predicted compressive strength, demonstrating the robustness of the developed approach.

Agarwal and John (2004) developed a reliability-based multidisciplinary design optimization framework using approximation techniques. Response Surface Approximations (RSA) were employed to represent limit-state functions and estimate failure probabilities while reducing the computational requirements associated with conventional Reliability-Based Design Optimization (RBDO). The methodology was tested using two problems. For a small analytical problem involving two design variables, significant computational savings were not obtained because constructing the RSA could require more effort than directly evaluating the reliability constraints. In contrast, substantial computational savings were achieved for a higher-dimensional multidisciplinary HPLC structural problem involving configuration, structural, and dynamic disciplines. The findings demonstrate that response-surface approximations can be particularly advantageous for computationally demanding multidisciplinary optimization problems.

Bamboo is a rapidly renewable lignocellulosic material belonging to the grass family Poaceae. Its combination of relatively low density, rapid growth, high specific strength and widespread availability has encouraged its investigation as an alternative construction material. However, bamboo should not be treated as a uniform engineering material because its physical and mechanical characteristics vary substantially with species, age, moisture content, growing conditions, culm geometry and position along the culm (Trujillo, 2013; Sharma et al., 2015).

Several species have been investigated for structural applications, including Bambusa vulgaris, Bambusa balcooa, Bambusa bambos, Dendrocalamus asper, Dendrocalamus strictus, Guadua angustifolia and Phyllostachys edulis. Guadua angustifolia has received considerable attention in structural engineering because of its favourable strength-to-weight characteristics, while Dendrocalamus and Bambusa species are important in Asian and African environments. Bambusa vulgaris is of particular interest in tropical regions because of its widespread availability, including in Nigeria. Nevertheless, the use of any local species in structural applications requires experimental characterization rather than assuming properties reported for another species. Reviews have identified species, age, location and treatment as important sources of variation in bamboo properties (Sharma et al., 2015; Maria et al., 2023).

The longitudinal arrangement of bamboo fibres gives the material comparatively high tensile strength parallel to the culm axis. This characteristic makes bamboo attractive for tensile applications. Conversely, its transverse properties are considerably weaker, and the natural hollow geometry and variation in wall thickness create additional challenges for structural detailing and connections.

The untreated bamboo culm is vulnerable to biological deterioration, particularly fungal attack and insects such as termites and beetles. Its relatively high concentration of starch and other soluble constituents contributes to this vulnerability. Consequently, treatment is generally considered necessary where bamboo is intended for long-term structural service.

Bamboo preservation techniques can broadly be divided into traditional/natural, chemical and physical treatments. Traditional methods include water immersion, smoking and controlled drying,

while chemical preservation commonly involves boron-based preservatives, particularly borax-boric acid formulations. Other approaches include pressure impregnation and copper-based preservatives. Treatment effectiveness depends on the ability of the preservative to penetrate the bamboo wall; therefore, treatment of only the external surface may not provide adequate protection for structural applications. Recent reviews also emphasize the need to standardize treatment procedures because different treatment methods can produce different effects on strength and durability (Maria et al., 2023).

Adequate durability therefore requires more than chemical preservation. Bamboo should be properly seasoned, treated throughout its thickness and protected from persistent moisture. Appropriate construction detailing—including drainage, ventilation, protection from direct wetting and separation from the ground—is equally important. These considerations have become part of modern structural-bamboo guidance. ISO 22156:2021 specifically includes durability as one of the performance requirements for structural bamboo (International Organization for Standardization (ISO) 2021).

The durability problem becomes more complex when bamboo is used as reinforcement in concrete. The concrete environment is highly alkaline, while bamboo is a lignocellulosic material. Research has reported deterioration of bamboo under prolonged alkaline exposure, while moisture movement between bamboo and concrete can cause swelling, shrinkage and loss of bond. Archila et al. (2018) consequently identified durability, bond and dimensional stability as major obstacles to the reliable use of bamboo as conventional reinforcement.

The development of standards has been important in moving bamboo from traditional construction towards engineered applications. ISO 22156:2021, Bamboo structures—Bamboo culms—Structural design, provides design provisions for structures whose primary load-bearing members are round bamboo culms or certain shear-panel systems. Its scope covers mechanical resistance, serviceability and durability and is principally directed towards relatively small bamboo structures, including one- and two-storey buildings not exceeding 7 m in height (International Organization for Standardization (ISO) 2021).

Statistical modelling and optimization techniques, including response surface methodology (RSM), provide useful means of examining relationships among influencing factors, responses, constraints, and optimization objectives (Usman et al., 2021). In the context of bamboo-reinforced concrete, the absence of established design codes, together with the increasing emphasis on sustainable and environmentally responsible construction, creates a need for systematic approaches to material and structural development. RSM offers a promising approach for evaluating and optimizing the combined effects of several parameters governing the engineering characteristics and performance of bamboo-reinforced concrete beams. Such modelling can improve understanding of the contribution of individual variables and their interactions while reducing the number of experimental trials required within the experimental programme to develop a numerical representation of the governing mechanisms and procedures (Usman et al., 2021). Accordingly, the adoption of RSM is justified in the present study.

2. MATERIALS AND METHODS

2.1 Materials

The data used for the predictive modelling as well as the model validation were obtained from experimental programs reported in the previous sections of this research for flexural properties (deflection and failure load) at:

(i) Curing age of 7-, 14-, 21- and 28-day;
(ii) Concrete grades of 25 MPa;
(iii) area of bamboo, 145-, 290-, 435-, 580mm^2 and
(iv) area of steel 50.3-, 100.6-, 150.9- and 201.2mm^2.

The modelling and validation were performed using Design Expert Software developed by Stat-Ease.

2.2 Methodology

Model Equation

The true functional relationship is given in Equation 1 where ε represents the noise or error observed in the response y while the variables are $x_1, x_2, \ldots x_k$.

$$y = f(x, \theta) + \varepsilon \quad (1)$$

The model is just a quantitative relationship (equation) between the response and the important design factors. In many cases, a low-order polynomial model will be appropriate. A first-order model in two variables is as given in Equation 2

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \cdots + \beta_k x_k + \epsilon \quad (2)$$

where y is the response, the x's are the design factors, the β's are unknown parameters that will be estimated from the data in the experiment, and ε is a random error term that accounts for the experimental error in the system that is being studied. A common extension of the first-order model is to add an interaction term, as shown in Equation 3

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2 + \epsilon \quad (3)$$

where the cross-product term $x_1 x_2$ represents the two-factor interaction between the design factors. Because interactions between factors is relatively common, the first-order model with interaction is widely used. Higher-order interactions can also be included in experiments with more than two factors if necessary. A widely used model is the second-order model given in Equation 4.

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2 + \beta_{11} x_{11}^2 + \beta_{22} x_{22}^2 + \epsilon \quad (4)$$

When there is curvature in the system, then a polynomial of higher degree must be used, such as the third-order model

A third order equation usually means a cubic response-surface model. It is used when the relationship between experimental factors and the measured response is sufficiently nonlinear that a first- or second-order model cannot adequately describe it as shown in Equation 5.

$$y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + \beta_{12} x_1 x_2 + \beta_{11} x_{11}^2 + \beta_{22} x_{22}^2 + \beta_{112} x_1^2 x_2 + \beta_{122} x_1 x_2^2 + \beta_{111} x_1^3 + \beta_{222} x_2^3 + \epsilon \quad (5)$$

Optimal (Custom) Design

In RSM, optimal (Custom) Design is used to determine the relationship between responses and independent variables (factors). Optimal (Custom) Design (OCD) is a flexible design structure to accommodate custom models, categoric factors, and irregular (constrained) regions. Custom designs are used when the process requires adjustments to the experimental data that cannot be accommodated by a standard design.

Fitting Response Curves and Surfaces

Many experiments involve at least one quantitative factor. It can be useful to fit a response curve to the levels of a quantitative factor so that the experimenter has an equation that relates the response to the factor. This equation might be used for interpolation, that is, for predicting the response at factor levels between those actually used in the experiment. When at least two factors are quantitative, a response surface can be fitted for predicting (y) at various combinations of the design factors. The dependent variables (responses) are deflection and flexural load, while the independent variables (factors) are: curing age and area of reinforcement.

Model validation

The models developed from the experimental data were validated via Optimal Custom Design in RSM of Design-Expert. The validation was done using the flexural properties (deflection and failure load) of reinforced bamboo and steel reinforced concrete beams at targeted concrete grades of 25 MPa mix design.

3 RESULTS AND DISCUSSION

3.1 Experimental Results and discussions

The experimental part of this research includes the analysis of results of flexural properties of bamboo and steel reinforced concrete specimens. The experimental data obtained from the flexural

behaviour of bamboo and steel reinforced concrete beams under flexure at grades 25 MPa concrete were used as input data for the comparisons in RSM for developing the model.

3.2 Model development

The controllable variable and the design summary of optimal custom design (OCD) used in this experiment is as shown in table 1. RSM allowed estimation of the linear, quadratic, cubic and factor interaction effects of the variables on the flexural properties. To obtain the optimum response, the suggested cubic model (third order polynomial) given in Equation 5 was used:

Table 1: Controllable variable in optimal custom design

No	Factor	Name	Units	Variation interval			
1	A	Age	day	7	14	21	28
2	B	Area of Bamboo	mm^2	145	290	435	580
3	S	Area of Steel	mm^2	50.3	100.6	160.9	201.2

3.3 Sequential Model Sum of Squares (SMSS)

Table 2 and 3 show the full details of the SMSS dataset for response 1 (deflection) and response 2 (failure load) at grade 25 MPa concrete with recommended regression model. It can be seen that third-order equations were suggested as the highest order of polynomial that was not aliased. Thus, the models are most suitably described with cubic polynomial model.

3.4 Analysis of variance (ANOVA)

The analysis of variance is a formal way to determine which factor effects are nonzero. It is probably the most useful technique in the field of statistical inference. Table 4 and 5 show the full ANOVA results for Cubic models suggested in table 2 and 3. It was shown that the models' terms for bamboo and steel reinforced concrete beams for the two responses (deflection and failure load) achieve significance at the 0.05 p-value threshold (95% confidence interval). This outcome translates to 99.99% confidence (calculated by taking [1 -0.0001] x 100) that the cubic model coefficient is not zero. In table 4 the models' terms: A, B/S, A(B/S), A^2, B^2/ S^2, A^3, B^3/ S^3 have significant effects on response (deflection) but A^2 is marginally significant. The models' terms: A, B/ S, A(B/S), A^2, A^2(B/S) and A^3 also have significant effect on response (failure load) as shown in table 5.

3.5 Selecting a good predictive model

The regression diagnostics, shown in Table 4 and 5 list the statistical parameters calculated at the 95% confidence level, commonly used in analyses of statistical data. The regression model in terms of both actual and coded variables from the above analysis for bamboo and steel reinforced concrete beam at 25 MPa concrete grade, are as given in Equation 6 to 13 below:

Where D = deflection; F.L. = failure load; A, B and represent the design factors: age and area of bamboo and area of steel, respectively. This regression model can be used to predict the flexural properties of bamboo and steel reinforced beams with the two factors (age and area of reinforcement).

1 CODED MATHEMATICAL MODEL FOR BAMBOO AND STEEL CONCRETE BEAMS RESPECTIVELY

25MPa concrete grade

$$\mathbf{Def.(Bam)} = 5.43 + 2.54A + 4.21B + 1.78\text{AB} - 0.13A^2 - 0.24B^2 + 0.47A^3 - 1.18B^3 \quad (6)$$

$$\mathbf{Def.(Ste)} = 6.96 + 3.26A + 5.39S + 2.28\text{AS} - 1.17A^2 - 0.30S^2 + 0.61A^3 - 1.51S^3 \quad (7)$$

25MPa concrete grade

$$\mathbf{Def.(Bam)} = 1.36 + 0.38A - 3.58(10^{-2})B + 7.81(10^{-4})\text{AB} - 2.27(10^{-2})A^2 + 1.19(10^{-4})B^2 + 4.09(10^{-4})A^3 - 1.14(10^{-7})B^3 \quad (8)$$

$$\mathbf{Def.(Ste)} = 1.75 + 0.48A - 0.13S + 2.88(10^{-3})\text{AS} - 2.91(10^{-2})A^2 + 1.27(10^{-3})S^2 + 5.24(10^{-4})A^3 - 3.51(10^{-6})S^3 \quad (9)$$

3 CODED MATHEMATICAL MODEL FOR BAMBOO AND STEEL CONCRETE BEAMS RESPECTIVELY

25MPa concrete grade

$$\mathbf{Fail.Load\ (Bam)} = 7.16 + 0.53A + 4.57B + 0.86\text{AB} - 0.89A^2 - 0.57A^2\text{B} + 0.89A^3 \quad (10)$$

$$\mathbf{Fail.Load\ (Ste)} = 10.76 + 0.72A + 6.08S + 1.13\text{AS} - 1.36A^2 - 0.77A^2\text{S} + 1.4A^3 \quad (11)$$

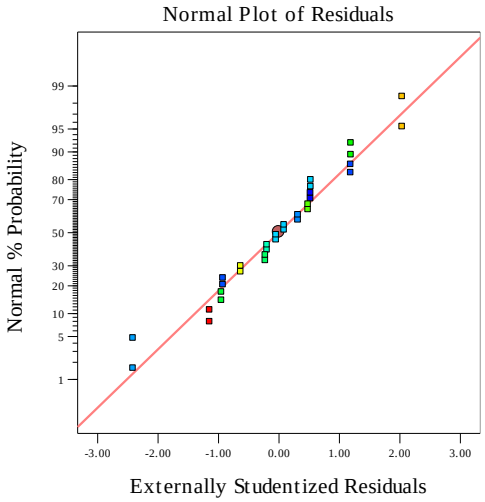
4 ACTUAL MATHEMATICAL MODELS FOR BAMBOO AND STEEL CONCRETE BEAMS RESPECTIVELY

25MPa concrete grade

$$\textbf{Fail. Load (Bam)} = -2.93 + 0.60A + 7.18(10^{-3})B + 1.20(10^{-3})\text{AB} - 3.99(10^{-2})A^2 - 2.40(10^{-5})A^2B + 7.69(10^{-4})A^3 \quad (12)$$

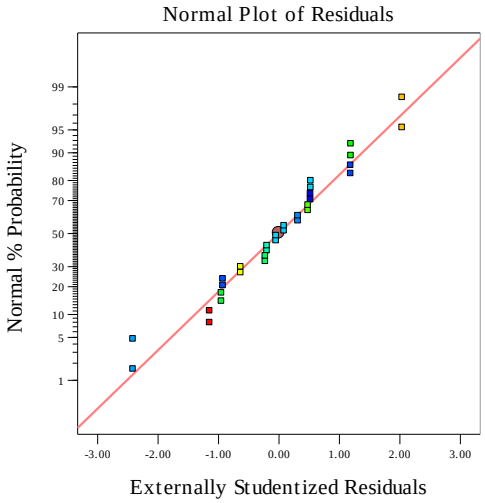
$$\textbf{Fail. Load (Ste)} = -4.16 + 1.03A + 2.72S + 4.67(10^{-3})\text{AS} - 6.44(10^{-2})A^2 - 9.30(10^{-5})A^2S + 1.21(10^{-3})A^3 \quad (13)$$

3.6 Diagnosing residuals to validate statistical assumptions



Tables 6 gives the fit summary of the models in terms of R^2, Adjusted R^2, predicted R^2 and Adequate precision. The adjusted R^2 values for all the models are between 0.9984 - 0.9992 which is an indication of good predictive powers of the models. The indicator of the quality of the regression models shows that Predicted R^2 values are in reasonable agreement with the Adjusted R^2; that is., the difference in values is less than 0.2 for the models, which is an indication of a good predictive power of the models. Adequate Precision which is a measure of the signal to noise ratio is also a confirmation tool. A ratio greater than 4 confirms adequate signals and is also an indication of good predictive powers of the models. These suggest that the predicted values obtained based on the regression models are very much close to the values obtained from the experiment.

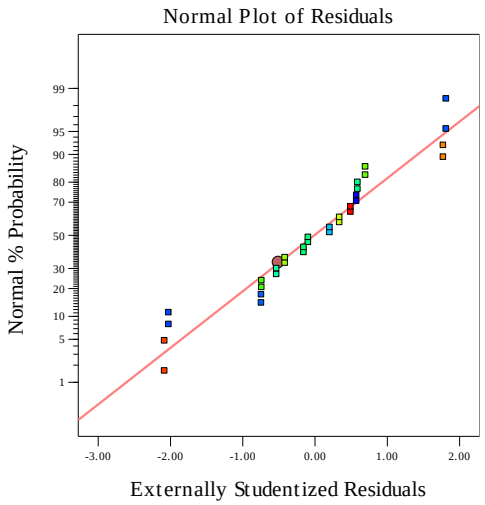
Table 6: Fit summary of the models



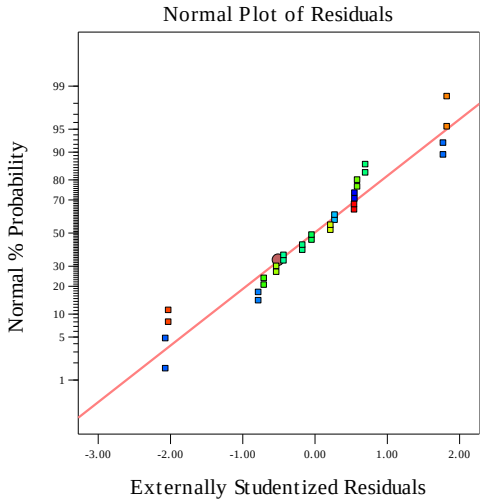
Beam	Flexural Property	Concrete Strength	R^2	Adjusted R^2	Predicted R^2	Adj(R^2) - Pred.(R^2) < 0.2	Adeq Precision > 4
Bamboo	Deflection	25	0.9988	0.9984	0.9978	$6(10^{-4})$	175.18
	Failure Load	25	0.9994	0.9992	0.9989	$9(10^{-4})$	242.13
Steel	Deflection	25	0.9988	0.9984	0.9978	$6(10^{-4})$	175.18
	Failure Load	25	0.9993	0.9992	0.9988	$4(10^{-4})$	238.05

For statistical purposes, it's expected that residuals are normally distributed and independent with constant variance. Two plots are suggested for checking the statistical assumptions: (i) Normal plot of residuals, (ii) Predicted versus Actual level.

Normal plot of residuals: These are shown in Figure 1 to 2. The over-all idea from this display is that the error distribution is approximately normal. The tendency of the normal probability plot to bend down slightly on the left side and upward slightly on the right side implies that the tails of the error distribution are somewhat thinner than would be anticipated in a normal distribution; that is, the largest residuals are not quite as large (in absolute value) as expected. These plots are used to predict the adequacy of the models adopted. In this case, giving the plots a pencil test, the deviations from linear (the normal line) are very minor, so the assumption of normality is supported. The normal plot of residual for bamboo reinforced concrete looks very much alike to that of steel reinforced concrete beam. This show that the flexural properties of bamboo reinforced concrete beam is almost the same as that of steel reinforced concrete beam.

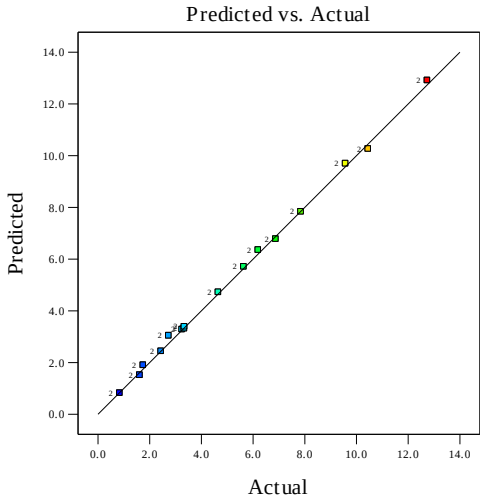


(a) Bamboo reinforced concrete beam

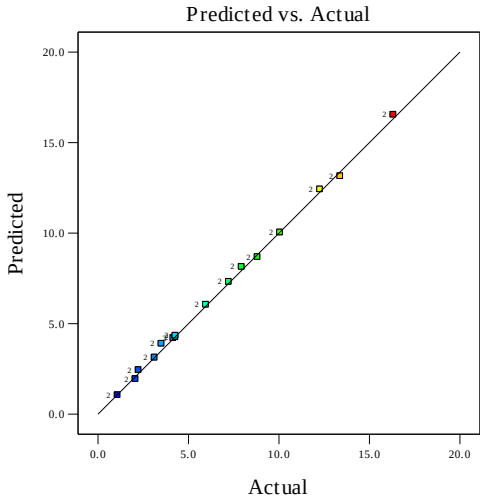


(b) Steel reinforced concrete beam

Figure 1 (a & b): Normal plot of residual for response 1 (deflection) at grade 25 MPa concrete



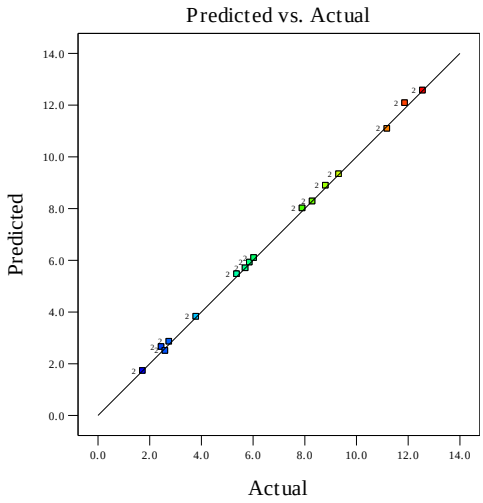
(a) Bamboo reinforced concrete beam



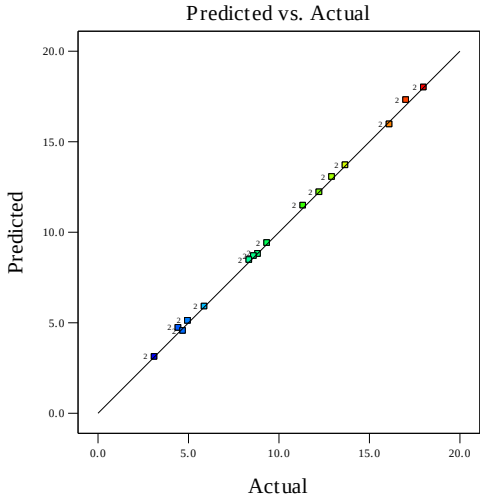
(b) Steel reinforced concrete beam

Figure 2 (a & b): Normal plot of residual for response 2 (failure load) at grade 25 MPa concrete

Predicted versus Actual level: The fit of predicted versus actual data for the cubic models in this study look very good as shown in Figure 3 to 4. In this case, the models are clearly confirmed as these plots line up nicely as expected from a normal distribution. The pencil test for linearity holds good for all the models as there are no deviations from the normal line. This further confirms that the assumption of normality is supported and the adequacy of the cubic models for predicting the flexural properties of bamboo and steel reinforced concrete beam. In turn, this suggests that bamboo is a substitute to steel reinforcement.



(a) Bamboo reinforced concrete beam



(b) Steel reinforced concrete beam

Figure 3 (a & b): Predicted vs Actual plot for response 1 (deflection) at Grade 25 MPa concrete

(b) Steel reinforced concrete beam

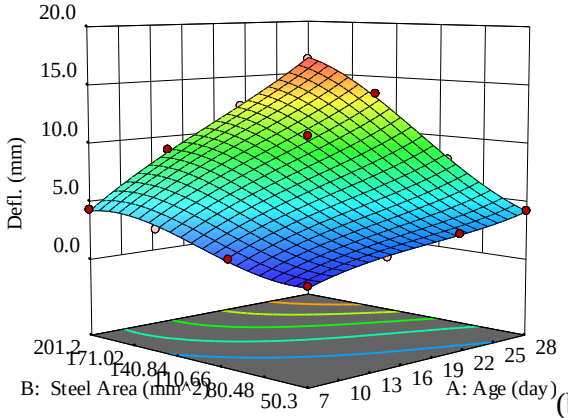

Figure 4 (a & b): Predicted vs Actual plot for response 2 (failure load) at Grade 25 MPa concrete

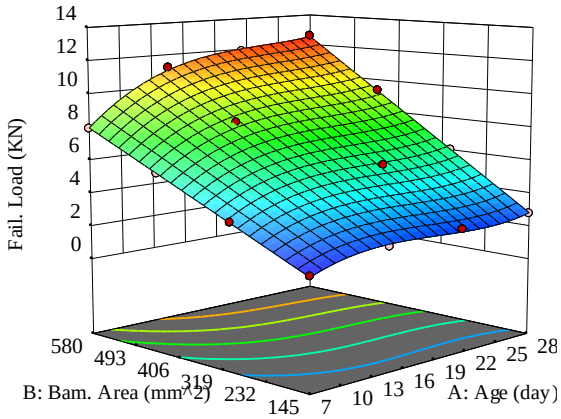
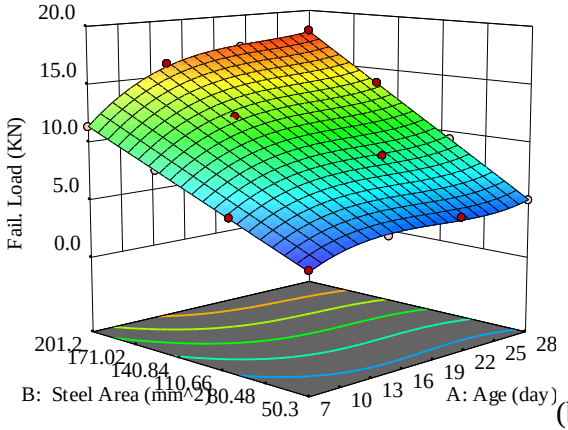
3.7 Surface plots of flexural properties of bamboo and steel reinforced concrete beams

The 3D surface plots show how the predicted responses (deflection and failure load) vary for the two factors (curing age and area of reinforcement) as shown in Figures 5 and 6. Results from the Figures show that the deflection and failure load of both bamboo and steel reinforced concrete beams increase with: increase in curing age, area of reinforcements (bamboo/steel) at 25Mpa concrete grade. However, it was observed from these figures that the difference in the values of bamboo reinforced concrete beams and steel reinforced concrete beams were caused by the ultimate strength of the steel reinforcement. Thus, the values of deflection and failure load in bamboo reinforced concrete beam are very close with that of the steel reinforced concrete beam.



(a) Bamboo reinforced concrete beam



(b) Steel reinforced concrete beam

Figure 5 (a & b): 3D Surface plot for response 1 (deflection) at grade 25 MPa concrete

(a) Bamboo reinforced concrete beam

(b) Steel reinforced concrete beam

Figure 6 (a & b): 3D Surface plot for response 2 (failure load) at grade 25 MPa concrete

4.8 Evaluation of multiple responses vie desirability function

Optimization of bamboo and steel reinforced concrete beams were done such that for response: deflection was minimized while failure load was maximized; for factors: area of bamboo and steel were maximized while age was set at default that is, in range of actual values in order to obtain the optimal curing age and area of bamboo/steel gave the best values. The optimization goals and constraints are as shown in table 7

Table 7: Optimization goals and constraints for grade 25 MPa concrete

Grade of Concrete	Bar	Name	Goal	Lower Limit	Upper Limit	Lower Weight	Upper Weight	Importance
grade 25 MPa	Bamboo	A:Age	is in range	7	28	1	1	4
		B:Bam. Area	maximize	145	580	1	1	4
		Deflection	minimize	0.8611	12.763	1	1	4
		Fail. Load	maximize	1.75	112.58	1	1	4
	Steel	A:Age	is in range	7	28	1	1	4
		B: Steel Area	maximize	50.3	201.2	1	1	4
		Deflection	minimize	1.10329	16.350	1	1	4
		Fail. Load	maximize	3.15	18.312	1	1	4

The result from table 7 shows: the importance placed on all inputs combinations; the curing age; area of bamboo and steel were set at 7-28 days; 145-580mm^2 and 50.3-201.2mm^2 respectively in which the best optimized flexural properties values were selected.

The summary of the optimized result is present in table 8. From the optimal parameters, approximately 10 days curing age was achieved for both bamboo and steel reinforced concrete showing that the method of curing was the same for both specimens. The deflection parameters show that steel reinforced concrete beam is 24.67 percent more ductile than bamboo concrete beam, while the failure load parameters show that steel reinforce concrete beam can sustain load up to 31.70 percent more than bamboo reinforced concrete beams. The large areas of bamboo is to complement the yield strength of bamboo due to its brittle nature. The desirability values are extremely close (0.785 vs. 0.782), showing how well the combinations of input factors satisfied the responses simultaneously. It means that the proposed factor combination provides a strong overall compromise among the response objectives. From the foregoing, Bamboo is the next substitute to steel for low-cost housing units.

Table 8: Summary of optimized result of bamboo and steel reinforced concrete beams

Grade of Concrete	Bar	Number of solutions	Age (day)	Area (Bamboo) (mm^2)	Deflection (mm)	Flexural Load (KN)	Desirability	
25 MPa	Bamboo	6	9.588	580.000	4.692	9.471	0.785	Selected
	Steel	11	9.926	201.200	6.229	13.865	0.782	Selected

CONCLUSION AND RECOMMENDATION

5.1 Conclusion

(i). The results of the mathematical models show that the flexural properties (deflection and failure load) of bamboo and steel reinforced concrete beams can be predicted by third-order polynomial equation (cubic models).

(ii). The P-values of all the models achieved significance at 0.0001 < 0.05 (95% threshold confidence interval). This outcome translates to 99.99% confidence (calculated by taking [1 - 0.0001] times 100). Thus, the cubic models are statistically significant.

(iii). The adjusted R^2 values are in reasonable agreement with the predicted R^2 for flexural properties as their difference $(Adjusted\ R^2 - Predicted\ R^2 \leq 0.2)$. Also, the adequate precision values are greater than four, which is an indicator that the predicted values obtained based on the regression models are very much close to that obtained from the experiment.

(iv). The deflection parameters show that steel reinforced concrete beam is 24.67 percent more ductile than bamboo concrete beam, while the failure load parameters show that steel reinforce concrete beam can sustain load up to 31.70 percent more than bamboo reinforced concrete beams.

(v). The desirability values showed that the combinations of input factors satisfied the responses simultaneously i.e., the proposed factor combination provides a strong overall compromise among the response objectives.

5.2 Recommendation

1. Validation programme should be extended to different concrete grades, bamboo species, bamboo ages, treatment methods and reinforcement configurations so as to establish the limits of applicability and reliability of the predictive models.
2. The developed RSM equations should subsequently be incorporated into a numerical/design software framework that can assist engineers in predicting structural performance and selecting appropriate bamboo reinforcement quantities.
3. Larger-scale experimental studies involving beams, slabs, columns and complete structural systems should be conducted to establish whether the laboratory-scale relationships remain valid at structural scale.
4. Field trials should monitor cracking, deflection, moisture effects, bond behaviour, durability, deterioration and long-term load response over an extended period. The field programme should also evaluate constructability, availability of suitable bamboo, treatment requirements, labour requirements, cost, maintenance and overall economic viability.

ABSTRACT

Heterogeneous Wireless Sensor Networks (HWSNs) have attracted significant attention because they can improve network performance and maximize operational lifetime by combining sensor nodes with diverse capabilities. However, node heterogeneity introduces new challenges for designing energy-efficient communication and routing mechanisms, especially under stringent energy constraints. This review introduces a comprehensive scrutiny of existing communication and routing strategies in HWSNs, with a primary focus on energy efficiency and sustainability. The study systematically scrutinizes fundamental HWSN concepts, energy consumption models, communication paradigms, and routing protocols, including flat and hierarchical approaches. Furthermore, recent improvements in energy harvesting, harvesting-aware routing, and hybrid energy storage systems are considered key enablers of sustainable network operation. By combining conventional and emerging techniques, this review identifies critical research challenges and future directions, offering valuable insights for researchers and system designers toward the development of scalable, adaptive, and energy-efficient HWSN solutions.

Keywords: *Communication strategies; Cross-layer communication approaches; Energy harvesting in HWSNs; Energy-efficient in HWSNs; Energy consumption models in HWSNs; heterogeneity in HWSNs; Routing strategies in HWSNs*

1. INTRODUCTION

Wireless Sensor Networks (WSNs) have evolved as a vital technology system, enabling a wide range of implementations, including environmental monitoring, industrial automation, smart agriculture, medical healthcare, and intelligent transportation systems. These networks classically consist of spatially dispersed sensor nodes that collectively sense, process, and send packets to a sink or base station (Soni Chaurasia *et al*., 2025). A dire limitation of traditional homogeneous WSNs is their unembellished energy-limited nature, as sensor nodes are usually battery-powered and positioned in harsh or inaccessible environments where battery replacement is impractical. To address the scalability and operational challenges inherent in homogeneous organizations, HWSNs, where sensor nodes vary in terms of energy capacity, communication range, processing capability, or functional tasks, have been extensively adopted in current research and real-world implementations. Despite their benefits, HWSNs present new limitations in energy-efficient communication and routing. The introduction of nodes with unequal abilities results in unbalanced energy utilization, predominantly for rich-energy nodes that are often selected as Cluster Heads (CH), relays, or gateways. This imbalance frequently leads to early node failures, hotspot formation near the sink, minimized network lifetime, and poor network service. Consequently, designing communication and routing schemes that logically exploit node heterogeneity while mitigating overall energy depletion remains a serious and unresolved research problem (Yang Zhang *et al*., 2025). The motivation for this

review stems from the swift increase of energy-aware communication and routing methods tailored for HWSNs, stretching from traditional clustering-based protocols to current optimization-based and intelligent schemes. Although various articles have addressed energy efficiency in HWSNs, existing studies repeatedly focus on specific protocol categories or lack an integrated comparative perspective that captures communication mechanisms, routing strategies, performance metrics, and emerging intelligent techniques within a unified framework (Namit Gupta *et al*,. 2025, Aveneesh Singh *et al*., 2025). This gap led us to a holistic review that systematically categorizes and critically analyzes these methods, underscoring their strengths, limitations, and suitability for diverse implementation scenarios. To address this gap, this review embraces a structured and comparative methodology. The review first defines fundamental concepts, energy models, and evaluation metrics pertinent to HWSNs. It then categorizes and analyzes energy-efficient communication strategies, followed by an in-depth review of routing protocols, including flat, hierarchical, and hybrid approaches. Current advances in energy harvesting-aware techniques are also examined to reflect current research trends. The chosen classification framework allows clear comparison across techniques in terms of energy usage, scalability, adaptability, and application complexity, thereby justifying the selection of these approaches as representative and impactful solutions in contemporary HWSN research. The key contribution of this review lies in its holistic synthesis of energy-efficient communication and routing strategies in HWSNs (Sumendra Thakur *et al*., 2025, Avaneesh Singh *et al*., 2025, M. Karthikeyan *et al*., 2025). Unlike prior works, this paper integrates conventional and intelligent approaches, identifies open research challenges, and outlines promising future directions, particularly in the context of IoT integration and autonomous network management. The findings presented in this study are relevant to researchers, practitioners, and system designers seeking to develop sustainable, scalable, and high-performance HWSNs (Aarti Sharma *et al*., 2025, Raghuveer Singh *et al*., 2025, Ayman A. Alharibi *et al*., 2025, Yihan Guan *et al.*, 2025). By providing a comprehensive reference and comparative insight, this review aims to support informed decision-making and stimulate further innovation in energy-efficient HWSN design.

2. REVIEW METHODOLOGY

This study used an organized literature-review methodology to identify, evaluate, screen, and synthesize research related to routing techniques and energy-efficient communication in HWSNs. Relevant literatures was extracted from major scientific databases, including Web of Science, ScienceDirect, IEEE Xplore, and Google Scholar. The search was conducted using combinations of keywords such as: Energy-efficient routing, energy harvesting, HWSNs, sustainable HWSNs, machine learning routing in WSN, energy-aware communication, and adaptive communication.

The literatures search was limited to publications between 2020 to 2026 to capture recent developments in energy-efficient HWSN design. Studies were included if they:

- Addressed energy-efficient communication or routing in WSNs/HWSNs.
- Reported performance metrics such as energy consumption, network lifetime, throughput, packet delivery ratio, or delay.
- Presented simulation, analytical, or experimental validation.

Studies were excluded if they:

- Focused solely on hardware implementation.
- Did not report energy-related performance metrics.
- Were duplicate publications.

The selection process followed four stages:

- Identification
- Screening
- Eligibility Assessment
- Final inclusion

The retrieved records were initially screened using their titles and abstracts. Duplicate records were removed before detailed assessment. The remaining studies were examined against the inclusion and exclusion criteria, followed by full-text assessment of potentially relevant publications. Table 1 depict PRISMA-Style summary.

Table 1: PRISMA-Style Summary

Stage	Number of Studies
Records identified	52
Duplicates removed	14
Records Screened	38
Full-text Reviewed	9
Final studies included	29

2.1. Review

Muhammad Haris & Haewoon Nam (2025) proposed an optimized particle swarm optimization (PSO)-based CH selection structure to enhance energy efficiency in IoT-based WSNs. Their method dynamically selects CHs based on residual energy and communication cost, resulting in balanced energy expenditure and prolonged network lifetime. Simulation results show that the developed scheme outperforms LEACH by approximately 28%, LEACH-FL and LEACH-FC by around 20%, and KM-PSO by nearly 10% in terms of nodes survivability and network lifetime. However, the study primarily targets homogeneous IoT-WSNs, with limited emphasis on heterogeneity-aware design and cross-layer energy optimization, which are critical in HWSN environments and also face challenges such as balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions

I.Gethzi Ahila Poornima *et al.*, (2025) proposed an energy-efficient hybrid optimization-based routing framework for IoT-based WBANs. Their model incorporates intelligent optimization techniques to realize optimal routing decisions, leading to minimized energy utilization and enhanced network lifetime. However, the work is application-specific to WBANs and does not explicitly address heterogeneous node capabilities or large-scale multi-hop scenarios typical of HWSNs, and also faced with challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

P.K. Poonguszhali *et al.*, (2025) presented a multi-objective, CH–based energy-efficient routing framework that combines a deep convolutional neural network (THDCNN) with hybrid Capuchin Search and Woodpecker Mating algorithms. The proposed method jointly optimizes CH selection and routing to reduce energy utilization while optimizing network stability and throughput. Simulation results show that the developed scheme outperformance with and attains 25.3, 10.76, 45.67, 49.15, 50.12 and 35% higher alive nodes and 22.32, 16.76, 27.67, 11.71, 30.32, and 27.02% higher detection rate when compared with existing methods. However, the study is primarily evaluated on homogeneous WSN settings, with limited consideration of node heterogeneity and practical deployment constraints in large-scale HWSNs, and also faced with challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions..

Sunawar Khan *et al.*, (2025), examined the integration of IoT and WSN architectures with the objective of optimizing quality of service via improved energy efficiency, scalability, and secure communication techniques. The study proposes a layered framework that enhances data communication and resource utilization in smart system environments. Simulation results show superior improvements in throughput, latency, and energy consumption compared to conventional IoT-WSN models. However, the work provides a system-level perspective and lacks detailed analysis of heterogeneity-aware routing and energy harvesting strategies essential for sustainable HWSNs, and also faces challenges comprising balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

Muhammad Akram *et al.*, (2025), the researchers proposed EEMLCR, an energy-efficient machine learning-based clustering and routing framework for wireless sensor networks. The technique leverages supervised learning to enhance CH selection and adaptive routing decisions, leading to optimized energy consumption and prolonged network lifetime. The developed scheme when compared with existing schemes, after 600 rounds in networks comprising 400 nodes, the developed scheme showed significant improvements. However, the model is primarily validated on homogeneous WSN scenarios and does not explicitly incorporate heterogeneity-aware energy

management or harvesting-based sustainability mechanisms relevant to HWSNs, and also faced with challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

Potu Arayana *et al. (2026)* estimated their secured energy-efficient opportunistic routing scheme using QualNet 5.02 and NS-2.34 with 50, 100, and 200 nodes under normal and attack scenarios. The simulation results showed higher throughput and lower average end-to-end delay than EEFCR, with performance remaining more stable as node speed and network dynamics increased. The proposed scheme also demonstrated improved energy efficiency through reduced unnecessary transmissions and better residual-energy preservation, thereby extending network lifetime. Quantitatively, the scheme was reported to be 2-3% faster than DLAMD and 10-13% faster than EEFCR**,** while its malware detection rate improved by approximately 23%. These results indicate that the proposed approach provides a better balance of throughput, delay, energy consumption, network lifetime, and security for WSNs, and also faces challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

Yang Zhang *et al*., (2025) proposed an energy-efficient adaptive routing framework for heterogeneous wireless sensor networks by integrating an Improved Particle Swarm Optimization (IPSO)-based cluster-head selection mechanism with dynamic clustering and hybrid single-/multi-hop routing. The framework was evaluated using 200 heterogeneous nodes deployed over a 200 × 200 m^2 area, comprising low-power sensors (0.5 J), battery-powered relays (1.0 J), and solar-powered hubs (2.0 J). Simulation results showed a 32.7% reduction in per-round energy consumption compared with LEACH, a 28% improvement in network lifetime based on the first-node-death metric, and a 63% reduction in energy variance among nodes. At a 20% solar-powered-hub proportion, the half-node-death lifetime increased by 36.8 ± 2.1%, from 1,518 ± 42 to 2,075 ± 55 rounds. The framework also demonstrated practical computational feasibility, with IPSO requiring 0.82 ± 0.07 ms per iteration on a Raspberry Pi 4B. However, the approach remains computationally dependent on gateway/edge nodes and primarily targets static HWSNs, indicating opportunities for lightweight distributed coordination and broader real-world validation.

Lina Elmoiz Alatabani *et al*. (2026) investigated cross-layer optimization using energy-efficient routing protocols for WSNs, focusing on interactions among network, MAC, and physical-layer operations. The chapter evaluates clustered routing protocols to examine their effects on throughput, average end-to-end delay, energy consumption, and network lifetime**.** Its analysis emphasizes the potential of cross-layer coordination to improve QoS while reducing energy expenditure and extending network lifetime. Therefore, the study provides a useful conceptual basis for cross-layer energy optimization, but its quantitative performance claims should be verified from the full chapter before inclusion in a comparative results table, and it also faces challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

Tumpa Pal *et al*. (2026) conducted a PRISMA-based systematic review of 43 high-quality studies on energy-efficient WSN routing for precision and smart agriculture, selected from an initial 250 studies published between 2016 and 2025. The reviewed protocols were evaluated mainly using network lifetime, energy consumption, packet delivery ratio (PDR), throughput, latency, routing overhead, and coverage. Quantitative evidence reported in the review indicates that a Dynamic Energy-based Clustering approach achieved 30-40% lower energy consumption, 50% longer network lifetime, and 90-98% PDR compared with traditional routing protocols. Across the reviewed studies, 15 clustering-based, 8 optimization-based, 5 fuzzy-based, 5 ML-based, 5 security-aware, and 5 hybrid approaches were identified. The review concluded that clustering and optimization methods provide strong energy and lifetime benefits, whereas ML and hybrid approaches offer improved adaptability and scalability for dynamic agricultural environments, and also faced with challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing environmental conditions.

The nine studies discussed above provide representative evidence of the principal approaches identified across the 29 included studies. The remaining studies were synthesized collectively rather than discussed individually to avoid repetitive descriptions and to maintain focus on the dominant methodological trends.

In summary, the reviewed articles show substantial progress in energy-efficient clustering, routing, and intelligent optimization for WSNs and IoT-based networks. However, most prior works are application-specific or assume homogeneous network settings, with limited consideration of node heterogeneity, harvesting-aware operation, and cross-layer energy optimization. This review addresses these gaps by providing a unified and comprehensive analysis of energy-efficient communication and routing strategies specifically tailored for sustainable Heterogeneous Wireless Sensor Networks.

3. FUNDAMENTALS OF HETEROGENEOUS WIRELESS SENSOR NETWORKS

HWSNs show a significant development of conventional wireless sensor network design, motivated by the need to enhance energy efficiency, scalability, and network longevity in resource-limited environments (Maryam Shafiq *et al*., 2021). Unlike homogeneous WSNs, where all sensor nodes are the same in capability and task, HWSNs deliberately integrate nodes with varied energy capacities, processing power, communication ranges, and sensing functions. These variations allow the network to better adapt to different traffic loads and implementation requirements, making HWSNs predominantly suitable for large-scale and long-term deployments (Maria Trigk *et al*., 2025).

3.1.Definition and Characteristics of HWSNs

HWSNs are an integral part of conventional WSNs in which sensor nodes have varying capabilities in terms of energy resources, processing power, communication range, memory, or functional roles. Unlike homogeneous WSNs, where all nodes are the same in terms of network resources, HWSNs deliberately use node variations to enhance network performance, scalability, and longevity (Bilal R. Al-Kaseem *et al*., 2021). Typical characteristics of HWSNs comprise unequal initial energy levels, role differentiation for example, “normal nodes, advanced nodes, super nodes”, adaptive communication ranges, and hierarchical data forwarding. These characteristics enable more efficient task allotment and energy usage, but also introduce complexity in communication and routing design (D. Pravin Kumar *et al*., 2025).

3.2. Types of Heterogeneity in HWSNs

Heterogeneity in HWSNs discusses the careful integration of sensor nodes with different capabilities and resources within the same network. In HWSNs, such variation leads to enhanced operation, energy efficiency, and scalability. These variations may exist in energy resources, computation, communication, or functional tasks assigned to nodes. Comprehending the types of heterogeneity is crucial for designing effective communication and routing strategies that fully exploit node diversity while minimizing energy imbalance. Table 2 briefly describes the subsection (Abdulla Juwaieda *et al*., 2025).

Table 2: Types of heterogeneity in HWSNs

Type of heterogeneity	**Description**	**Impact on Network Performance**
Energy heterogeneity	Nodes are equipped with varying energy levels	Improves network lifetime but may cause energy imbalance
Computational heterogeneity	Nodes vary in processing and memory capacity	Enables local packets and intelligent routing
Communication heterogeneity	Nodes have different transmission power and range	Enhances connectivity and coverage
Functional heterogeneity	Nodes perform specialized roles (CHs, gateways)	Improves efficiency and data aggregation
Hardware heterogeneity	Varying sensor types and hardware platform	Supports diverse sensing applications

3.3.Network Architectures and Deployment Models

HWSNs are regularly structured using flat, hierarchical, or hybrid architectures. In flat architectures, all nodes execute similar networking functions despite basic heterogeneity, which simplifies design but may underutilize high-rich nodes. Hierarchical architectures, such as clustering-based models, assign energy-rich or high-capability nodes as cluster heads or relay nodes, enabling efficient data aggregation and reduced transmission overhead. Hybrid architectures integrate flat and hierarchical features to balance flexibility and energy efficiency. Deployment models in HWSNs may be deterministic (organized placement of rich-energy nodes at strategic locations) or random, often followed by adaptive role assignment. Strategic deployment of powerful nodes near the sink or in high-traffic regions is commonly used to mitigate hotspot and bottleneck problems (Nisha B. *et al*., 2025).

3.4.Energy Consumption Models in HWSNs

Energy utilization modeling is vital to the design and estimation of energy-efficient protocols in HWSNs. Most articles embrace a first-order radio energy model, where energy dissipation relies on both electronic circuitry and communication distance. The energy utilized to transmit a *k*-bit data packet over distance *d* is given in equation (1) (Xiaoying Liu *et al*., 2025):

$$E_{tx}(k,d) = \begin{cases} kE_{ele} + kE^{d^2}{}_{fs}, d < d_0 \\ kE_{ele} + kE^{d^4}{}_{mp}, d \geq d_0 \end{cases} \quad (1)$$

The energy utilized to receive the same data is given in equation (2):

$$E_{rx}(k) = kE_{ele} \quad (2)$$

Where E_{ele} signifies the energy utilized by transmitter/receiver electronics, E_{fs} and E_{mp} defines the free-space and multipath fading amplification coefficient, respectively, and d_0 denotes the threshold distance. In HWSNs, nodes with higher residual energy or improved hardware are often designated with more energy-intensive tasks, thereby ensuring accurate energy modeling critical for fair load distribution and maximized network lifetime (Ali Forghani *et al*., 2022).

4. COMMUNICATION STRATEGIES IN HWSNS

Efficient transmission is a foundation of energy conservation in HWSNs, as data communication typically dominates overall energy usage. The presence of nodes with varying capabilities allows flexible transmission designs that can use rich-energy or rich-capacity nodes for energy-intensive tasks. This section reviews key communication strategies used in HWSNs, accentuating their functional principles, advantages, and energy-efficiency implications.

4.1. Single-Hop vs. Multi-Hop Communication

Single-hop and multi-hop transmission introduce two vital data delivery paradigms in HWSNs. In single-hop transmission, sensor nodes transmit data directly to the sink/base station (BS), which simplifies routing but suffers high energy utilization costs for distant nodes. Multi-hop transmission, on the other hand, transmits data via intermediate nodes, minimizing communication distance per hop and enhancing scalability. In HWSNs, node heterogeneity enables high energy-resource nodes to function as relays, thereby balancing energy usage and minimizing hotspot problems. Table 3 briefly describes single-hop and multi-hop communications.

Table 3: Single-hop and multi-hop communications

Communication Mode	**Description**	**Energy Implication**	**Sustainability in HWSNs**
Single-hop	Direct node-to-sink transmission	High energy cost for distance nodes	Small-scale or dense networks
Multi-hop	Data forward via intermediate nodes	Lower per-hop energy usage	Large-scale heterogeneous deployments

4.2.Data Aggregation and Fusion Techniques

Data aggregation and fusion techniques aim to minimize redundant communications by integrating data from numerous sensor nodes before forwarding it to the BS. By using spatial and temporal data correlation, these methods meaningfully lower communication overhead and energy usage. In HWSNs, nodes with higher processing ability are typically allocated aggregation tasks, enhancing efficiency without overburdening resource-limited nodes. Table 4 briefly defines data aggregation and fusion techniques (Tumpa Pal *et al*, 2026).

Table 4: Data aggregation and Fusion techniques

Technique	**Operation**	**Energy Benefit**	**Typical Aggregator Node**
Data Aggregation	Summarization (average, min.	Reduces packets count max	Cluster heads
Data Fusion	Intelligent combination of multi-sensor data	Improves data quality and efficiency	Advanced nodes

4.3. Adaptive Transmission Power Control

Adaptive transmission power control dynamically adjusts a node's transmission power based on transmission distance, link quality, or residual energy. In HWSNs, this technique allows low-energy nodes to manage power while enabling high-energy nodes to sustain robust links over longer distances. Such adaptability not only reducing unnecessary energy wastes but also minimizes interference and enhances overall network reliability (Lina Elmoiz Alatabani *et al*., 2026).

4.4. Clustering-Based Communication Mechanisms

Clustering is one of the most extensively adopted communication techniques in HWSNs. In this method, sensor nodes are categorized into clusters, with CHs responsible for intra-cluster management, data aggregation, and inter-cluster communication. Heterogeneity is obviously leveraged by chosen energy-rich or high-capability nodes as CHs, thereby maximizing network lifetime, enhancing scalability, and minimizing communication overhead among ordinary nodes.

4.5.Cross-Layer Communication Approaches

Cross-layer transmission approaches break the conventional layered protocol design by allowing data exchange across numerous network layers. In HWSNs, parameters such as residual energy, channel conditions, and routing decisions can be jointly optimized to improve transmission efficiency. By enabling coordinated adaptation across the physical, MAC, and network layers, cross-layer designs provide critical energy savings and performance gains, albeit at the cost of increased design complexity.

5. ROUTING STRATEGIES FOR ENERGY EFFICIENCY IN HWSNS

Routing shows a pivotal role in shaping the energy efficiency and effective lifetime of HWSNs. Since data routing typically determines for the largest portion of node energy utilization, routing protocols must be cautiously designed to exploit node heterogeneity while mitigating communication overhead and load imbalance. This section briefly explains major routing strategies adopted in HWSNs, highlighting their energy-saving techniques, design trade-off, and applicability to diverse network scenarios (Potu Arayana *et al*., 2026).

5.1. Flat Routing Protocols in HWSNs

Flat routing protocols consider all sensor nodes as equals and rely on data-centric or location-driven transmission rather than predefined roles. In HWSNs, flat routing is modified by allowing nodes with higher remaining energy or superior transmission capability to participate more actively in data routing. While this technique reduces the overhead connected to role assignment and cluster formation, it may result to excessive control traffic and limited scalability in large-scale networks. Flat routing is therefore more suitable for moderately sized HWSNs where node heterogeneity can be dynamically exploited without incurring significant coordination costs.

5.2.Hierarchical and Cluster-Based Routing Protocols

Hierarchical routing protocols structure HWSNs into clusters, with CHs responsible for packets aggregation and long-range transmission to the sink/BS. Energy efficiency is obtained by minimizing redundant transmissions and allocating energy-intensive tasks to high-energy or advanced nodes. Cluster-based routing efficiently balances energy utilization and improves scalability, making it one of the most extensively used strategies in HWSNs. However, frequent CH selection and maintenance may present overhead, particularly in highly dynamic or dense deployments.

5.3. Chain-Based and Tree-Based Routing Protocols

Chain-based routing protocols organize sensor nodes into linear chains, where data is sequentially routed/forwarded and aggregated before getting to the sink. This approach reduces long-distance communications and evenly distributes energy utilization among nodes. Tree-based routing protocols, in contrast, organize hierarchical packets forwarding approaches rooted at the sink, allowing efficient multi-hop transmission and data aggregation. In HWSNs, energy-rich nodes are frequently positioned closer to the sink or higher in the tree to assuage hotspot problems. Although these protocols provide improved energy efficiency, they may suffer from increased latency and minimized robustness to node failures.

5.4.Mobility-Aware Routing Strategies

Mobility-aware routing approaches are designed to address dynamic network conditions emanating from mobile sinks, mobile sensor nodes, or both. By modifying routes in response to topology changes, these protocols minimize transmission distance and prevent high energy depletion near static sinks. In HWSNs, mobility can be leveraged to redistribute traffic loads and maximize network lifetime. However, mobility-aware routing presents additional complexity in route management and may incur higher control overhead if not cautiously managed.

5.5.Comparative Discussion of Routing Approaches

Each routing approach introduces distinct benefits and limitations in terms of energy efficiency, scalability, and adaptability. Flat routing provides simplicity and flexibility but suffers with scalability. Hierarchical and cluster-based routing attained superior energy savings and load balancing, making it ideal for large-scale HWSNs. Chain-based and tree-based routing further minimize communication energy but may increase latency and sensitivity to node failures. Mobility-aware routing improves adaptability and hotspot management but at the cost of increased protocol complexity. Consequently, the selection of an energy-efficient routing approach in HWSNs should be guided by application requirements, network size, node heterogeneity, and mobility characteristics. Table 4 briefly describes the energy-efficient routing strategies in HWSNs.

Table 4: Comparative Summary of Energy-Efficient Routing Strategies in HWSNs

Ref.	**Routing Strategy**	**Energy Efficiency**	**Scalability**	**Control overhead**	**Latency**	**Heterogeneity utilization**	**Typical Applications**
Joanna Kulik et al., 2002	Flat routing	Moderate	Low-medium	High	Low	Limited (dynamic role sharing)	Small-scale monitoring
Yang Zhang et al., (2025)	Hierarchical/Cluster-based	High	High	Medium	Medium	High (energy-rich CH selection)	Large-scale sensing
Raghuveer Singh etal., (2025)	Chain-Based	Very High	Medium	Low	High	Moderate	Energy-critical deployments
Aart Sharma et al., (2025)	Tree-based	High	High	Medium	Medium	High (Relay placement)	Structured data collection
Abdulla Juwaied et al., (2025)	Mobility-aware	High	Medium-High	High	Low-medium	High(adaptive routing)	Mobile sink/node scenarios

6. ENERGY HARVESTING AND SUSTAINABLE HETEROGENEOUS WIRELESS SENSOR NETWORKS

Energy harvesting has developed a fundamental enabler for realizing long-term sustainability in HWSNs. Conventional battery-powered HWSNs are strictly constrained by limited energy reserves, which limit network lifetime and raise maintenance cost due to battery replacement. Energy harvesting presets the ability for sensor nodes to reload their energy from ambient environmental sources, thereby maximizing network operation and minimizing human intervention. In heterogeneous environments, nodes vary not only in hardware and energy capacity but also in harvesting ability, making energy harvesting a powerful balance to heterogeneity for creating self-sustaining and adaptive sensor networks (Bilal R. Al-Kaseem *et al*., 2025).

6.1. Energy-Harvesting Models and Sources

Energy harvesting in HWSNs depicts the process by which sensor nodes transform external energy into usable electrical power. Common energy sources include "solar radiation, thermal gradients, mechanical vibrations (piezoelectric), wind energy, and radio-frequency (RF) signals". Solar harvesting is the most extensively employed due to its relatively high energy density, while RF and vibration harvesting are predominantly attractive for indoor and industrial deployments (Yu Song *et al*., 2025).

A commonly used energy-harvesting model represents the harvested energy at node *i* during a time interval *t* as:

$$E_h(i,t) = \eta_i P_s(i,t).t \tag{3}$$

Where $E_h(i,t)$ defines the harvested energy, η_i denotes the energy conversion efficiency of node *i*, and $P_s(i,t)$ depicts power available from the environmental source. The residual energy of a node is then updated as:

$$E_{res}(i,t+1) - E_{res}(i,t) + E_h(i,t) - E_C(i,t) \tag{4}$$

Where $E_C(i,t)$defines the energy utilization for sensing, processing, and communication. These models offer a mathematical basis for designing harvesting-aware protocols and evaluating sustainability performance.

6.2.Harvesting-Aware Communication and Routing

Harvesting-aware communication and routing schemes explicitly integrate energy harvesting dynamics into protocol design. Instead of depending solely on residual energy, routing decisions are prepared based on both current energy level and forecast harvested energy. Nodes with higher harvesting rates are chosen as CHs, relay nodes, or data aggregators, while energy-poor nodes function in low-duty or sleep modes. Such adaptive schemes allow enhanced load balancing, minimizing the risk of network sub-division, and optimize long-term stability by aligning communication tasks with energy availability.

6.3. Rechargeable and Hybrid Energy Storage Systems

To sustain harvested energy, sensor nodes are usually furnished with rechargeable batteries or super-capacitors. Rechargeable batteries offer higher energy density but experience limited charging cycles, whereas super-capacitors provide fast charging and maximize lifespan but minimize energy density. Hybrid energy storage schemes integrate both technologies, using super-capacitors for short-term buffering and batteries for long-term storage. In HWSNs, high-capability nodes usually use hybrid storage schemes to support energy-intensive operations, while low-end nodes depend on lightweight rechargeable units.

6.4.Challenges in Sustainable HWSNs

Despite their potential, viable HWSNs face numerous critical challenges. Energy harvesting is intrinsically unpredictable and recurrent, making reliable performance problematic to guarantee. Hardware cost and efficiency limitations limit large-scale deployment, mostly for RF and vibration harvesters. Moreover, harvesting-aware protocols proliferation system complexity and necessitate accurate energy prediction models. Other challenges comprise balancing fairness among nodes, managing heterogeneous harvesting rates, and guaranteeing reliable operation under changing

environmental conditions. Addressing these challenges remains a key research direction for the realization of fully autonomous and sustainable HWSNs.

7. CONCLUSION

This review has introduced a holistic examination of energy-efficient communication and routing strategies in Heterogeneous Wireless Sensor Networks, emphasizing how node diversity can be successfully exploited to improve network performance, scalability, and operational lifetime. By systematically scrutinizing communication mechanisms, routing protocols, and energy harvesting-based sustainability models, the review article has revealed that no single solution is universally optimal, and that protocol design must be steered by application requirements, network dynamics, and energy availability. The findings highlight the rising importance of harvesting-aware for sustainable HWSNs, while also showing insistent challenges related to scalability, complexity, and real-world deployment. Overall, this review offers a unified reference framework that can sustain informed protocol selection and inspire future research toward harvesting-aware reinforcement learning routing protocols, standardized heterogeneity metrics for fair protocol evaluation, public benchmark datasets for HWSNs routing comparison, Integration of machine learning with energy harvesting prediction, cross-layer optimization frameworks incorporating communication, routing, and energy management.

ABSTRACT
The counterfeit Nigerian banknote (Naira) is still an ongoing challenge; the development of automated image analysis of the Nigerian banknote has been undertaken. This study is a Systematic Literature Review (SLR) spanning 2016-2026 to map the past, present, and future trends of Nigerian currency image analysis. From 150 initial bibliographic entries in the journal, 55 methodologically sound articles were completely published and appraised. The evolution from the review to the report is emphasized, encompassing traditional image processing and conventional machine learning methods, such as color histograms, HOG, etc., as well as ensemble and deep learning architectures (CNN, LSTM, RNN), with some level of accuracy; despite these accuracies often being above 99%, reliable real-world deployment remains elusive. Persistent limitations include small proprietary datasets, sensitivity to defective notes, and high computational demands. The new redesign of the CBN currency in 2022 rendered models invalid. The prediction of other series was done using older series. To make a contribution to the existing knowledge, the research proposes six key research directions: The components of a set that includes benchmarks, domain adaptation for redesigns, the use of lightweight edge AI, multimodal sensor fusion, environmental robustness, and inclusive design. The overall aim of the study is to steer researchers and financial institutions in the right direction and on how to create highly reliable banknote authentication systems, going beyond just getting good scores in the test set.

Keywords: *Nigerian Naira; Currency Authentication; Computer Vision; Pattern Recognition*

Decadal Review

1. INTRODUCTION

The Nigerian economy's continued reliance on physical cash transactions is problematic due to widespread counterfeiting of banknotes. While digital financial products, such as the government-introduced e-Naira, aim to promote cashless payments, these initiatives appear insufficient to fully address the issue. Consequently, Nigerian banknotes remain the primary medium of exchange for most people, especially in crowded markets, informal settings, and taxi services (Olowu & Olasupo, 2023). In fact, the entire financial structure is reliant on fiat money, and that creates serious security concerns, mostly the diffusion of counterfeit notes. Both financial institutions and sellers have, for many years, used manual processes for currency verification. By the use of touch, sight, and quick inspection. But that kind of process has inherent flaws; it takes too long, and it depends on subjective judgments and human errors. Automated machine-based identification can be a substantial productivity is considered effective for identifying genuine banknotes, especially when a computer vision approach is applied to define the security characteristics accurately (Adeniyi et al, 2024). The automation system architecture has changed over the past 10 years. The changes have been quite dramatic. The former image processing method involves manual feature extraction, while the latter deep learning method directly classifies the banknote without the need for an intermediate feature extraction step. This latter technique will provide improved results, but it is likely to require more computational power, require data resources, and deal with a variety of conditions that occur in the actual use of Nigerian banknotes. The number of studies on currency recognition in Nigeria is growing, though the works are somewhat disjointed and found in a variety of academic journals and conference proceedings. Taken as a whole,

these research findings on the image analysis of Nigerian currency over the past decade are far from adequate in terms of the availability of usable material as it is in today's academic literature. Due to this, it is difficult for researchers and industry experts to identify established methods, and this delay is experienced when implementing reliable verification and automated processes for daily operations by banks in Nigeria (Mogaji & Nguyen, 2022). This research study therefore sets out to bring a comprehensive overview of the developments in image analysis of Nigerian currency over every decade. The main results of this effort are displayed below:

i. This study presents an evaluation of metrics for the purposes of assessing them. examines both the data and the performance of researchers who are currently conducting studies using metrics, and it also shows the difficulties that pop up where data is scarce, and problems such as replication. Gaps and whether the testing environment is really authentic at the time of research.
ii. The research also highlights strategic research directions towards enhancing the capacity and skills in practice.

2. REVIEW METHODOLOGY

The researchers conducted a systematic literature review (SLR) study framework to maintain both scientific research standards and results that other researchers could reproduce. The review framework includes three components, which are used to retrieve literature, select research material, and screen articles until researchers identify their final set of publications for examination. The screening and quality assessment summary of this study is found in the appendix section of this paper.

2.1 Literature Search Strategy and Data Repositories

The researchers conducted an extensive study that examined major digital academic platforms along with their associated repositories to study both worldwide scientific developments and local research efforts. The researchers used IEEE Xplore, SpringerLink, and Google Scholar as the primary electronic databases, which provided international research about currency validation technologies. The review process uses multiple sources to establish complete research activities that apply to Nigeria.

2.2 Search Queries and Key Terms

The retrieval procedure used tailored Boolean search queries that were meant to dig out research studies on digital image analysis together with Nigerian currency computational learning methods. The researchers then used key terms such as every form they could find of “Nigerian Currency”, “Naira Note”, “Banknote Recognition”, and “Authentication”. After that, they mixed these with more specialized terms, for example, “Image Processing”, “Computer Vision”, “Machine Learning,” and also “Deep Learning.”

2.3 Inclusion and Exclusion Parameters

The study used strict inclusion and exclusion criteria because it needed to zero in on visual data analysis only while judging the relevance of particular studies. In other words, the selection method is summarized in Table 1.

2.4 Article Selection Procedure and Quantitative Overview

The literature selection process followed a three-phase screening protocol, which includes three main steps. This included the collection of bibliographic records from selected databases. The process required a title and abstract assessment to determine which materials matched the required content. The process required a full-text article review to determine which materials met the established inclusion standards. The initial search process across academic databases produced 150 documents, which were found through the search. The screening process removed 60 articles because they duplicated existing

content and contained themes that did not match the main subject matter. The remaining 90 abstracts required thorough evaluation, which led to the disqualification of 35 submissions because they either studied non-image sensor methods or lacked scientific proof. The remaining articles comprising 55 articles were further scrutinized and further excluded 38 articles because they were pre-2016 published. The remaining 17 articles that were found germane to this study thoroughly appraised and studied..

Table 1: *Inclusion and Exclusion Parameters*

Parameters	Inclusion	Exclusion
Publication Date	2016 – 2026 (Decadal span)	Publications before 2016
Language	English	Non-English publications
Subject Focus	Image analysis, Computer Vision, Pattern Recognition	RFID, RF Sensors, Magnetic-only sensors (unless hybrid with image)
Geographic Context	Specific to Nigerian Naira notes	Generic currency models have not been tested on the Naira
Document Type	Peer-reviewed journals and conference proceedings	White papers, unpublished thesis, editorials

2.5 Denominations and Structural Evolution (2016–2026)

Not only a shift in the Nigerian monetary system, but a complete overhaul occurred over the entire 10-year period the researchers examined. Before December 2022, there were 8 different nominal values in existence: ₦5, ₦10, ₦20, ₦50, ₦100, ₦200, ₦500 and ₦1000. Later, on 26th October, 2022, the Central Bank of Nigeria (CBN) announced a fresh initiative in the redesign of banknotes, which resulted in the release of new banknotes (₦200, ₦500 and ₦1000) in December, 2022. Meanwhile, the smaller denominations, from ₦5 to ₦100, remained the same. The banknotes shared some common design features, such as their size and color, but each note also featured its own unique design with different Nigerian historical figures. The re-issuance, however, necessitated a complete redesign for the higher denomination banknotes, which meant changes in the colors, size of notes, and even security features' placement. This poses a significant challenge for the automated image analysis platforms, as the models developed in the 2016 series need to adapt, or recalibrate, for the 2022 series. The review basically acknowledges this coexistence of physical data between two different states.

2.6 Visual Features for Machine Analysis

Automated identification systems require the extraction of salient distinguishing features from the image of a currency. The performance of any computational approach, including traditional edge detection approaches and more recent advanced deep convolutional networks, is based on the detection of visible physical properties such as:

2.6.1 Chromatic Signatures (Color): This is the most prominent feature as far as the denominational categorization is concerned. The primary green color of each banknote is its main color: this is evident on the ₦50 banknote and on the ₦500 banknote. These elements are displayed by the image analysis systems in RGB and HSV color space. If only color is used as a means of identification, it will give false readings where light conditions vary and where pigments have faded.

2.6.2 Textural Properties: The production process of Nigerian banknotes uses a fibrous cellulose substrate, which undergoes intaglio engraving to create raised ink patterns. The basic process

of RGB sensors becomes limited because they cannot detect raised surface patterns, but high-resolution capture systems enable users to observe the basic micro-patterns and random surface textures present on paper materials. The Gray-Level Co-occurrence Matrix method serves as a standard technique that authenticates material properties by differentiating between real substrate material and fake substrate material.

2.6.3 Security Features: This includes

i. *Watermarks:* The paper matrix contains embedded effigies which become visible through trans-illumination. The features remain inaccessible to standard reflective imaging systems, which require specialized backlighting systems to achieve proper capture.

ii. *Security Threads:* The banknote contains metal or plastic threads that create reflective surfaces, which protect against unauthorized detection. The system identifies the objects through two methods: highlight detection algorithms and frequency domain analysis.

iii. *See-Through Registers*: The two patterns create identical overlaps when light strikes their surfaces. The system requires two sensor systems and special light systems to verify their authenticity because they function like watermarks. Serial Numbers and Typography Each banknote displays a unique alphanumeric serial number, which maintains the same font style and location throughout the banknote.

iv. *Optical Character Recognition (OCR)* methods can verify results, yet different printing quality and the existence of dust or physical damage often reduce OCR performance, which makes it a supporting element, not a primary identification method.

Table 2 displays essential visual attributes that researchers need to understand the available feature domain for their algorithm development work. The table presents specific challenges that each banknote faces because it displays similar colors between different denominations and shows security features differently under various lighting conditions. The data presented in Table 2 emphasizes a fundamental consideration for the architects of identification systems: that sole reliance on chromatic attributes is insufficient. The system requires algorithms to identify both old and new currency notes because it operates in an environment where lower-value notes stay unchanged while higher-value notes get redesigned.

Table 2: *Visual Characteristics Of Nigerian Banknotes Relevant to Image Analysis (2016–2026)*

(https://www.cbn.gov.ng)

Denomination	Dominant Color (2013 Series)	Dominant Color (2023 Redesign)	Key Security Features	Image Analysis Challenge
₦5	Green	Green (Unchanged)	Watermark, Security Thread	Small size makes feature extraction difficult.
₦10	Brown	Brown (Unchanged)	Watermark, Security Thread	Often heavily soiled; low contrast in images.
₦20	Blue	Blue (Unchanged)	Watermark, Security Thread	Color similarity with higher denominations under poor light.
₦50	Green	Green (Unchanged)	Watermark, Security Thread	Chromatic confusion with ₦5 note in grayscale conversion.
₦100	Brown/Orange	Brown/Orange (Unchanged)	Watermark, Security Thread	High circulation volume leads to significant wear/tear.
₦200	Brown	Yellow/Brown	Watermark, Thread, See-through	Color shift in redesign affects trained models.
₦500	Purple	Green/Red	Watermark, Thread, See-through	Major color change in redesign; high counterfeit target.
₦1000	Blue/Purple	Blue/Purple (Shifted)	Watermark, Thread, See-through	Dimension change affects cropping and scaling algorithms.

2.7 THE EVOLUTION OF TECHNIQUES

This section assesses the development through the classification system, allowing a better understanding of process requirements, accuracy, and system reliability competing with each other in the Nigerian financial system.

2.7.1 Conventional Image Processing and Classical Machine Learning (2016–2026)

Iwok and Akpan (2016) proposed a statistical way to sort real Naira notes from fake ones. The authors used discriminant analysis. The authors also relied on multivariate tools like Hotelling's T^2 and Mahalanobis distance. The goal was to identify the notes apart, using measured physical features. So the work was mainly about statistical classification, not about matching image pixels. Almu and Muhammad (2020) took a photo of a suspected banknote, then compared that photo with a stored image of an original note. It looked for pixel patterns and also tracked where key features were on the note. Those features included color details, a strip, and the watermark. The method produced one percentage score for how close the two images were. If the score was above 95%, the note was marked as genuine. Their tests showed it could separate real from fake notes. Still, the authors reported a problem when the note was worn, damaged, or too degraded. A proposed approach used color histograms in the HSI color space, and then it sorted Nigerian Naira notes, specifically the #200, #500, and #1000 denominations. Hence, a rule-based classifier worked with 10-bin histograms for the hue component, the saturation component, and the intensity component too, and it reported an average accuracy of around 98.66%. They also mentioned that the method worked well because it did not need many preprocessing operations. Even so, the approach still ran into difficulties in situations where notes were damaged or stained, and in those cases, lower denomination accuracy was more difficult to maintain, as cited in (Omeiza et al, 2020). The research conducted followed a three-step process, which included three distinct stages of research work (Adewole et al, 2023). The first step involved using an advanced object detection system to identify different types of currency. The second step involved using an existing algorithm that had been specifically developed to identify serial numbers of various currency denominations. The three different optical character recognition systems, which included Pytesseract, Easy OCR, and Keras OCR, were used to perform character recognition. The results showed that the system achieved perfect accuracy for currency classification because it reached 100 percent accuracy. The character recognition stage, which used the Easy OCR system, reached its highest accuracy level at 81%. The approach presents several problems that need to be addressed despite its current achievements. The OCR models do not include special features that enable them to recognize Nigerian currency serial numbers. The system experiences errors because it depends on three different factors, which include note condition, image quality, and visual background complexity.

2.7.2 *Hybrid and Traditional Techniques (2016-2026)*

The research process began with background elimination through Otsu thresholding and connected component analysis. The research team calculated HOG features from standardized grayscale images measuring 154×302 pixels. The research team used PCA to reduce the features to retain essential data while decreasing computational requirements. The ECOC-MCSVM system enabled the identification and classification of multiple banknote denominations, which could be shown from either side of the currency note. The research team examined a dataset that contained 5200 banknote pictures from four different currencies: 1800 Nigerian Naira, 1000 US Dollars, 1000 Canadian Dollars, and 1400 Euros. The Canon T2i digital camera captured these images at 200 dpi to display various viewing conditions, which included front and back views as well as upward and downward orientations of new and worn notes; full and partially hidden notes. Through the application of 10-fold cross-validation, the MCSVM classifier achieved better recognition results than multiple baseline methods, which included Naïve Bayes, Random Forest, NNge, Hyperpipes, IB1, and SMOSVM. The system achieved 99% accuracy for Naira, 97% for USD, 96% for CAD, and 98.6% for Euro while displaying fast processing capabilities. The method faced several major restrictions during its operation. In the modeling part, the researchers employed a multiple-layer ensemble strategy, and they blended multiple K-Nearest Neighbor (KNN) distance measurement concepts. The distances included Euclidean distance, Manhattan distance, Chebyshev distance, and Minkowski distance. Following this, the system used a weighted voting approach to combine the distance-metric predictions, enhancing the robustness of the system under image changes and also aiding with unexpected external conditions. This research was conducted using a set of Nigerian Naira banknotes, including N100, N200, N 500, and N1000. The team then collected photographs of real banknotes and fake notes taken in different lighting, from different angles, and they also ensured that the banknotes were in various states of wear. Later, the

application was tested on two different types of devices, namely; on Android devices (such as Samsung Galaxy S6) and iOS devices (such as iPhone 6). The results indicated an accuracy rate of 99.27% in identifying the denomination and 94.70% in detecting fake banknotes. The system also processed the images in a very short time (0.02 milliseconds per image), which means it could run in real time on standard mobile devices. However, during implementation, there were some key problems encountered as a result of illumination imaging, and thus it had difficulty in detecting more sophisticated counterfeits, particularly those that preserve visually realistic features of the banknotes. This indicates that additional sensing equipment (such as UV or infrared) and adaptive image processing algorithms are required to guarantee the deployment's reliability in practical environments (Dittimi & Suen, 2018). Subsequently, (Dittimi & Suen, 2019) developed a mobile app based on a client-server system, which utilized Unity 3D and MATLAB for banknote recognition and verification. The methodology adopted the following: Feature Extraction using Histogram of Oriented Gradients (HOG) and High Correlation Filters (HCF) to reduce the feature space, followed by the application of an ensemble classifier, which consisted of Multi-Layer Perceptron Neural Networks (MLPNN) and Multi-Class Support Vector Machines (MCSVM). They simulated the technique with full banknote sets comprising the Nigerian Naira, US Dollar, Canadian Dollar, and Euro banknotes. Authentic samples were taken as pictures using a Canon T2i camera, and the counterfeit samples were printed using an HP Color LaserJet printer, resulting in samples with differing viewing angles and lighting conditions. The results showed that the designed HOG-HCF-WMA system identified the images with 99.00% accuracy and a time of approximately 0.051 seconds per image. The system outperformed all the top systems established that have been used in their respective fields, with respect to its accuracy outcomes and its operational efficiency. The approach was successful, but had significant limitations. The system needed a tremendous amount of computing power to extract features, requiring the user to process features on a server and not on their mobile device. Ismail et al (2024) employed a two-stage image processing methodology. The process starts with the resizing, grayscale conversion, and rotation of ₦500 and ₦1000 banknotes, which undergo scanning to prepare them for SURF-based analysis. The system uses three image quality assessments to evaluate note eligibility for automated teller machine (ATM) operation. The algorithm achieved perfect accuracy in denomination identification when tested on a dataset containing 562 banknotes, which included 286 ₦500 notes, 270 ₦1000 notes, and 6 other notes. The Peak-Signal-to-Noise Ratio (PSNR) metric showed excellent results because it accurately classified every one of the 60 "fit" ₦500 notes and 93.8% of the 226 "unfit" notes. The PSNR metric for ₦1000 notes achieved accurate classifications of 136 "fit" notes and 120 "unfit" notes from a total of 142 "fit" notes and 128 "unfit" notes. The system recorded an overall accuracy rate of 97% for fit records and 93.8% for unfit records because PSNR demonstrated better accuracy than both SSIM and MSE. The two main obstacles that need resolution stemmed from the dataset's restricted size and its unbalanced distribution, which contained only 654 images and an extremely small quantity of non-target notes. The quality-metric stage required detailed pre-processing and threshold selection because it responded strongly to both image orientation and image degradation. The unfit notes showed decreased performance with SSIM and MSE, which suggests that these metrics fail to assess all types of banknote damage or wear. Woods & Oladosu (2020) built CNNs (VGG-16) with TensorFlow and OpenCV, reaching 92.75% accuracy. The model encountered difficulties when attempting to extend its functionality to different currencies.

2.7.3 The Traditional to Machine Learning. Ensemble learning and Deep Learning (2020–2026)

Researchers began using Deep Learning (DL) architectures after 2020 because they needed to adopt a new research methodology. The literature from this period shows a primary focus on Convolutional Neural Networks (CNNs), which help researchers extract essential features from their work. The VGG16, ResNet50, and InceptionV3 models enable users to identify complex design elements through their processing of unprocessed image data. The era shows a dominant pattern of researchers applying transfer learning to their work. Researchers used ImageNet-trained models, which they modified through training on their limited Naira note datasets because they could not find enough

Nigerian currency data for their research. The research used this methodology to achieve performance metrics that exceeded 98% through the use of limited training resources. The period from 2023 to 2026 marks the beginning of research into MobileNetV2 and EfficientNet, which academic institutions use to enhance their processing speed and precision rates. (Richard-Nnabu et al., 2024) used Convolutional Neural Networks (CNNs) to detect counterfeit Nigerian Naira notes. The model achieved 95% accuracy because the testing included both folded notes and partially faded notes. The strength of CNN's in handling such complexities underlines their potential for counterfeit currency identification. The study demonstrated that the approach needs larger and more diverse datasets to improve its ability to identify currency. Ibitoye (2024) developed a Modified Faster R-CNN system which uses the Inception V3 architecture. The method achieved 97% detection accuracy, but it failed to identify worn-out or damaged notes and needed high-quality photos for precise recognition. Nwokoye & Moru, (2025) developed a cost-effective technological solution that enables visually impaired users to identify Nigerian naira banknotes. The system was created by customizing an SSD-MobileNet V2 FPNLite detector, which operated at 320x320 pixel resolution. The system was optimized for mobile devices through TensorFlow Lite, while Google Text-to-Speech provided spoken feedback. The development process started with image capture and proceeded through image preparation, which involved size adjustments, standardization, and data expansion techniques. The recognition model training used a specially assembled dataset of 3,468 images, which contained duplicate photos of each currency type that had undergone extensive editing. The researchers utilized the optimized model for real-time identification purposes. The system testing with previously unused image data demonstrated exceptional detection accuracy for all seven naira denominations. The system reached 97.11% mean average precision (mAP) at Intersection over Union (IoU) 0.55 and 93.29% at IoU 0.90 and 83.81% at IoU 0.95, while the total system exceeded 90% mAP. Convolutional Neural Networks extract image features. Feature selection was done by the Networks (CNNs) for deciphering the note values. A custom CNN structure, as well as some structures provided by the library, were used for this purpose. The experimental results indicate that both the custom CNN and pre-trained CNN models reached the correct answer for all the questions on the test. data. The CNN models required both large sets of training data and higher-level graphics processing units, which produced problems in their use with mobile devices. Meanwhile, deep learning methods were reviewed in academic literature. which is used by researchers for making a fake banknote is a fascinating area. Using deep learning for forging a fake banknote is a fascinating field. This was accomplished by examining papers that were published from 2018 to 2024. (Yusuf et al, 2025) conducted several Convolutional Neural Network (CNN) architectures, and in this set, there are AlexNet, MobileNet, VGG16, ResNet, which form the foundation of the DNN networks. The DNN networks are based on Inception V3, along with Recurrent neural Networks. RNNs and generative adversarial networks (GANs). The studies used datasets with images of several different countries' banknotes, including the Indian Rupee, Nigerian-Naira, CFA Franc, and Saudi Riyal. The studies were successfully classified with accuracy rates of 70% to 99.84%. The methods of approach gave better results.

2.7.4 Comparative Examination of Selected Studies

Table 3 will be used to compare the research methods used in the 11 most important papers studied and evaluate them. The table illustrates the changes from traditional methods to deep learning methods and some of the key constraints of dataset size and environmental durability.

3. PROSPECTS AND FUTURE DIRECTIONS

The study, considered the Nigerian banknote identification systems for the next decade, 2016-2026, revealed that the Nigerian banknote identification systems have entered a new technological area. Although laboratory tests have demonstrated top-level performance results ranging up to 99 percent, the academic work of the research has yet to yield profitable financial systems. The current research methods can only partially improve classification accuracy to a small degree and will increasingly meet with the challenges of data standardization, system adaptation, system performance, and security feature combination in the future. The following list of areas presents key areas that need to be further explored:

Table 3: *Comparative Analysis of Nigerian Image Analysis Techniques (2016-2026)*

Author/Year	Method/Algorithm	Data Size	Accuracy	Limitation
Omeiza et al., 2023	Color histograms in HSI color space with a rule-based classifier using 10-bin histograms for hue, saturation, and intensity components	Not explicitly specified; focused on ₦200, ₦500, ₦1000 Naira notes	98.66%	Performance issues with soiled or damaged notes; mitigation focused on lesser denominations
Dittimi et al., 2017	Background removal (Otsu thresholding + connected component analysis), HOG feature extraction, PCA dimensionality reduction, ECOC-MCSVM classification framework	5,200 banknote images: 1,800 Naira, 1,000 USD, 1,000 CAD, 1,400 EUR; captured with Canon T2i at 200dpi under varied conditions	99% Naira, 97% USD, 96% CAD, 98.6% Euro	Performance decline under extreme lighting/distortion; PCA may discard subtle discriminative patterns; high computational complexity from ECOC-MCSVM; denomination recognition only (no counterfeit detection)
Dittimi & Suen, 2018	Mobile application (Unity 3D); layered ensemble KNN combining Euclidean, Manhattan, Chebyshev, and Minkowski distance metrics with weighted voting system	Nigerian Naira (₦100-₦1000) photographed via smartphone cameras; diverse lighting, angles, wear states; included genuine and counterfeit samples (exact count unspecified)	99.27% denomination recognition; 94.70% counterfeit detection; 0.02ms avg processing time	Visible-light imaging limits the detection of sophisticated counterfeits; performance drops with severely dirty/torn/creased notes; requires precise parameter tuning; dependent on image resolution and stable camera positioning
Dittimi & Suen, 2019 Dittimi & Suen, 2019	Client-server mobile app (Unity 3D + MATLAB); blended framework: HOG feature extraction, High Correlation Filters (HCF) for dimensionality reduction, Weighted Majority Average ensemble of MLPNN and MCSVM	Multi-currency dataset (Naira, USD, CAD, EUR); genuine images (Canon T2i) + counterfeit samples (HP Color LaserJet); varied angles and illumination (exact counts unspecified)	99.00% identification accuracy; 0.051s average processing time	High computational demands requiring server-side processing; smartphone camera focusing/resolution limitations at close range; sensitivity to background interference and lighting variations; processing time fluctuations based on note size and pixel density

Author/Year	Method/Algorithm	Data Size	Accuracy	Limitation
Almu & Muhammad, 2020	Pattern recognition system (Visual Basic + MS Access); preprocessing, feature extraction (color, watermarks, serial numbers), pixel-wise comparison against reference database with 95% similarity threshold	Reference database of genuine Nigerian banknotes; user trials with 15 participants (exact image dataset size not specified)	Successful identification of authentic/fake notes under typical conditions; no specific accuracy percentage reported.	Unreliable with heavily damaged, soiled, or degraded notes due to pixel-comparison approach; limited robustness to visual obstructions; recommended integration of multiple image-processing techniques and mobile interface
Adewole et al., 2023	Three-stage pipeline: enhanced object detection for currency classification, pre-trained algorithm for serial number localization, three OCR systems (Pytesseract, EasyOCR, KerasOCR) for character recognition	Not explicitly specified in the provided text	100% accuracy for currency classification; peak 81% character recognition accuracy (EasyOCR)	Insufficient OCR accuracy for practical deployment; OCR models not specifically adapted to Nigerian currency serial number formats; prone to errors from note condition variations, image quality issues, and complex visual backgrounds
Ismail et al., 2024 Ismail et al., 2024	Two-stage pipeline: (1) Preprocessing (resizing, grayscale, rotation) + SURF feature extraction + KNN classifier for denomination recognition; (2) Fitness assessment module using MSE, PSNR, and SSIM image quality metrics	562 test banknotes (286 ₦500, 270 ₦1000, 6 other notes); total dataset approximately 654 images with noted class imbalance	Denomination recognition: 100%; Fitness classification (PSNR metric): ₦500 fit=100%, unfit=93.8%; ₦1000 fit=95.8%, unfit=93.8%; Overall averages: 97% fit notes, 93.8% unfit notes	Modest dataset size with class imbalance; fitness metrics sensitive to image orientation and degradation requiring careful preprocessing/threshold tuning; SSIM and MSE underperformed on unfit notes; may not comprehensively capture all wear/damage patterns

Author/Year	Method/Algorithm	Data Size	Accuracy	Limitation
Adeniyi et al., 2024	Hybrid approach: Circular Local Binary Pattern (CLBP) for rotation-invariant texture feature extraction combined with CNN architectures (custom design + transfer learning models: VGG, ResNet variants) for feature selection and classification	Higher-value Naira notes (₦200, ₦500, ₦1000) with various damage types (ripped edges, faded ink, creases, partial coverage); captured under diverse lighting/orientations (exact count not specified)	100% classification accuracy on testing data for both custom CNN and pre-trained transfer learning models	CLBP extraction is computationally intensive and vulnerable to severe noise/physical damage; CNN models require extensive training data and powerful GPUs, limiting mobile/embedded deployment; untested on lower denominations (₦5–₦100); high controlled-test accuracy may not translate to real-world scenarios with sophisticated counterfeits; recommends multi-modal authentication (UV, magnetic, tactile)
Richard-Nnabu et al., 2024	Convolutional Neural Networks (CNN) for binary classification of genuine vs. counterfeit Nigerian Naira notes	Not explicitly specified in the provided text	95% accuracy maintained even with folded or partially faded notes	Limited by dataset size and diversity; authors emphasized need for larger, more varied datasets to enhance model generalizability and practical relevance for real-world currency identification scenarios
Nwokoye & Moru, 2025	SSD-MobileNet V2 FPNLite object detector (320x320 input), optimized with TensorFlow Lite for mobile deployment; integrated with Google Text-to-Speech for auditory feedback	3,468 annotated images (each of 7 Naira denominations photographed twice with extensive data augmentation techniques)	mAP: 97.11% at IoU 0.55, 93.29% at IoU 0.90, 83.81% at IoU 0.95; overall system >90% mAP; ~80% accuracy when trained on restricted/lower-quality data	Small dataset size with limited variety; reliance on standard-resolution camera images; accuracy degradation (~80%) with lower-quality training data; requires more extensive, higher-resolution datasets and advanced augmentation for improved reliability

Author/Year	Method/Algorithm	Data Size	Accuracy	Limitation
Yusuf et al., 2025	Systematic review of deep learning approaches: CNN architectures (AlexNet, MobileNet, VGG16, ResNet, Inception V3), RNNs, and GANs for counterfeit detection	Multi-currency datasets (Indian Rupee, Nigerian Naira, CFA Franc, Saudi Riyal) from public archives, web scraping, and organizational holdings (exact sizes not specified in review)	Reported classification accuracy range: 70% to 99.84%; ensemble and pre-trained model approaches typically yielded superior performance	Limited adaptability to degraded or imperfect banknotes; imbalanced datasets with scarce counterfeit examples; high computational requirements hindering mobile/embedded deployment; model capacity/lack of interpretability impedes adoption in transparent, rule-based financial decision-making contexts

3.1 Establishment of Standardized Public Benchmarks

The most frequently reported limitation identified during the literature review is that the datasets are incomplete in various capacities, such as basically. It is not always complete, so even if search thoroughly and look at them, there is still some missing information. The lack of data makes it impossible to confirm findings, while it makes models develop excessive dependence on their training data, according to the research of (Dittimi et al, 2017). The research community requires a collaborative effort to develop a publicly shared reference dataset that serves as a standard benchmark for research. The collection should include:

a) *Comprehensive Denomination**:*** The complete legal currency collection includes all current denominations, which range from ₦50 to ₦1000 and feature both the old design and the new design introduced after 2023.

b) *Diverse Physical State**:*** The research team built classification models for note quality assessment by intentionally including new notes together with worn notes, dirty notes, damaged notes, and creased notes.

c) *Challenging Examples:* The study requires a validated collection of advanced counterfeit banknotes to address the issue of example distribution imbalance, which Dittimi and Suen (2018) and Richard-Nnabu et al. (2024) identified.

d) *Environmental Diversity:* The images were taken under various illuminations, backgrounds, and camera settings to simulate situations that mimic market and ATM conditions.

3.2 Domain Adaptation for Currency Redesigns

The Central Bank of Nigeria implemented a currency redesign in December 2022, which creates a major obstacle for people who need to research and identify Nigerian currency because they must learn new recognition methods. The current recognition models, which were created before 2022, become useless when they try to recognize banknotes that have different color patterns, security elements, and design features. The process of developing new models requires organizations to allocate substantial resources and dedicate extended periods of time to development work.

Future Direction: Research should focus on Transfer Learning and Few-Shot Learning methods as primary research objectives. The research team aims to develop model architectures that can learn new currency designs with only small amounts of labeled data. Generative Adversarial Networks (GANs) will enable the creation of authentic images that represent new currency denominations and their counterfeit versions. The system will use limited real-world data to help secure procedures; this will boost its generalization capabilities, but maybe not in a perfectly linear way

.

3.2 Optimize for lightweight Edge AI and mobile devices.

The creation of deep learning models such as VGG and ResNet establishes a sort of high-precision standard, but the processing requires the resources of central servers, so it is a tight bottleneck. This means that the system may exhibit performance delays and, at the same time, it is also a challenge for data protection due to the same processing requirement. Also, the incorporation of a compact version of MobileNet called MobileNet in our design, which also increases the speed of the operations, but at the cost of accuracy, as is only fair given the requirement.

Further direction: More attention should be paid to the research of model compression techniques in the future, which is not only a side step but is the main focus, such as pruning, quantization, and knowledge distillation. The goal is to deploy powerful convolutional neural network (CNN)-based systems directly onto low-power devices, such as ATMs, point-of-sale terminals, and even some simple cell phones, soon and with minimal delay or power consumption. The study should also really focus on Federated Learning, as it seems like it is an important part of this whole scenario. In practical terms, mobile technology can improve their recognition models through collective learning whilst preserving users' image data. This means improved overall privacy protection and more security measures that's the point.

3.3 Anti-Counterfeiting using Multi-Modal Sensor Fusion

The problem with this analysis is that it relies on the visual characteristics alone for its evaluation. Research shows that sophisticated counterfeiting can be able to replicate the appearance of an optical identification system in a convincing way, making optical systems incapable of providing security in a secure facility.

Future Direction: Future authentication systems should be based on more than one type of sensor, which is also referred to as multimodal sensor fusion. The concept is that the visual information in the normal color image is matched to other information such as that under UV, IR, and magnetic ink detection. Additionally, there is surface texture analysis, which is quite useful in practice. These pieces, when combined, should make the authentication system seem more secure, and it's the combination of the pieces that makes it secure, not just one of them. So, the research should be centered on making useful evidence integration algorithms for several sources and getting all that into an authenticity result. It should do that to lower the rates of false identification, which is where fake products are mistaken as real products.

3.4 Environmental Robustness and Light-Condition Handling

The studies indicate that when conditions are less than optimal, performance decreases. The system demonstrated two major issues, which included failing to process soiled currency notes and also not being able to cope with changes in lighting and viewing angles, in general.

Future Direction: The researchers really do need to make algorithmic resilience a little stronger by implementing ways of identifying and fixing errors that crop up as the notes are classified. In the first stages of data processing, advanced techniques that get rid of the background noise and also standardize lighting conditions, even across different currency note materials and those varied surfaces, are implemented. Basically, the quality determination of a currency (for ATM suitability, like it or not) should be considered a different and concurrent task, in addition to denomination. For that, it might be able to rely on more nuanced texture analysis, instead of basic pixel measurements.

3.5 Inclusivity and Accessibility

While it may feel a bit odd, the use of Text-to-Speech (TTS) technology looks like a good idea for increasing access to financial services for persons with visual impairments. In practice, the function shows up at certain moments; it is not something users see all the time.

Future Direction: The next step in the process should focus on adopting universal design concepts. The system for recognition requires the developers to create functions determining values and to push the user toward immediate alerts, which should be achieved through sound. Multiple local languages should be supported simultaneously. Further research on tactile feedback mechanisms for user validation would also benefit other groups of users in the identification of currency. That's the whole direction that we're going in, towards financial equity, and if it's a bit uneven, that's what we're going in.

4. CONCLUSION

This study reviewed the developments of image analysis research in Nigeria's currency from 2016-2026, which aimed at evaluating the development of image analysis of Nigerian currency during the mentioned time period. Of the 150 publications retrieved, 55 methodologically eligible studies were identified, and 17 of these were subjected to detailed critical appraisal to gain a detailed understanding of the methods, performance trends, and research gaps. The review clearly shows the technological evolution from traditional image processing methods and handcrafted feature extraction techniques to hybrid machine learning methods and, more recently, to deep learning architectures like CNNs, transfer learning, and lightweight object detectors. The accuracy of reported recognition varied from around 70% to 100% across the studies reviewed, with some recent deep learning models able to reach above 99% accuracy under controlled experimental conditions. However, such great success has not been achieved yet for successful deployment in the wild due to the lack of widely available datasets, the absence of good representation of worn and counterfeit banknotes, the sensitivity to illumination and environmental changes, heavy computational demands, and insufficient model generalization. One of the major conclusions of this review is that the redesign of banknotes by the Central Bank of Nigeria (CBN) in 2022 has completely changed the appearance and security features of the higher denominations, making the effectiveness of models trained only on the previous series of banknotes null and void. Therefore, future studies should focus on the development of adaptive learning strategies that could continue to facilitate the recognition of banknotes even if they were redesigned, without necessitating a complete redevelopment of the banknote model. Overall, the review points towards the development of a system that is robust, adaptive, explainable, and efficient in terms of computation, as well as optimizing classification accuracy in future Nigerian currency authentication systems. The development of standardized benchmark datasets, leveraging transfer learning and few-shot learning to handle redesign challenges, the integration of multimodal sensing, the enhancement of environmental robustness, and the promotion of inclusive accessibility features will be crucial in bringing research innovations to viable financial authentication solutions that can thrive in the practical Nigerian banking and commercial landscape.

APPENDIX: SCREENING PROCESS AND QUALITY ASSESSMENT

1.1 Screening Flow Summary

Identification: Records identified (n=150)
Removed before screening: Duplicates/irrelevant (n=60)
Screening: Abstracts screened (n=90)
Excluded after abstract screening (n=35)
Eligibility: Full texts assessed (n=55)
Included in qualitative synthesis (n=55)
Detailed comparative appraisal in Table 3 (n=17 representative studies).

1.2 Quality Assessment Criteria

Each eligible study was evaluated against: (1) clear objectives, (2) adequate dataset description, (3) reproducible methodology, (4) appropriate validation metrics, (5) limitations discussed, (6)

relevance to Nigerian currency image analysis. Each criterion was scored 0–2 (maximum 12). Studies scoring ≥8 were considered methodologically sound and retained.

1.3 Inter-rater Procedure

Two reviewers independently screened titles/abstracts and full texts using the predefined inclusion/exclusion criteria. Disagreements were resolved through discussion and consensus; unresolved cases were adjudicated by a third reviewer. Agreement was monitored using Cohen's kappa, with $\kappa \geq 0.80$ targeted before full screening.

ABSTRACT
Network Intrusion Detection Systems (NIDS) require informative features to distinguish benign from malicious traffic. This study investigates Random Forest feature importance for reducing the dimensionality of NSL-KDD. Using KDDTrain+, an 80:20 stratified split was applied after preprocessing, producing 121 predictive features. The top 30 features selected by Random Forest reduced dimensionality by 75.21%. Evaluated with an optimized Random Forest, the reduced representation achieved 99.83% accuracy, 99.93% precision, 99.70% recall, 99.82% F1-score, and 0.0594% false-positive rate. The results demonstrate that Random Forest can identify a compact and informative feature subset under the stated experimental conditions. However, computational efficiency was not directly measured, and a full 121-feature baseline must be rerun before confirming performance preservation or improvement.

Keywords: *Network Intrusion Detection; Feature Selection; Random Forest; Feature Importance; NSL-KDD; Machine Learning; Dimensionality Reduction*

1. INTRODUCTION

The continued growth of computer networks and Internet services has increased the need for automated detection of malicious activities. Network Intrusion Detection Systems (NIDS) monitor network traffic and classify connections as normal or suspicious. Machine-learning techniques are widely used because they can learn attack patterns and support automated detection (Buczak & Guven, 2016; Khraisat et al., 2019).

The NSL-KDD dataset remains a widely used benchmark for evaluating machine-learning-based intrusion detection methods. It was developed to address limitations of the original KDD Cup 1999 dataset and provides a structured basis for IDS research (Tavallaee et al., 2009). However, categorical encoding can produce a high-dimensional feature space containing variables with limited contribution to classification.

Feature selection reduces this problem by identifying relevant variables while preserving their original meaning. Common approaches include filter, wrapper, and embedded methods (Chandrashekar & Sahin, 2014). Random Forest provides an embedded feature-importance mechanism that can rank variables according to their contribution to model performance (Breiman, 2001).

Recent studies have highlighted the importance of feature selection in IDS research, including the use of Random Forest on NSL-KDD (Umar et al., 2025). However, differences in preprocessing, data partitioning, and evaluation procedures make direct comparison difficult.

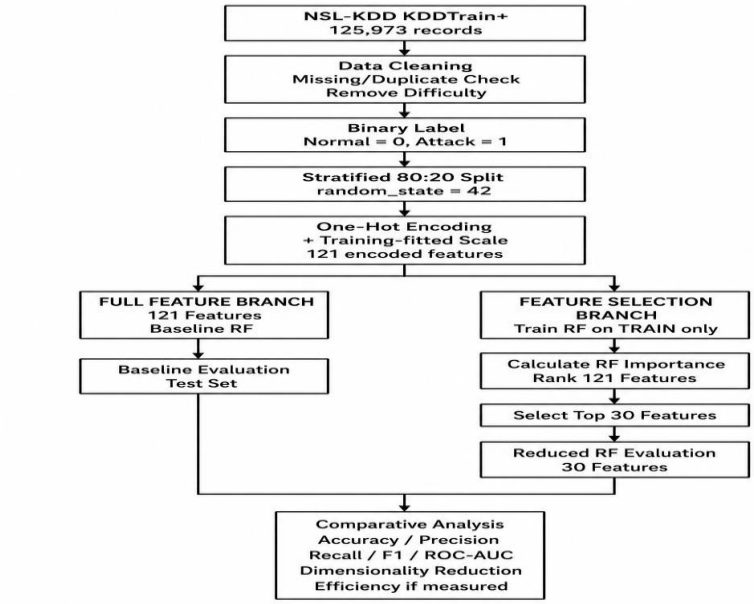
Therefore, this study investigates Random Forest feature importance for ranking the 121 encoded predictive features of NSL-KDD and selecting the top 30 features for intrusion detection classification. The study (i) applies a reproducible Random Forest-based feature-ranking procedure, (ii) reduces the feature space from 121 to 30 features, and (iii) evaluates the selected features using an optimized Random Forest classifier on a held-out test set.

2. RELATED WORK

Machine learning is widely used for intrusion detection, with studies emphasizing dataset characteristics, algorithm selection, and computational considerations (Buczak & Guven, 2016).

Feature selection reduces redundant and irrelevant variables and can improve IDS efficiency. Methods are commonly classified as filter, wrapper, and embedded approaches, with Random Forest providing embedded feature-importance measures during training.

Recent NSL-KDD studies demonstrate the value of feature selection. RF-based and other selection methods have achieved strong detection performance while reducing feature dimensionality.



This study applies Random Forest impurity-based feature importance to select the top 30 features from 121 one-hot-encoded NSL-KDD features and evaluates them using an optimized Random Forest under an 80:20 stratified KDDTrain+ split.

3. METHODOLOGY

3.1 Research Design

An experimental machine-learning design was adopted. The complete workflow consisted of data preparation, train-test partitioning, binary label transformation, categorical encoding, feature scaling, Random Forest feature-importance estimation, feature ranking, top-30 selection, classification and comparative analysis.

The test partition was not used to calculate feature-importance scores or select features.

3.2 Dataset

The experiment used the KDDTrain+ file from the NSL-KDD dataset. The loaded file contained 125,973 records and 43 columns, comprising 41 predictive attributes, the attack label and the auxiliary difficulty attribute.

The three categorical attributes were:

- protocol_type
- service
- flag

The original attack labels were retained during initial loading and subsequently transformed into a binary classification target.

KDDTest+ was not used in the reported experiment. Instead, KDDTrain+ was partitioned into training and testing subsets.

3.3 Data Preprocessing

Data integrity checks were performed before modelling. The notebook recorded no missing values and no duplicate rows in the loaded KDDTrain+ data.

The auxiliary difficulty attribute was removed before the final experimental pipeline. Consequently, the model input contained 41 predictive attributes before categorical encoding.

The preprocessing procedure therefore consisted of:

1. loading KDDTrain+;
2. checking missing and duplicate records;
3. removing difficulty;
4. separating predictors and target;
5. splitting the data into training and testing partitions;
6. converting the target to binary labels;
7. one-hot encoding categorical predictors; and
8. standardizing the resulting numerical representation.

3.4 Binary Label Transformation

The original attack categories were transformed into a binary target:

$$y = \begin{cases} 0, & \text{normal} \\ 1, & \text{attack} \end{cases}$$

After the 80:20 stratified partition, the training set contained 100,778 records, comprising 53,874 normal and 46,904 attack records. The test set contained 25,195 records, comprising 13,469 normal and 11,726 attack records.

3.5 Categorical Encoding

The categorical attributes protocol_type, service and flag were converted into binary indicator variables using one-hot encoding.

After removal of the difficulty attribute, the resulting representation contained 121 encoded predictive features.

The encoding was performed separately on the training and test partitions, after which the test representation was aligned to the training feature columns. This ensured that both partitions had the same model-input structure.

3.6 Feature Scaling

Standardization was applied using StandardScaler.

For a feature x, the standardized value is:

$$z = \frac{x - \mu}{\sigma}$$

where $\mu$and σrepresent the mean and standard deviation estimated from the training data.

Importantly, the scaler was fitted only on the training partition:

$$X_{train}^{scaled} = Scaler.fit(X_{train})$$

and subsequently applied to the held-out test partition:

$$X_{test}^{scaled} = Scaler.transform(X_{test})$$

Thus, test-set statistics were not used when fitting the scaler.

Although Random Forest is relatively insensitive to feature scaling, scaling was retained as part of the implemented preprocessing pipeline.

3.7 Train/Test Strategy

The 125,973 KDDTrain+ observations were divided using an 80:20 stratified train-test split:

- training: 100,778 records;
- testing: 25,195 records;
- test_size=0.20;
- random_state=42;
- shuffle=True;

- stratification based on the binary target.

The stratified procedure preserved the relative distribution of normal and attack instances between the two partitions.

No KDDTest+ records were used in the reported experiment. Consequently, the results should be interpreted as performance on a random held-out portion of KDDTrain+ rather than as results obtained using the standard KDDTrain+/KDDTest+ benchmark separation.

3.8 Random Forest Feature Importance

Random Forest was used as the feature-importance estimator. The optimized Random Forest configuration obtained through five-fold randomized cross-validation was:

Parameter	**Value**
Number of trees	100
Maximum depth	30
Minimum samples split	10
Minimum samples leaf	1
Maximum features	sqrt
Criterion	Gini (default)
Bootstrap	True (default)
Class weight	None (default)
Random state	42
Number of parallel jobs	-1

The hyperparameter search considered 20 randomly selected parameter combinations using five-fold cross-validation and accuracy as the scoring measure. The best cross-validation accuracy recorded in the notebook was 0.9995634.

Feature importance was obtained from the Random Forest feature_importances_ attribute. This corresponds to impurity-based, or Mean Decrease in Impurity (MDI), importance. For a feature j, its overall importance can be represented as the sum of the impurity reductions attributable to that feature across the trees, weighted by the number of samples reaching the corresponding nodes.

The feature-importance estimator was fitted using the training partition only. The test labels were not used in feature ranking.

3.9 Feature Ranking and Top-30 Selection

The 121 encoded training features were ranked in descending order according to their Random Forest importance scores. The 30 highest-ranked features were retained.

The reduction was:

$$121 - 30 = 91$$

and the percentage reduction was:

$$\frac{121 - 30}{121} \times 100 = 75.21\%$$

Thus, the selected representation contains:

$$\frac{30}{121} \times 100 = 24.79\%$$

of the original encoded feature space.

Table 1: Feature Representation Progression

Representation	**Features/Attributes**	**Description**
Raw predictive representation	41	Original predictive attributes after removing label and difficulty
Encoded representation	121	Predictive features after one-hot encoding
Selected representation	30	Top-ranked features selected using Random Forest importance
Features removed	91	Features excluded from the reduced representation

30	srv_rerror_rate	0.007518

3.10 Final Classifier and Configuration

The classifier used to generate the reported 99.83% performance was the optimized Random Forest classifier operating on the 30 selected features.

This distinction is important. Random Forest was first used to estimate feature importance and rank the 121 encoded training features. The resulting 30-feature subset was then used to retrain the Random Forest classifier for the final evaluation.

The final classifier used:

- 100 trees;
- maximum depth of 30;
- minimum samples split of 10;
- minimum samples leaf of 1;
- square-root feature selection at each split;
- Gini impurity criterion;
- random_state=42;
- parallel execution using n_jobs=-1.

The classifier was fitted using the training records and evaluated using the held-out test records.

3.11 Baseline and Reduced-Feature Experiments

A valid comparison requires evaluation of the same classifier and experimental procedure using both the complete 121-feature representation and the reduced 30-feature representation.

The supplied notebook contains earlier baseline experiments, but those experiments were conducted before removal of difficulty and therefore used a different 122-feature representation. Those values should not be presented as the 121-feature baseline required for this comparison.

Table 3: Full-Feature Versus Reduced-Feature Random Forest Performance

Feature Representation	**Accuracy**	**Precision**	**Recall**	**F1-score**
Full 121 features	**99.96%**	**99.97%**	**99.94%**	**99.96%**
Selected 30 features	99.8293%	99.9316%	99.7015%	99.8164%

The full-feature baseline must be rerun using exactly the corrected 121-feature pipeline before the paper can state whether the selected representation preserves, improves or reduces predictive performance relative to all available encoded features.

3.12 Computational Efficiency Evaluation

The experiment did not record training time, prediction time or memory consumption. Therefore, computational efficiency cannot be claimed as an experimentally demonstrated outcome.

The demonstrated result is feature-space reduction from 121 to 30 features, corresponding to 75.21% dimensionality reduction.

Measure	**Full 121 Features**	**Selected 30 Features**
Training time	Not measured	Not measured
Inference time	Not measured	Not measured
Memory usage	Not measured	Not measured
Number of input features	121	30
Feature reduction	—	**75.21%**

4. RESULTS AND DISCUSSION

4.1 Feature Selection Results

Random Forest feature importance produced a ranked representation of the 121 encoded features. The most important features were dst_bytes, src_bytes, flag_SF, dst_host_srv_count, diff_srv_rate and same_srv_rate.

The importance scores indicate that byte-volume characteristics and connection-level or host-level traffic statistics contributed substantially to the fitted Random Forest model. For example, src_bytes and dst_bytes quantify traffic volume associated with a connection, while variables such as count, srv_count and destination-host statistics describe patterns of repeated or related connections. State and service indicators, including flag_SF, flag_S0 and service-specific encoded variables, also appeared among the highly ranked features.

These observations should not be interpreted as proving that any individual feature causes an intrusion. Rather, they indicate that the features provided useful discriminatory information to the trained Random Forest under the experimental conditions.

4.2 Reduced-Feature Classification Performance

Using the 30 selected features, the optimized Random Forest achieved an accuracy of 99.8293%. Precision was 99.9316%, while recall was 99.7015%. The resulting F1-score was 99.8164%.

The confusion matrix was:

	Predicted Normal	**Predicted Attack**
Actual Normal	13,461	8
Actual Attack	35	11,691

Only eight normal instances were incorrectly classified as attacks, giving a false-positive rate of 0.0594%. Thirty-five attack instances were incorrectly classified as normal.

4.3 Full-Feature Baseline Comparison

The supplied notebook does not contain a valid post-correction 121-feature baseline using the same final preprocessing configuration. Consequently, no scientific conclusion can yet be made about whether the 30-feature representation improves or preserves performance relative to the complete 121-feature representation.

The earlier baseline Random Forest result in the notebook should not be substituted for this comparison because it was generated before difficulty was removed and therefore corresponds to a different feature representation.

The required baseline experiment is:

1. use the corrected KDDTrain+ data after removal of difficulty;
2. retain all 121 encoded features;
3. use the same 80:20 stratified split with random_state=42;
4. fit preprocessing only on training data;
5. train the same optimized Random Forest configuration;
6. evaluate on the same held-out test partition; and
7. report accuracy, precision, recall and F1-score.

Only after this experiment is completed can the paper determine whether feature selection preserved, improved or reduced predictive performance.

4.4 Leakage and Evaluation Integrity

The corrected experimental pipeline follows an appropriate order for avoiding direct test-set leakage during preprocessing and feature selection.

The sequence was:

$$KDDTrain+ \rightarrow Train/Test\ Split$$

followed by:

$$Train \rightarrow Encoding/Scaling \rightarrow RF\ Feature\ Importance$$

and:

$$RF\ Ranking \rightarrow Top\ 30$$

The selected feature names were then applied to both the training and held-out test representations. The test labels were not used to calculate feature importance.

The scaling procedure was also training-dependent: the StandardScaler was fitted on training data and subsequently applied to test data.

Nevertheless, the very high performance warrants additional verification. NSL-KDD is a benchmark dataset with a structured distribution, and unusually high results can arise from dataset characteristics, feature distributions, preprocessing choices or differences in evaluation protocols. Recent research has similarly emphasized that NSL-KDD results can vary substantially according to preprocessing, feature-selection strategy, normalization and classifier configuration (Umar et al., 2025).

The present study therefore avoids interpreting the 99.83% result as evidence of equivalent performance on contemporary operational network traffic.

4.5 Comparison with Previous Studies

Comparison with previous NSL-KDD studies should be interpreted cautiously because differences in preprocessing, data partitioning, feature selection, class definitions, and classifiers can substantially affect performance.

Umar et al. (2025) reported 99.86% accuracy using Random Forest, while Anagha et al. (2025) reported F1-scores of 98.7–98.9% using SHAP- and correlation-based feature selection. These results provide useful context but are not directly comparable due to methodological differences.

The 99.83% accuracy obtained in this study is therefore reported specifically for the stated KDDTrain+ 80:20 experimental protocol and should not be interpreted as a universal NSL-KDD performance level.

4.6 Dimensionality Reduction and Potential Efficiency

The principal demonstrated reduction was from 121 encoded features to 30 selected features. This removes 91 model inputs and reduces the feature representation by 75.21%.

The reduction may potentially lower the amount of data processed by subsequent models. However, because training time, inference time and memory consumption were not measured, the study does not claim that computational efficiency was experimentally improved.

A future efficiency experiment should measure both training and prediction time under identical hardware and software conditions for the 121-feature and 30-feature representations.

5. LIMITATIONS

Several limitations should be considered. First, the study uses the NSL-KDD benchmark rather than contemporary network traffic, limiting generalisation to modern environments.

Second, an 80:20 stratified split of KDDTrain+ was used instead of the standard KDDTrain+/KDDTest+ separation, limiting direct comparison with studies using the official test set.

Third, a complete 121-feature baseline under the same preprocessing configuration is not yet available; therefore, claims about performance preservation after feature selection remain preliminary.

Fourth, computational efficiency was not directly measured, so the results demonstrate dimensionality reduction rather than confirmed reductions in training time, inference time, or memory.

Finally, feature-selection stability was not evaluated across repeated partitions or independent datasets, meaning the selected features may partly depend on the specific KDDTrain+ split.

6. CONCLUSION

This study investigated Random Forest feature importance for feature selection in network intrusion detection using the NSL-KDD KDDTrain+ dataset. After removing the difficulty attribute and one-hot encoding, 41 predictive attributes produced 121 features. A stratified 80:20 split was used, with the top 30 features selected from the training data, reducing dimensionality by 75.21%.

The optimized Random Forest achieved 99.83% accuracy, 99.93% precision, 99.70% recall, 99.82% F1-score, and 0.0594% false-positive rate. These results demonstrate that Random Forest

feature importance can identify a compact and informative feature subset under the stated experimental conditions.

However, computational gains were not measured, and the full 121-feature baseline requires rerunning under the same preprocessing configuration. Future work should therefore compare full and reduced representations, measure computational efficiency, perform repeated validation, and evaluate contemporary network-traffic datasets.

ABSTRACT

Structural reliability is the probability of the structure performing its required function adequately for a specific period of time under stated conditions. Reliability analysis on reinforced concrete beam containing Groundnut shell ash as a partial replacement for cement was conducted in this research. The properties of concrete constituents were determined, COREN concrete mix design guidelines were used and the fresh concrete density was 2130Kg/m^3. Twenty (20) samples of concrete cubes of 150mm x 150mm x 150mm size were tested each for 7, 14, 21 and 28 days after casting at 0, 5, 10, 15 and 20% of groundnut shell ash replacement, making a total of 400 cubes. The samples were cured for ages of 7, 14, 21 and 28 days and the compressive strengths were determined. The average compressive strength of 21.38N/mm^2 at 5% replacement for 28 days curing was determined and used for structural design of the beam. The designed beam was subjected to reliability analysis using First Order Reliability Method (FORM). It was observed that the beam designed was safe in bending under Ultimate Limit State of loading, at the span of 2.7m, 300mm depth, 402mm^2 area of steel and 7.454kN/m live load with safety index of 3.90091. Sensitivity analysis revealed that safety index is directly proportional to the depth/area of steel but inversely proportional to the span/ live load of the reinforced concrete beam.

Keywords: *Structural reliability; Compressive strength; RC Beam; Groundnut shell ash*

1. INTRODUCTION

1. INTRODUCTION

Beams are structural elements made to withstand loads that can cause bending and they are always identified using parameters like its length, material and cross-sectional shape. Concrete is one of the most commonly used construction materials in the world. Reinforced concrete is a widely used material in structural engineering practices due to its strength and durability. Due to its unique feature combination of workability, mechanical properties, durability, fire resistance and the wide availability of raw materials sources, concrete has become highly attractive for many applications in the civil engineering industry (Rosa, *et al*., 2023). Several studies have been conducted to investigate the behavior of reinforced concrete structures under different loading and environmental conditions (Szép *et al.* 2023). Concrete is obtained by mixing cement, fine aggregate, coarse aggregate and water in required proportions. The mixture when placed in forms and allowed to cure becomes hard like stone. The hardening is caused by chemical action between water and the cement due to which concrete grows stronger with age. The strength, durability and other characteristics of concrete depend upon the properties of its ingredients, proportion of the mix, the method of compaction and other controls during placing and curing. Concrete possess a high compressive strength and is usually more economical than steel and is non-corrosive which can be made with locally available materials.

Structural reliability is the probability of the structure performing its required function adequately for a specific period of time under stated conditions (Aguwa, 2010; Aguwa, 2013). Structural assessment is a procedure utilized to check the adequacy, integrity and soundness of structures and their components, made to evaluate a structures current and future use and conformance to codes. A reliability evaluation of a structure in engineering is well-defined as the assurance on its

capacity to achieve its design determination within a specified time. Reliability evaluation is founded on the probability philosophies which provide the platform for its measurement. The reliability of a system can be regarded as the likelihood of its acceptable performance based on certain given performance functions. This function is for a definite purpose and it is laid open to extreme settings within a given time (Dey and Kudmetha, 2013; Ishola *et al*, 2021).

All structures have two basic requirements in common; safety from collapse and satisfactory performance of the structure for its intended use. The limit states define the various ways in which a structure fails to satisfy these basic requirements. Ultimate limit states relate to satisfactory performance and correspond to excessive deflection, vibration and local deformation. Limit state design thus refers to the calculations made by the designer to ensure that these failures do not occur.

Due to increasing industrial and agricultural activities, tons of waste materials are deposited in the environment with little effective method of waste managing/recycling. Some of these deposits are not easily decomposed and the accumulation is a threat to the environment and people at large. Some of these waste materials are groundnut shell, rice husks, maize combs, snail shells, palm-kennel shell, coconut shell and saw dust. Groundnut shell is an agro-waste generated from milling of groundnut (Usman, *et al*, (2019). The rising cost of housing and construction materials especially cement in developing countries in the world including Nigeria is a major concern. Therefore, Groundnut shell being a total waste in agriculture for decade has resulted for a decade research to ascertain the use of the ash as soil stabilizer in clay brick production, as a fertilizer on soil and in partial replacement of cement Samuel, (2020).

This study was conducted to address the Limited information available on the structural behavior and load-carrying capacity of reinforced concrete beams incorporating Groundnut Shell Ash (GSA) for tilapia concrete incubator support systems. The uncertainties associated with GSA concrete properties, applied loads, material strength, and structural dimensions are not adequately addressed by conventional deterministic design methods, making the actual safety and probability of failure of the beam uncertain and also to address the inadequate reliability-based assessment for determining the optimum GSA replacement level that can achieve sufficient structural strength, acceptable reliability, and sustainable performance in reinforced concrete beams for tilapia concrete incubators.

The aim of this research is to carry out structural reliability assessment of reinforced concrete beams incorporating groundnut shell ash for tilapia concrete incubators. The objectives are; to determine the physical properties of concrete constituent materials and chemical oxide composition of groundnut shell ash, to determine the compressive strength of concrete, to carry out structural design of the reinforced concrete beam using data from objective one and two and to carry out reliability analysis of the reinforced concrete beam.

2. METHODOLOGY

The materials that were used in this study are Limestone cement, River sharp sand, River gravel, Groundnut Shell Ash and water.

2.1 Limestone Cement

Limestone cement of 42.5 grade was used in this study. It was sourced from a nearby building material shop in Minna. The Limestone cement conformed to requirement for cement to be used for concrete production in accordance with BS 8615-1&2 (2019).

2.2 Fine Aggregates (River Sharp Sand)

The sharp sand used in this study was locally sourced from New Bussa, Niger State which passed through 4.75mm BS sieve. The fine aggregate conformed to requirement for fine aggregate to be used for concrete production in accordance with BS EN 1008: part 1: (2002).

2.3 Coarse Aggregates (River Gravel)

The natural stone used in this research was locally sourced from New Bussa, Niger State. New Bussa natural stone is characterized with rough surface, reddish-brown in color and consist of maximum size of 19mm. The coarse aggregate conformed to requirement for coarse aggregate to be used for concrete production in accordance with BS EN 1008: part 1: (2002).

2.4 Groundnut Shell Ash

The groundnut shell ash used in this study was sourced locally, from New Bussa, Niger State. The groundnut shell was dry and burnt ensuring control burning to produce ash which passed through BS sieve 0.075mm size. The chemical composition of the groundnut shell ash was conducted using x-ray fluorescence (XRF). XRF is an analytical technique that uses the interaction of x-rays with materials like groundnut shell ash to determine its elemental composition; The oxide composition of groundnut shell ash was conducted in conformity to requirement for natural pozzolana used with Portland cement in concrete production in accordance with ASTM C143/C143M (2020).

2.5 Water

Clean potable water devoid of acid and organic substances from Civil engineering laboratory tap of Federal University of Technology, Minna was used during the study. In accordance with BS EN 1008 (2002).

2.6 Mix Design and Casting of Concrete

The mix design that was used for all concrete cubes cast in this work was COREN Standard for Concrete Mix Design Manuel (2017). Table 1 shows the quantity of materials for each mix batch.

Table 1: Quantity of Materials for each Mix Batch

Mix batch	GSA Content(%)	Water (kg)	Cement (kg)	Sand (kg)	Gravels (kg)	GSA (Kg)
M1	0	13.41	21.28	45.48	90.68	0.00
M2	5	13.41	20.22	45.48	90.68	1.06
M3	10	13.41	19.15	45.48	90.68	2.13
M4	15	13.41	18.09	45.48	90.68	3.19
M5	20	13.41	17.02	45.48	90.68	4.26
Total Sum		67.03	95.76	227.42	453.40	10.64

2.7 Compressive Strength Test

The compressive Strengths of the concrete cubes were determined in accordance with the standard procedure given in ASTM C143/C143M (2020). In accordance with small sample theory in statistical analysis, which deals with small samples sizes, typically less than 30 samples, twenty (20) samples of concrete cubes were tested each for 7, 14, 21 and 28 days after casting at 0, 5, 10,15 and 20% of groundnut shell ash replacement. The average compressive strength for 28days curing at 5% replacement was used for structural designs.

2.8 Cylindrical tilapia concrete incubator

Five cylindrical tilapia concrete incubators were idealized as five concentrated point loads acting at their respective positions on the supporting beam, which forms a major component of the incubator stand as shown in figure 1. Each point load represents the combined weight of the reinforced concrete cylindrical incubator, water, and tilapia eggs. Considering the maximum moment of the beam, the incubator loads were further considered as uniformly distributed load. During the deterministic design**,** the load was used to calculate the beam's support reactions, bending moments, and required structural capacity. In structural reliability analysis, the same load effects were treated as uncertain variables together with material and geometric properties, allowing the relationship between the beam's structural resistance (R) and applied load effect (**S**) to be evaluated through a limit-state function, $g(X)=R-S$, using reliability methods such as FORM. Thus, the five incubators provide the discrete loading system, while the beam provides the load-carrying and load-distribution mechanism for assessing both structural safety and reliability.

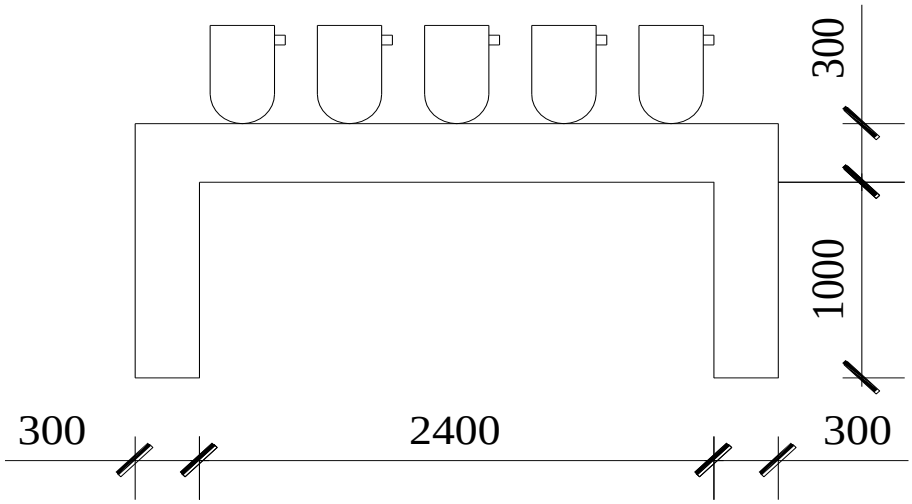

Figure 1: Structural frame (column and beam) carrying five tilapia concrete incubator

2.9 Deterministic Design

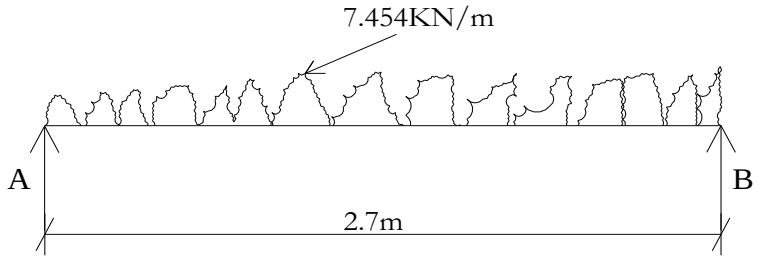

Figure 2: The Cross section of loaded beam to be designed structurally

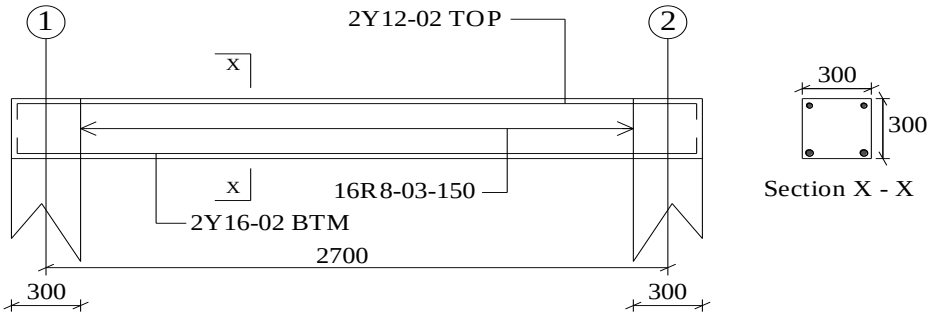

Figure 3: The section of designed beam detail.

2.10 Reliability of the Designed Beam

2.10.1 Estimation of Parameters for Reliability of Beam

The load component of the beam considered was dead load and live load. The live load is the total load of five (5) cylindrical concrete incubators of 15 litres capacity. Load components are treated as random variables, their variation is described by a mean value and a coefficient of variation.

2.10.2 Applied Dead and imposed Load on the beam

Mode of failure by bending.

A beam is subjected to the following failure modes; Bending, Shear, Deflection and Compression failure. For the purpose of this research, Beam failure by bending occurs when the moment capacity is exceeded, causing excessive bending.

From the deterministic design carried out, total live load from the five cylindrical concrete incubators to the beam $= 7.454\ kN/m$

Self-wt of beam$= 2.67kN/m$

Hence, Dead load G_K on the beam $= 2.67kn/m$

Live load Q_K on the beam $= 7.454kN/m$

Design load, $w = 1.4G_K + 1.6Q_K$

Applied moment, $M_S = \frac{wl^2}{8}$; (2.1)

where w = design load and L = span length

$$M_S = \frac{(1.4G_K+1.6Q_K)L^2}{8}; \quad (2.2)$$

$$\therefore M_S = 0.125l^2(1.4G_k + 1.6Q_K)$$

Hence, Applied Moment; $M_S = 0.175l^2G_k + 0.2l^2Q_K$ (2.3)

2.10.3 Structural Resistance Models and equation

Applying force Equilibrium in simply supported reinforced concrete beam above,

According to (Aguwa *et al*, 2015), The Moment resistance of the beam.

$M_R = \phi A_s F_y \left(d - \frac{\phi A_s F_y}{0.85F_{cu}2b}\right)$; Where: ϕ=0.87,

$$M_R = 0.87A_sF_y\left(d - \frac{0.87A_sF_y}{1.7F_{cu}b}\right) \quad (2.4)$$

Where; g(x) = Performance function, R = Resistance (material strength) and S = Demand (Applied stress).

Therefore, the limit state equation is

In reliability, the limit state function (G(X)) is used to ensure the moment of resistance (M_R) exceeds the applied moment (M_S)

$$G(X) = M_R - M_S \quad (2.5)$$

$$G_{(X)} = 0.87A_sF_y\left(d - \frac{0.87A_sF_y}{1.7F_{cu}b}\right) - 0.175G_KL^2 - 0.2Q_KL^2 \quad (2.6)$$

Let, $X_1 = F_y,\ X_2 = F_{cu}, X_3 = L,\ X_4 = G_K,\ X_5 = Q_K, X_6 = d,\ X_7 = A_s,\ X_8 = b,$

Initial values; $X_1(f_y) = 460N/mm^2,\ X_2\ (f_{cu}) = 21.38N/mm^2, X_3(L) = 2700mm,$ $X_4(G_K) = 2.67KN/m,$ $X_5\ (Q_K) = 7.454KN/m,$ $X_6(d) = 260mm,\ X_7(A_s) = 402mm,\ X_8(b) = 300mm,$

Table 2: Input Variables

Variables	Property	Mean (μ)	C.O.V (%)	STD (σ)	PDF(Distribution)
X1	$f_y(\mathrm{N}/mm^2)$	460	0.15	69	Normal
X2	$F_{CU}(\mathrm{N}/mm^2)$	21.38	0.0347	0.7428	Normal
X3	L (mm)	2700	0.1	270	Normal
X4	$G_K(KN/m)$	2.67	0.09	0.2403	Normal
X5	$Q_K(KN/m)$	7.454	0.3	2.24	Normal
X6	$d\ (mm)$	260	0.05	13	Normal
X7	$A_S(mm^2)$	402	0.07	28.14	Normal
X8	$b(mm)$	300	0.05	15	Normal
X9	h_b(mm)	300	0.05	15	Normal
X10	$\gamma_c(\mathrm{N}/mm^2)$	21.30	0.04	0.852	Normal
X11	⏀bar (mm)	16	0.04	0.64	Normal

2.10.4 Performance function linearization

$$G_{(X)} = 0.87X_7X_1\left(X_6 - \frac{0.87X_7X_1}{1.7X_2X_8}\right) - 0.175X_4X_3^2 - 0.2X_5X_3^2 \quad (2.7)$$

Using the equation 2.7, substitute the variables as indicated in Table 2.

$$G_{(X)} = 90932.4X_1 - 239.87X_1^2X_2^{-1} - 1275750X_4 - 1458000X_5 \quad (2.8)$$

The calculation for the reliability analyses was carried out using excel spreadsheet.

$$\mu_G = 90932.4X_1 - 239.87X_1^2X_2^{-1} - 1275750X_4 - 1458000X_5$$

$$\therefore \mu_G = 25181005.46$$

Partial derivatives of equation 2.8

$$\sigma_G^2 = \sigma_{X_4}^2\left(\frac{\partial_G}{\partial X_4}\right)^2 + \sigma_{X_2}^2\left(\frac{\partial_G}{\partial X_2}\right)^2 + \sigma_{X_6}^2\left(\frac{\partial_G}{\partial X_6}\right)^2 + \sigma_{X_7}^2\left(\frac{\partial_G}{\partial X_7}\right)^2 \quad (2.9)$$

$$\sigma_G = 6455164.586$$

$$\beta = \frac{\mu_G}{\sigma_G} = \frac{25181005.46}{6455164.586} = 3.90091$$
$$\therefore \ \beta = 3.90091$$

2.10.5 Sensitivity Analysis.

The sensitivity analyses carried out were done using Excel spreadsheet. The research considered span of the beam, area of steel, effective depth of beam and live load. Iterations were carried out and they converged after three iterations.

3. RESULTS AND DISCUSSION

3.1 Material Characterization.

The physical characteristics and chemical oxide composition were tested and the results were adequately utilized during testing of the concrete strengths and the deterministic design carried out.

3.1.1 Average Specific Gravity for the Materials used or this Study

The average specific gravity reported in Table 3 are suitable and fall within expected ranges based on established literature and technical standards: Fine aggregate (2.63), coarse aggregate (2.55), and cement (3.15) conform to BS EN 1097-6:(2013) specifications. Groundnut shell ash (2.39), falls within the expected range for many agricultural waste ashes and pozzolans, suggesting it is a lightweight, porous material compared to OPC.

Table 3: Average Specific Gravity of the materials after 3 trials

Material	Bulk Density
Fine Aggregate	2.63
Coarse aggregate	2.55
Groundnut Shell Ash	2.39
Cement	3.15

3.1.2 Average Bulk Density of the materials for Uncompacted and Compacted

The average bulk densities reported in Table 4 are suitable and fall within expected ranges based on established literature and technical standards: Fine aggregate (1503.26 kg/m³) and coarse aggregate (1459.86 kg/m³) conform to BS EN 1097-3 and ASTM C29 specifications. Groundnut shell ash (230.90 kg/m³), though much lower than conventional materials, is consistent with published data on agricultural biomass ashes.

Table 4: Average Bulk Density of the materials for Uncompacted and Compacted

Material	Bulk Density		
	Uncompacted	Compacted	Avg. Density
Fine Aggregate	1445.55	1560.96	1503.26
Coarse aggregate	1376.95	1542.77	1459.86
Groundnut Shell Ash	194.33	267.47	230.90

3.2 Chemical Composition of Groundnut Shell Ash

Table 4 shows the results obtained from Inorganic Geochemical Analysis using X- Ray Fluorescence Spectrophotometry. However, the total of 68.6% for its main oxides (SiO_2 + Al_2O_3 + Fe_2O_3) is classified as Class C pozzolan according to ASTM C618 which is suitable for partial replacement of cement in structural work.

Table 5: Chemical Composition of Groundnut Shell Ash

Sample	SiO_2	AI_2O_3	Fe_2O_3	TiO_2	CaO	P_2O_5	K_2O	MnO	MgO	Na_2O	SO_3	CO_2	LOI
GSA	57.5	9.8	1.3	0.6	4	0.4	1.1	0.15	1.8	0.75	0.4	1.8	4.1

3.3 Compressive Strength

The replacement percentages of GSA used for this study were 0, 5, 10, 15 and 20% by weight of cement. The strength of the five replacement percentage samples was tested. The average compressive strength (21.38N/mm^2) for 28days and 5% replacement was used throughout the design.

3.4 Reliability Analysis.

The results of deterministic design carried out were subjected to reliability tests using First order reliability method (FORM). The Reliability index was obtained using Equation (2.8-2.16), at 2.7m span of the beam; the result was 3.90091 which is an indication of safe for such concrete mixture.

3.4.1 Sensitivity Analysis

Figure 3 presents the result of sensitivity analysis conducted in bending for beam varying the span (L) of the beam. As seen from Figure 3, increasing the span of the beam reduce the safety index with reliability index lower than the 3.0 target reliability (β_T), whereas decrease in the span increases the safety level for the concrete under consideration. The beam is reliable at span of 2.7m with reliability index of 3.90091. Kolo, *et al*, (2021) reported that safety index is very sensitive to the span and depth of the beam, hence they are the critical factors to be put into consideration when designing reinforced concrete beam utilizing the natural stone (gravel) as coarse aggregate.

Increasing the span of beam increases the bending moment experienced which contributes to the bending of beam. The span is indirectly proportional to safety index.

Table 6: Reliability index values against the varying beam span

Beam Span, L (mm)	2.700	3.000	3.300	3.600	3.900	4.200
Reliability Index, β	3.90091	3.11644	2.41611	1.73309	1.09189	0.50662

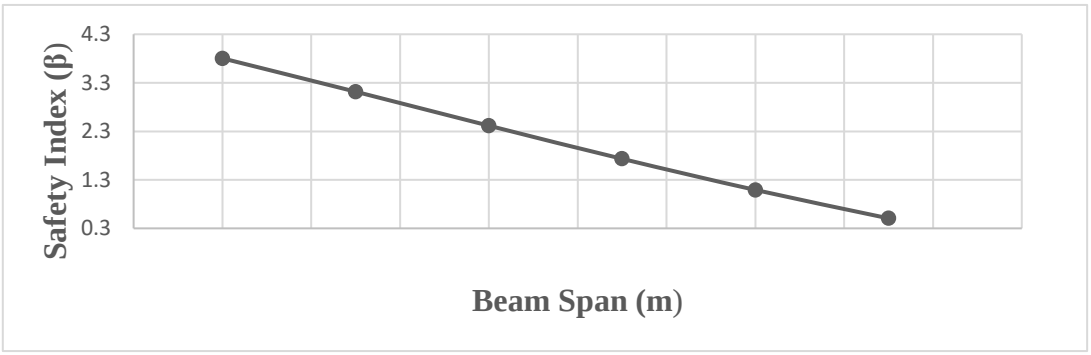

Figure 3: Safety Index-Span Relation for Reinforced Concrete Beam in Bending.

Figure 4 shows the result of sensitivity analysis conducted in bending for beam varying the effective depth of the beam. The Figure indicated an increase in safety index (β) as the effective depth (d) increased from 180mm to 340mm. Safety index was found to be directly proportional to the effective depth for the beam.

Table 7: Reliability index values against the varying effective depth of beam

Effective Depth d (mm)	180.000	220.000	260.000	300.000	340.000	380.000
Reliability Index, β	2.46198	3.24172	3.90123	4.21976	4.53701	4.78533

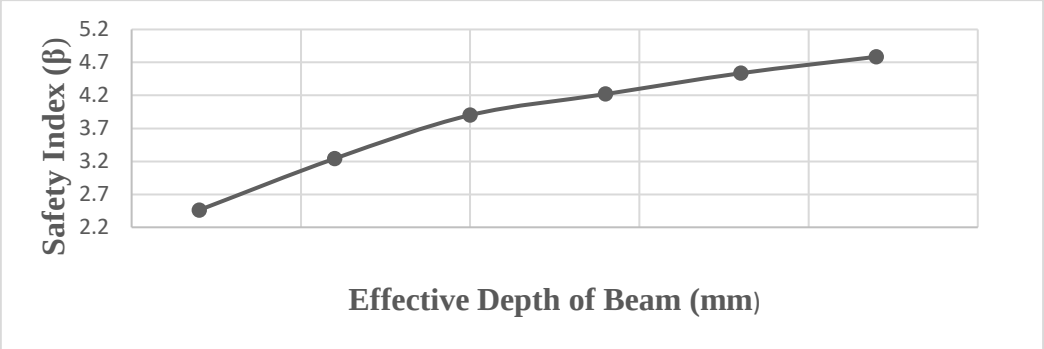

Figure 4: Safety Index-Depth Relation for Reinforced Concrete Beam in Bending

Figure 5 shows the result of sensitivity analysis conducted in bending for beam varying the live load (Q_K) of the beam. The Figure indicated a decrease in safety index (β) as the live load increased from 7.454kN/m to 14.954kN/m. Safety index was found to be indirectly proportional to the live load of the beam.

Table 8: Reliability index values against the varying live load

Live Load, QK (KN/m)	7.454	8.954	10.454	11.954	13.454	14.954
Reliability Index, β	3.90123	3.31016	2.84248	2.40799	2.00889	1.64593

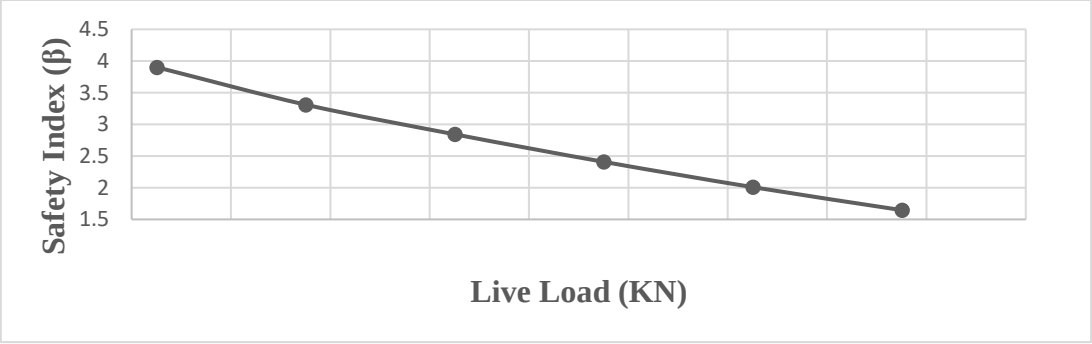

Figure 5: Safety Index-Live Load Relation for Reinforced Concrete Beam in Bending

Figure 6 shows the result of sensitivity analysis conducted in bending for beam varying the area of steel (A_S) for beam. The Figure indicated an increase in safety margin (β) as the area of steel increased from 302mm^2 to 552mm^2. Safety index was found to be directly proportional to the area of steel for the beam.

Table 9: Reliability index values against the varying Area of steel

Area of Steel, AS (mm2)	302.000	352.000	402.000	452.000	502.000	552.000
Reliability Index, β	2.88573	3.39813	3.90123	4.12919	4.39435	4.6133

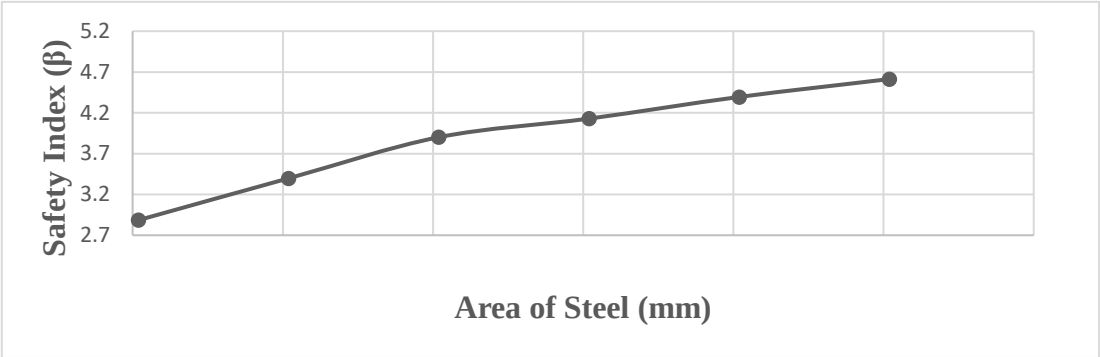

Figure 6: Safety Index-Area of Steel Relation for Reinforced Concrete Beam in Bending

4. CONCLUSION AND RECOMMENDATION

The comprehensive analysis of the Data revealed the following key conclusions, which provide insight into the feasibility of using groundnut shell ash as a partial replacement for cement in structural concrete applications:

(i) The specific gravities of river natural stones, river sand and groundnut shell ash were found to be within the required range. The results obtained from oxide composition shows that the percentage of various chemical oxide compositions of GSA was within the ranges obtainable for the cement.

(ii) The optimum result obtained at 5% replacement GSA was used throughout the structural design.

(iii) From the structural design carried out on tilapia incubator support beam using the average result of compressive strength at 5% replacement showed very impressive results with little increase in reinforcement.

(iv) Safety index was found to be directly proportional to the effective depth and area of steel but inversely proportional to the span and live load of the reinforced concrete beam during Sensitivity Analysis.

ACKNOWLEDGEMENTS

I am very grateful to God Almighty for giving me the grace, wisdom and strength to accomplish this research work. To my darling wife, who has been the pillar and supportive to all my decisions towards my academic attainment.

My special thanks go to my team of supervisors Engr. Prof. J.I. Aguwa, Engr. Prof. A. Mohammed and Engr. Dr. S.F. Oritola for their constructive criticism, corrections, patience and very good Teacher-student relationship which existed throughout the research work. I also thank in a special way the head of department Engr. M. Saidu for his fatherly advice and attention.

I am gratefully indebted to all the staff of civil engineering department of Federal University of Technology, Minna. Words alone cannot express how satisfied I am identifying with each of you. I can only say thank you and may God keep you in His love.

Finally, my thanks go to my PhD mates especially Engr. C.C. Ogbobe's cooperation and understanding which existed throughout the research processes. Thank you and God bless.

ABSTRACT

This study examines how local engineering innovation can drive sustainable industrial growth and support Nigeria's progress toward the Sustainable Development Goals, using a SWOT analysis framework. Nigeria's urgent need for economic diversification and technological self-reliance motivates the research. While the federal government has prioritized local content through Presidential Executive Order No. 5 and the Nigeria First Policy, engineering innovation remains essential for building economic resilience and creating jobs. However, the nation continues to struggle with weak university-industry linkages, limited commercialization of research, and inadequate infrastructure. Guided by the Triple Helix Model of academia-industry-government collaboration, the study draws on policy documents, industry reports, and academic literature to assess Nigeria's engineering innovation ecosystem. The findings reveal promising strengths: a vibrant entrepreneurial culture, a growing startup ecosystem with over 98 tech hubs, and supportive policy momentum. Ahmadu Bello University, Zaria host to Nigeria's first Huawei ICT Academy Support Centre exemplifies local innovation potential; its students won the Innovation Competition Grand Prize and the Women in Tech Award at the 2026 Huawei ICT Competition Global Finals, competing against 177 teams from 49 countries. Yet significant weaknesses persist. Only about 5% of engineering graduates are considered industry-ready, while brain drain, low patent commercialization, and fragile infrastructure remain pressing concerns. Opportunities exist through NASENI's 3Cs initiative, which has brought 44 products to market and created over 25,000 jobs, alongside the African Continental Free Trade Area. However, threats such as economic instability, insecurity in the North-East and North-West, and reliance on foreign technology cannot be overlooked. The study concludes that stronger partnerships, increased applied research funding, intellectual property reforms, infrastructure upgrades, and education improvements are vital for harnessing local engineering innovation and advancing SDG 1, 8, 9, and 17 in Nigeria.

Keywords: *SWOT Analysis; Local Engineering Innovation; Triple Helix Model; Sustainable Industrial Growth; SDGs; Nigeria*

1. INTRODUCTION

Nigeria's quest for sustainable industrial development has been hindered by poor adoption of local technology, dependence on imported engineering innovations, and limited utilization of locally developed solutions (Onoh & Enekwe, 2024). Globally, the engineering sector is being reshaped by digitalization, artificial intelligence, and the demand for sustainable infrastructure. The Chinese Academy of Engineering (2025) reported that 74 of 189 engineering frontiers are AI-related, signalling a new phase of automation and intelligence in engineering practice. Trends like smart cities, renewable energy, and circular economy principles are now central to engineering across developed economies.

Nigeria's federal government has shown commitment to local content through Presidential Executive Order No. 5 (2018), which mandates the use of local talent and products in government-funded projects (Federal Ministry of Information and National Orientation, 2025). The Nigerian Content Bill 2025 (HB. 1167) builds on this by establishing a legal framework to enforce local

content across science, technology, and innovation sectors. However, previous local content legislation, such as the Nigerian Oil and Gas Industry Content Development Act of 2010, has had limited impact on local value creation due to weak in-country capacity, a lesson with clear implications for current policy (Nwankwo & Iyeke, 2022).

The National Agency for Science and Engineering Infrastructure (NASENI) has emerged as a key institution translating policy into industrial action. Through its "3Cs" initiative Creation, Collaboration, and Commercialization NASENI has developed over 44 market-ready products, including laptops, solar irrigation pumps, and electric tricycles, generating over 30,000 direct and indirect jobs. Its DELT-Her programme has awarded over ₦229 million in grants to female engineers, and the 40-hectare NASENI Solar Industrial Park in Nasarawa State is expected to become Africa's largest clean energy manufacturing hub.

Despite these efforts, serious challenges persist in engineering education. Studies indicate that over 70% of Nigerian engineering graduates lack practical skills, with only about 5% considered industry-ready (Ejilah et al., 2023). The curriculum remains outdated, laboratories are poorly equipped, and only 22% of engineering programs have meaningful industry partnerships a clear reflection of weak university-industry linkages. This skills gap has been identified by the Nigerian Content Development and Monitoring Board as a threat to national productivity.

Nigeria continues to face an "engineering vacuum" a structural gap that keeps the country reliant on foreign expertise and imported solutions (Chukwueke, 2025). Its 113th place ranking out of 133 countries in the 2024 Global Innovation Index highlights the scale of the problem. Professor Sesan Peter Ayodeji of FUTA has called for a shift toward human-centered, process-driven innovation, arguing that engineering must be measured by its relevance to local realities and that the Triple Helix model of university-industry-government collaboration should be institutionalized across teaching, research, and policy.

Studies by Onoh and Enekwe (2024), Ibitoye et al. (2022), and Osunkwo (2025) confirm that inadequate infrastructure, unreliable energy, limited access to modern technology, and weak industrial policies continue to limit local competitiveness and deepen dependence on imports. Over-reliance on foreign machinery exposes Nigeria to exchange-rate volatility and supply-chain disruptions, widening the technological gap with advanced economies.

Nevertheless, Nigeria's 301 universities 74 federal, 68 state, and 159 private represent a vast reservoir of potential (National Universities Commission, 2025). Local innovations in civil, electrical, mechanical, and materials engineering could improve industrial operations and reduce environmental impacts. Renewable energy systems, sustainable building materials, and locally fabricated machinery offer pathways to greater self-reliance (Firoozi et al., 2025; Onuh et al., 2024; Taiwo et al., 2024). However, weak commercialization frameworks and fragmented collaboration between academia, industry, and government continue to hinder progress (Ajibo et al., 2019; Nwaichi et al., 2025).

This study is motivated to critically evaluate the role of local engineering innovation in driving sustainable industrial growth and SDG realization in Nigeria. The specific objectives are to:

i. Identify strengths and opportunities within Nigeria's engineering innovation ecosystem.
ii. Analyse weaknesses and threats hindering innovation-driven industrial development.
iii. Assess Nigeria's position relative to global and African engineering innovation trends.
iv. Propose strategic recommendations for harnessing engineering innovation to accelerate SDG attainment.

This research contributes to the growing body of knowledge on engineering innovation in developing economies by providing a comprehensive SWOT analysis grounded in empirical evidence from policy documents, industry reports, and academic literature.

2. METHODOLOGY

2.1 SWOT Analytical Framework

The SWOT analysis framework a strategic planning tool that systematically evaluates an organization or ecosystem's Strengths, Weaknesses, Opportunities, and Threats provide the primary analytical lens for this study. Originally developed for business strategy, SWOT analysis has been widely applied to assess innovation ecosystems, national competitiveness, and policy effectiveness (Auwalu et al., 2026). The framework enables a structured examination of internal factors (strengths

and weaknesses) and external factors (opportunities and threats) that influence the performance of engineering innovation systems. In the context of developing economies, SWOT analysis has been effectively utilized to identify systemic barriers to technology adoption and to formulate strategic interventions for industrial development (Kilaso & Adegbembo, 2025).

2.2 Theoretical Framework: The Triple Helix Model

This study is anchored on the Triple Helix Model of academia–industry–government collaboration, which provides a robust theoretical lens for understanding innovation ecosystems. The Triple Helix Model, originally developed by Etzkowitz and Leydesdorff, posits that effective innovation requires close interaction among three institutional spheres: universities (research and education), industry (production and commercialization), and government (policy and funding) (Cai & Etzkowitz, 2021). The model emphasizes that innovation does not occur in isolation but emerges from the dynamic interplay among these three actors, where each takes on roles traditionally associated with the others universities engage in entrepreneurial activities, industry participates in research, and government facilitates innovation through policy and funding.

In the Nigerian context, the Triple Helix Model has gained significant traction as a framework for understanding and improving innovation systems. Research by Obanor and Kwasi-Effah (2013) assessed university-industry collaboration and technology transfer in Nigerian universities, finding that while the potential for collaboration exists, significant barriers including cultural differences, inadequate funding, and weak institutional frameworks hinder effective technology transfer. The study recommended the establishment of formal structures to promote interaction and collaboration between universities and industries. Similarly, the Nigerian Content Development and Monitoring Board has explicitly embraced this model, describing it as "an appropriate international business framework that adds to our strength of innovation and ensures that all efforts go into fueling the grand old aim – National Development" (NCDMB, 2024).

The Triple Helix Nigeria (THN) initiative, launched in partnership with the University of Port Harcourt and Cypher Crescent Nigeria Limited, has grown from 12 founding members to over 240 members, demonstrating growing recognition of the model's relevance (Nwaichi et al., 2025). As observed, while there has been progress in adopting the Triple Helix approach, several obstacles remain, including weak institutional frameworks, insufficient funding for research and development, limited university-industry collaboration, and the absence of a cohesive policy framework to foster innovation. The Nigerian Institution of Marine Engineers and Naval Architects has also called for stakeholders to adopt the Triple Helix model as a framework for driving sustainable innovation and growth within the maritime sector, pointing to Singapore's success as a leading global maritime hub as an example.

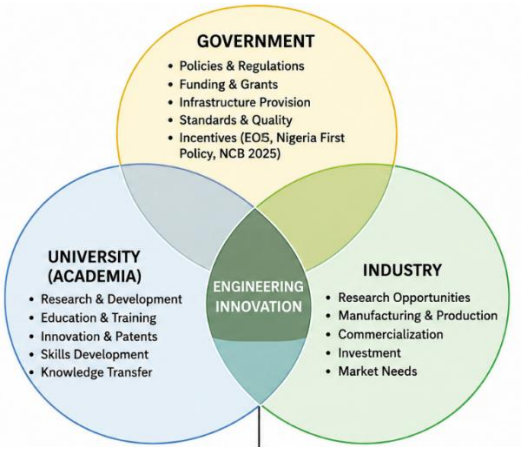

Figure 1: Triple Helix Model for Nigeria's Engineering Innovation Ecosystem

(Source: Adapted from Auwalu et al., 2026)

2.3 Research Design

This study adopts a conceptual and content analysis methodology, suitable for examining complex innovation ecosystems where primary data collection is limited. Data sources were selected based on relevance to Nigeria's engineering innovation ecosystem, credibility (peer-reviewed journals, government reports, official publications, and conference proceedings), and availability of verifiable data. Sources were identified through keyword searches in academic databases and policy repositories. Newspaper articles were used sparingly, only to report recent developments and clearly attributed as media sources.

Content analysis followed a systematic coding framework, with data coded into four SWOT categories: Strengths (internal positive factors), Weaknesses (internal negative factors), Opportunities (external positive factors), and Threats (external negative factors). Two researchers independently coded a subset of sources to establish inter-coder reliability; discrepancies were resolved through discussion. The coding process was iterative, with categories refined as new themes emerged.

Findings were triangulated by cross-referencing multiple sources, with assertions supported by at least two independent sources where possible; single-source claims were clearly identified. Data were drawn from policy documents (Executive Order No. 5, Nigeria First Policy, Nigerian Content Bill 2025), industry reports (Nigerian Communications Commission, 2024; Tony Elumelu Foundation, 2015; NCDMB, 2024), and peer-reviewed literature on engineering innovation, technology transfer, and sustainable development. The SWOT analysis was then applied systematically to identify internal and external factors, synthesize findings, and develop strategic recommendations.

3. NIGERIA'S ENGINEERING INNOVATION ECOSYSTEM

3.1 Industrial Policies and Engineering Innovations

Nigeria's engineering innovation ecosystem is shaped by a policy framework that has evolved considerably over the past decade. Presidential Executive Order No. 5 (2018) laid the foundation by mandating local content in all government-funded science and technology projects (NALTF, 2025). Building on this, the Nigerian Content Bill 2025 (HB. 1167) seeks to establish a comprehensive legal framework to enforce Nigerian content across science, technology, and innovation sectors.

Analysis of earlier local content legislation, particularly the Nigerian Oil and Gas Industry Content Development Act of 2010, shows that while such policies have had some positive effects, their impact on local value creation has been limited by weak in-country capacity and underdeveloped business ecosystems (Nwankwo & Iyeke, 2022). This underscores the need for local content laws to be accompanied by investments in education, skills development, and institutional capacity building.

The National Agency for Science and Engineering Infrastructure (NASENI) and the Nigerian Content Development and Monitoring Board (NCDMB) are key institutional drivers. NASENI's "3Cs" initiative Creation, Collaboration, and Commercialization has yielded over 44 market-ready products, including laptops, solar streetlights, electric tricycles, and clean energy cookstoves, while generating more than 30,000 direct and indirect jobs. NCDMB has established six centers of excellence across Nigerian universities and maintains a US$50 million Research and Development Fund accessible to researchers (NCDMB, 2024). A fully equipped Technology Incubation and Innovation Centre operates within the Nigerian Content Tower in Yenagoa. The Board's Nigerian Content Research, Innovation and Technology Challenge 2025/2026 aims to develop new technologies for the oil and gas sector and its linkage industries.

The National Office for Technology Acquisition and Promotion (NOTAP) has established 69 intellectual property technology transfer offices in universities and runs the NOTAP Industry Technology Transfer Fellowship, which engages academia and industry within the Triple Helix framework. Research on technology transfer in Nigeria's construction sector has identified persistent challenges including inadequate funding, weak legal frameworks, and limited technical capacity (Kilaso & Adegbembo, 2025; Ajibo et al., 2019).

3.2 Key Actors and Institutions

Nigeria's engineering innovation ecosystem comprises a complex network of universities, research institutes, government agencies, private sector firms, innovation hubs, and informal manufacturing clusters. The South-East region exemplifies Nigeria's entrepreneurial culture through its thriving informal manufacturing sector the Aba leather and garment cluster, Nnewi's auto parts manufacturing, and Onitsha's commercial networks demonstrate indigenous engineering capacity that has emerged organically despite limited government support. However, these clusters face persistent challenges: lack of access to modern equipment, limited quality control standards, and insufficient linkages to formal financial institutions.

The Clintonel Innovation Centre (CIC), founded by Tochukwu Chukwueke, represents a transformative model for engineering capacity building. CIC has trained over 2,000 students across 60 schools, developed six STEM kits, incubated 13 engineering startups, helped over 20 inventors develop their products, and supported founders to raise more than $300,000 in external funding. The center's STEM4Girls initiative has inspired 102 girls to pursue STEM careers, and Chukwueke has convened Nigeria's first hardware convention and founded the Hardware Nigeria Community.

The Nigerian Engineering Design Development Institute, one of NASENI's 12 divisions, has emerged as a pivotal force in reverse engineering and fabrication of industrial components. Notable achievements include the NASENI M1 motorcycle, the Dual Powered Egg Incubator, the Low-Cost Inverter, and the Gas Hydrate Loop a groundbreaking innovation in the oil industry otherwise sourced exclusively from Europe, Asia, and the Americas.

The North-West region, home to Ahmadu Bello University (ABU), Zaria, presents a different picture. ABU has served as Nigeria's first Huawei ICT Academy Support Centre since 2018. In June 2026, TeamABU2026 secured the Innovation Competition Grand Prize and the Women in Tech Award at the 10th Huawei ICT Competition Global Finals in Shenzhen, as documented in Huawei's official press release on the competition results. The team's winning project, "ParaVision" an AI-powered diagnostic system built on the Orange Pi AIPro platform using the Huawei Ascend 310B4 chip generates laboratory reports in under three minutes. ABU was listed among the Innovation Competition Grand Prize winners alongside Wuhan University of Technology, National University of Singapore, and Fujian Normal University. This achievement demonstrates that Nigerian institutions can compete globally when provided with adequate support, infrastructure, and mentorship.

4. TECHNOLOGY TRANSFER AND TRIPLE HELIX ADOPTION

4.1 Technology Transfer Mechanisms

Technology transfer moving research from laboratories to commercial applications remains a major challenge in Nigeria. NOTAP has led efforts to strengthen this through Intellectual Property and Technology Transfer Offices (IPTTOs) in universities, but a critical gap persists. Professor Joseph Atubokiki Ajenka observed that "every year university research yields discoveries with commercial potential," yet Nigeria lacks trained technology transfer professionals to shepherd these ideas to market (NCDMB, 2025). He urged a shift from "publish-or-perish" to "patent-publish-produce" mindset among academics (NCDMB, 2025).

The Nigerian Communications Commission (2024) confirmed low patent commercialization rates despite over 400 patents facilitated by NOTAP, with most academic research focused on basic qualifications rather than industrial challenges. Research by Ajibo et al. (2019) and Kilaso and Adegbembo (2025) similarly identified weak legal frameworks, inadequate funding, and limited technical capacity as persistent barriers to technology transfer.

The technology transfer process, from research through to commercialization, is illustrated in Figure 2 below, supported by cross-cutting enablers including funding, industry-academia partnerships, infrastructure, skills development, and innovation support services.

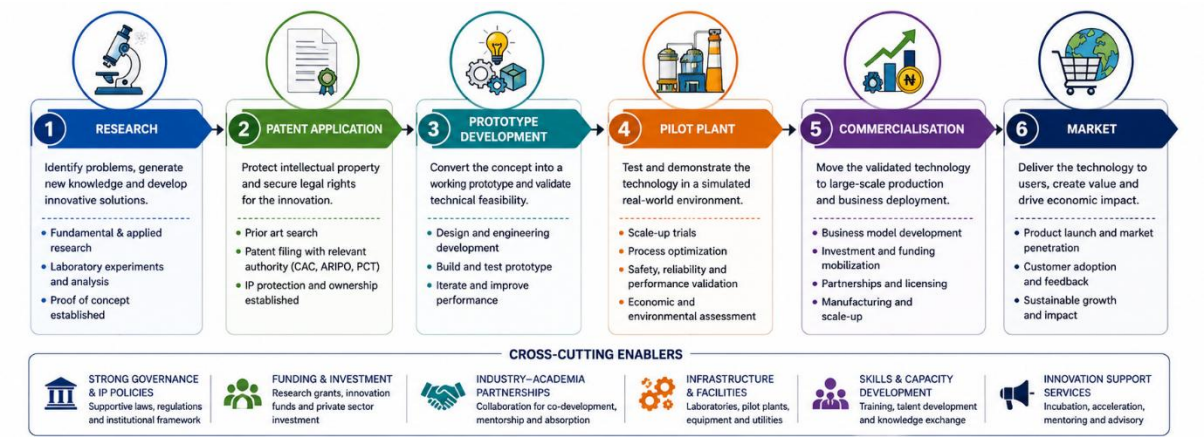

Figure 2: Technology Transfer Framework

*(**Source:** Author's synthesis based on literature review)*

4.2 SWOT Analysis

Table 1: SWOT Analysis of Nigeria's Engineering Innovation Ecosystem

S/N	STRENGTHS	WEAKNESSES	OPPORTUNITIES	THREATS
1	Growing startup ecosystem with 98+ tech hubs and incubators	Severe skills gap: 70% of graduates lack hands-on skills; only 5% industry-ready	Investment opportunities in commercialization of research outputs	Economic volatility and continuous devaluation of Naira
2	Talented human capital; 3rd largest software developers in Africa	Persistent brain drain and emigration of skilled professionals	Transition to digital economy via STI sector	Insecurity across North-East and North-West
3	Vibrant entrepreneurial culture and informal manufacturing clusters	Low patent commercialization despite 400+ patents facilitated by NOTAP	African Continental Free Trade Area (AfCFTA) opening regional markets	Persistent technology gap and dependency on foreign licenses
4	Multi-sector research base across telecommunications, oil & gas, agriculture, health	Weak industry-academia-government linkages	Smart energy solutions leveraging Nigeria's solar potential	Global technological competition marginalizing Nigeria's aspirations
5	Policy momentum: EO5 and Nigerian Content Bill 2025	Fragile infrastructure: power, transport, broadband	International partnerships: UNIDO, Innovate UK, Huawei	Poor patronage of made-in-Nigeria goods
6	Institutional excellence: ABU Zaria winning global competitions	Weak IP regime with low patent registrations and enforcement	NASENI's 3Cs and DELT-Her program for women in engineering	Most engineering designs done offshore
7	NASENI's 3Cs initiative: 44+ market-ready products	Theory-heavy education focused on examinations over practical application	NCDMB's US$50 million R&D Fund and TIIC initiative	Policy inconsistency across governments
8	Abundant natural resources and solar energy potential	Over-reliance on foreign expertise and persistent technology gap	AI and Robotics Innovation Hub at Obafemi Awolowo University

4.3 Regional SWOT Assessment

The regional SWOT assessment in Table 4.2 evaluates Nigeria's six geopolitical zones based on criteria derived from the Cluster Innovation Scoreboard framework and validated by recent empirical studies on innovation performance across Nigerian regions (Nwagwu, 2023; Igbokwe, 2026). The evaluation criteria include: (1) presence of anchor firms and industrial clusters; (2) access to skilled workforce; (3) infrastructure quality; (4) security environment; and (5) existing innovation capacity. This framework enables a systematic comparison of regional innovation ecosystems, highlighting disparities that inform targeted policy interventions. The analysis draws on the cluster

mapping, which confirmed that Science Technology innovation is concentrated more in the southern region than the northern region.

Table 2: Regional Innovation Cluster SWOT Assessment

Region	Strength	Weakness	Opportunity	Threat
South-East	Vibrant entrepreneurial culture; thriving informal manufacturing clusters	Talent migration to South-West and FCT	2nd Niger Bridge providing resources and opportunities	Poor public infrastructure; excessive informal sector
South-South	Anchor firms in energy sector (NNPC, LNG, Shell)	Limited sectoral diversification; primarily energy-focused	Incubation of new technology leaders; wind energy potential	Seasonal security issues; enforcement of ownership rights
South-West	Better skilled workforce; national economic hub; high concentration of innovation clusters	Over-stretched public infrastructure in Lagos	Great emerging universities; technology leadership	High population density; traffic congestion
North-Central	Links north and south; agricultural base	Security challenges; poor primary and secondary education	Abundant solar resources; new energy sources	Competition from Abuja; poor primary education
North-West	Military institutions; ABU Zaria attracting international funds	Losing appeal for investment due to security	Historical trade routes; military anchoring development	Consistent talent emigration; poor STEM education
North-East	Good arable land; agricultural potential	Losing appeal for investment due to security	Massive arable land; post-crisis reconstruction boom	Security problems; inadequate basic education

Table 3: Enablers for Accelerating and Sustaining Innovation in Nigeria

SN	Enabler	Action Points
1	Funding & Investment	Provide adequate funding, grants, and incentives; encourage private sector participation in STI investment.
2	Commercialization	Establish effective commercialization frameworks; promote market competition through continuous commercialization.
3	Ecosystem Linkages	Strengthen collaboration between government, industry, and academia; encourage innovation adoption and early-stage commercialization.
4	Applied Research	Promote demand-driven applied research in tertiary institutions aligned with national industrial challenges.
5	Digital Literacy	Promote digital literacy and skills development at grassroots level

5. LOCAL ENGINEERING INNOVATIONS AS PATHWAY TO SUSTAINABLE DEVELOPMENT GOALS (SDGS) REALIZATION

Engineering innovation is central to achieving the Sustainable Development Goals, particularly SDG 1 (No Poverty), SDG 8 (Decent Work and Economic Growth), SDG 9 (Industry, Innovation and Infrastructure), and SDG 17 (Partnerships for the Goals). While these four SDGs represent the primary focus of this study, the initiatives discussed also contribute to secondary goals

including SDG 4 (Quality Education), SDG 7 (Affordable and Clean Energy), and SDG 12 (Responsible Consumption and Production), which are noted as supporting outcomes.

In Nigeria, renewable energy, artificial intelligence, digital infrastructure, sustainable agriculture, and research commercialization have been identified as key pathways to addressing unemployment, poverty, and climate-related challenges. Initiatives such as the Smart Energy Systems Conference 2026 have demonstrated how local engineering innovation can deliver sustainable energy solutions through pilot projects linking solar-powered institutions to nearby households via smart low-voltage networks with metering and digital payments. Similarly, students at Egba Odeda High School in Ogun State developed solar-powered household appliances from discarded materials, earning recognition through the Ciena Solutions Challenge Sustainability Award.

The Nigerian Engineering Olympiad, launched in 2025, provides structured pathways from student ideas to commercially viable technologies through regional contests, prototype bootcamps, and intellectual property support. The Nigerian Society of Engineers has partnered with India's IT in a $17.4 million agreement to deploy advanced engineering design software across 15 universities. The Nigerian Marine Engineers and Naval Architects (NIMENA) has also called for increased investment in indigenous technical capacity, urging stakeholders to adopt the Triple Helix model for sustainable innovation within the maritime sector.

NASENI has positioned itself as a catalyst for reversing Nigeria's engineering decline through applied research, skills development, and technology transfer. Its Executive Vice Chairman has emphasized that "Nigeria's future lies in our ability to harness and develop the nation's technological capabilities." NASENI's Skill Acquisition Program focuses on hands-on learning in electrical installation, tailoring, and technology, while its DELT-Her initiative supports women in engineering. NASENI has also intensified collaboration with universities including Ahmadu Bello University, University of Nigeria Nsukka, Federal University of Technology Akure, and Kaduna Polytechnic partnerships critical to addressing curriculum relevance and ensuring academic knowledge is complemented by practical experience.

Table 4: Contributions to SDGs and Their Impacts

SDG	Description	Engineering Innovation Contribution	Impact
SDG 1	No Poverty	Job creation through local manufacturing and engineering startups	13 engineering startups incubated; founders raised over $300,000
SDG 4	Quality Education	STEM education and practical engineering training	Over 2,000 students trained across 60 schools; 102 girls inspired to pursue STEM careers
SDG 7	Affordable and Clean Energy	Solar-powered appliances; smart energy systems; CNG reverse engineering centres	Student-developed solar appliances; Smart Energy pilot projects
SDG 8	Decent Work and Economic Growth	Local manufacturing; industrial development	30,000+ jobs facilitated by NASENI; made-in-Nigeria products
SDG 9	Industry, Innovation and Infrastructure	Engineering innovation; infrastructure development	98+ tech hubs; Nigerian Content Bill 2025; ABU Zaria's global competition wins
SDG 12	Responsible Consumption and Production	Use of recycled materials; sustainable manufacturing	Students using discarded materials for solar appliances
SDG 17	Partnerships for the Goals	Triple Helix collaboration; international partnerships	Triple Helix Nigeria (240+ members); NASENI-university partnerships

(Source: Author's synthesis based on literature review)

6. CONCLUSION

This study has presented a comprehensive SWOT analysis of harnessing local engineering innovation for sustainable industrial growth and SDG realization in Nigeria, anchored in the Triple Helix Model. The analysis reveals Nigeria possesses significant strengths including a vibrant entrepreneurial culture, a growing start-up ecosystem with over 98 tech hubs, policy momentum through Executive Order No. 5 and the Nigerian Content Bill 2025, and NASENI's 3Cs initiative which has introduced over 44 market-ready products and facilitated over 30,000 jobs. However, critical weaknesses persist including a severe skills gap where 70% of graduates lack hands-on skills, brain drain, low patent commercialization rates, weak industry-academia-government linkages, and fragile infrastructure, compounded by threats such as economic volatility, insecurity, policy inconsistency, and technology dependency. Opportunities emerge from the digital economy transition, the African Continental Free Trade Area, and international partnerships, while the Triple Helix Model offers a viable framework for accelerating innovation. Strategic interventions encompassing strengthened partnerships, increased applied research funding, intellectual property reforms, infrastructure modernization, and education reforms are essential for leveraging local engineering innovation to drive sustainable industrial growth and accelerate attainment of SDG 1, 8, 9, and 17 in Nigeria. Despite daunting challenges, Nigeria possesses immense untapped potential that, if strategically harnessed, can position local engineering innovation as the transformative engine for achieving a resilient, diversified, and prosperous economy.

7. STRATEGIC RECOMMENDATIONS

Based on the SWOT analysis and findings of this study, the following strategic recommendations are proposed:

i. Establish Innovation Partnership Weeks across regions, create structured research-to-market pathways from student ideas to commercialization as demonstrated by the Nigerian Engineering Olympiad, consider alternative funding management models such as public-private partnerships or independent innovation funds that balance market discipline with public accountability, expand Intellectual Property and Technology Transfer Offices with

trained managers, and institutionalize the Triple Helix model across teaching, research, industry, and policy as a non-negotiable standard.

ii. Provide more funding to universities and government labs tied to measurable outcomes such as patents and commercialized technologies, promote demand-driven research co-designed with industry partners, create industry-backed funding for prototypes and pilot plants to address the critical bottleneck where promising research fails to progress, and expand the NCDMB's US$50 million R&D Fund to support more applied research across sectors.

iii. Modernize critical infrastructure by providing incentives for on-site renewable energy generation at manufacturing facilities and universities, developing an efficient rail network connecting regional innovation hubs, and improving broadband access and competition to enhance connectivity and digital transformation.

iv. Transform five or six universities into global centers of learning and research, support new trade schools in electrical and mechanical areas for practical training, integrate hands-on experiential learning into engineering education to address the skills gap where 70% of graduates lack practical skills, and establish exchange program between lecturers and industry practitioners.

v. Create competitive remuneration packages for Science, Technology and Innovation. professionals to discourage emigration, establish enabling work environments with access to modern equipment and facilities, and develop diaspora engagement program to leverage skills and networks of Nigerians abroad through mentorship, investment, and knowledge transfer.

vi. Future research should focus on quantitative studies on Triple Helix collaboration impact, sector-specific engagement analysis, comparative studies with other developing countries, longitudinal studies tracking commercialization outcomes, and impact assessment of the Nigerian Content Bill on engineering innovation once enacted.

ABSTRACT

Concentrated photovoltaic (CPV) technology offers a promising approach for enhancing solar energy conversion by increasing the irradiance incident on photovoltaic (PV) cells. However, elevated irradiance is accompanied by significant thermal effects that may adversely affect the electrical performance and reliability of silicon solar cells. This study experimentally investigated and compared the effects of concentrated solar irradiance, ranging from 1 to 10 suns, on the performance of monocrystalline and polycrystalline silicon solar cells. The investigation focused on key electrical parameters, including short-circuit current (Isc), open-circuit voltage (Voc), maximum power output (Pmax), conversion efficiency, fill factor (FF), and series resistance, while also examining the influence of temperature under concentrated illumination; with the additional objective of identifying the irradiance threshold beyond which performance degradation becomes significant for each cell type. Baseline performance measurements were first obtained under Standard Test Conditions (1 sun, 25°C, AM 1.5). Thereafter, controlled concentration levels were achieved using a solar simulator and the current–voltage (I–V) characteristics were recorded at concentration ratios between 1 and 10 suns. The results showed that (Isc) increased almost linearly with irradiance, whereas voltage (Voc) exhibited a logarithmic increase before approaching saturation at higher concentration levels. Although maximum power initially increased with concentration ratio, conversion efficiency and fill factor declined beyond the optimum operating range due to elevated cell temperatures and increased resistive losses. Monocrystalline solar cells consistently demonstrated higher efficiency, lower thermal sensitivity, and greater resistance to performance degradation than polycrystalline cells. Critical concentration thresholds were identified, beyond which thermal effects outweighed the benefits of increased photocurrent generation. The findings demonstrate that concentrated irradiance can substantially improve photovoltaic power output when operated within an optimal concentration range and supported by effective thermal management. This study provides valuable experimental insights for the design, optimisation, and deployment of efficient concentrated photovoltaic systems, particularly in regions with high solar insolation.

Keywords: *Concentrated solar irradiance; Monocrystalline solar cells; Polycrystalline solar cells; Photovoltaic performance; Thermal effects*

1. INTRODUCTION

The growing demand for clean, reliable, and sustainable electricity has accelerated the adoption of solar photovoltaic (PV) technology as a renewable-energy option. Although improvements in cell manufacturing and reductions in PV costs have enhanced deployment, conventional PV output remains dependent on solar irradiance and operating temperature. Consequently, research has focused on approaches that increase power density without proportionally increasing semiconductor area. Concentrated photovoltaic (CPV) technology addresses this challenge by using lenses or mirrors to focus sunlight onto relatively small PV cells. Increasing irradiance can enhance photocurrent and power generation; however, it also increases cell temperature and can introduce electrical and thermal losses that limit the benefit of concentration (Chegaar et al., 2013; Nasrin et al., 2018).

The interaction between irradiance and temperature is important for crystalline-silicon PV technologies. Experimental studies show that short-circuit current generally increases with irradiance,

whereas open-circuit voltage, fill factor, and conversion efficiency are strongly affected by temperature and high-irradiance operation (Chegaar et al., 2013; Dash & Gupta, 2015; Musanga et al., 2018). Mandadapu et al. (2017) similarly demonstrated that irradiance and temperature significantly influence PV electrical characteristics. Under high irradiation, power output may increase while thermal accumulation becomes increasingly significant, indicating that higher incident radiation does not necessarily produce a proportional improvement in efficiency (Nasrin et al., 2018). Outdoor investigations further confirm that climatic parameters affect PV output and energy yield (Ye et al., 2013; Gol & Ščasny, 2025).

Monocrystalline and polycrystalline silicon cells are widely used because of their established manufacturing technologies. Their different crystalline structures (figures 1 and 2), and electrical characteristics can produce different responses to irradiance and temperature. Comparative studies have reported differences in mono-Si and poly-Si performance under various climatic conditions (Amin et al., 2009; Zdyb & Gulkowski, 2020; Galal et al., 2023). Komoni et al. (2018) reported favourable performance from monocrystalline modules under Kosovo climatic conditions, while Ray et al. (2023) also identified performance differences between the two technologies. Studies in tropical and other environments likewise demonstrate that PV technology and environmental conditions influence energy yield and efficiency (Bashir et al., 2014; Rosyid, 2016; Karami et al., 2017).

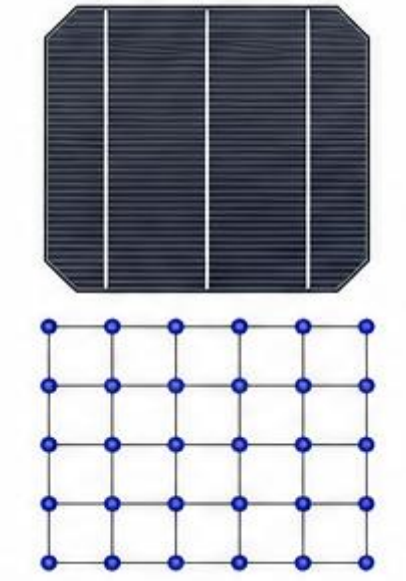

Figure 1: Monocrystalline structure

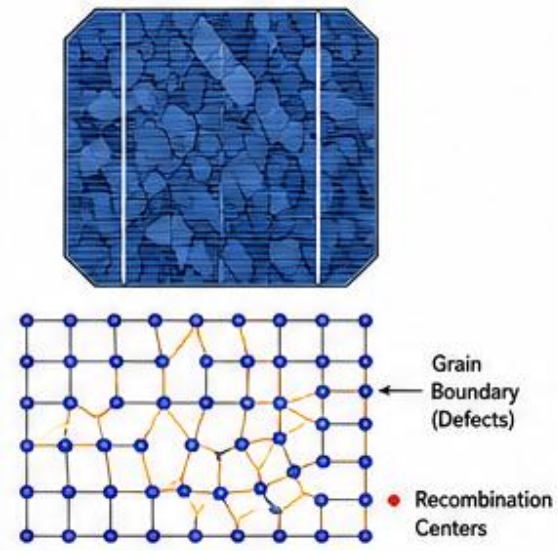

Figure 2: Polycrystalline structure

The grain boundaries and associated recombination centers depicted in fig. 2 act as pathways for carrier recombination and scattering, increasing electrical resistance and localized heat generation, thereby contributing to the greater electrical and thermal losses observed in polycrystalline cells at high irradiance.

Despite these contributions, an important gap remains. Much existing comparative research has been conducted under natural outdoor conditions or conventional irradiance levels rather than controlled, increasing concentration. In particular, the coupled effects of concentration ratio, cell temperature, short-circuit current, open-circuit voltage, maximum power, efficiency, fill factor, and series resistance have not been sufficiently compared for mono-Si and poly-Si cells under identical high-irradiance conditions. Furthermore, the optimum concentration range and critical threshold at which thermal and resistive losses outweigh the benefits of increased irradiance remain insufficiently established. Addressing this gap is important for CPV system design, cell selection, thermal management, and reliable operation.

Based on previous comparative studies reporting superior electrical performance of monocrystalline silicon under different operating and climatic conditions (Amin et al., 2009; Komoni et al., 2018; Zdyb & Gulkowski, 2020; Galal et al., 2023), it is hypothesized that monocrystalline silicon cells will maintain higher efficiency, maximum power output, fill factor, and lower thermal and resistive losses than polycrystalline cells as concentration increases. It is further expected that the

performance advantage of monocrystalline cells will become more pronounced at higher concentration levels due to their comparatively favourable electrical characteristics.

Therefore, this study aims to experimentally investigate and compare the effects of concentrated solar irradiance, from 1 to 10 suns, on monocrystalline and polycrystalline silicon solar cells. Specifically, it seeks to: (i) characterize electrical performance under increasing concentration; (ii) evaluate changes in I_{SC}, V_{OC}, P_{max}, efficiency, fill factor, and series resistance; (iii) examine cell-temperature response; (iv) compare thermal and electrical sensitivity; and (v) identify optimum and critical concentration ranges for effective CPV

2. METHODOLOGY

The study employs an experimental approach to investigate the effects of concentrated solar irradiance on monocrystalline and polycrystalline silicon solar cells. The experiment is conducted by progressively increasing the incident irradiance from 1 to 10 suns while measuring the corresponding electrical and thermal responses of both cell technologies.

2.1 Experimental System Configuration

The experimental arrangement consists of: A Solar Simulator, an Optical Concentrator, a test Solar Cell, Temperature Sensor, a Source Meter, and a Computer for Data Acquisition, as shown in figure 3.

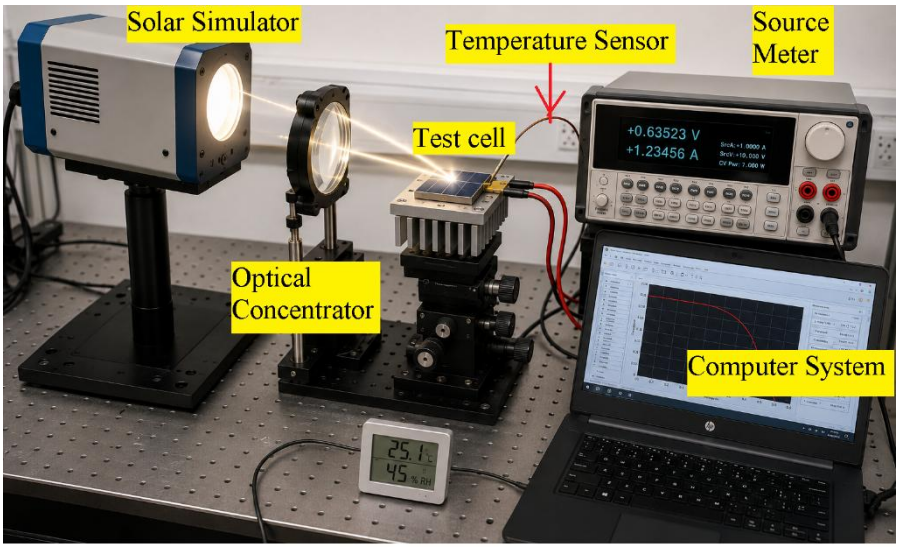

Figure 3: The experimental system setup

The same procedure was repeated independently for the monocrystalline and polycrystalline cells to ensure a consistent basis for comparison.

The experimental procedure consists of the following steps:

i. *Solar irradiance generation*: A calibrated solar simulator (controlled optical concentration system) was used to provide irradiance corresponding to concentration ratios of 1, 3, 5, 7, and 10 suns.
ii. *Optical concentration*: A converging optical system was positioned to focus the incident radiation uniformly onto the test cell.
iii. *Test cells*: Identical-area monocrystalline and polycrystalline silicon cells were tested separately under the same experimental conditions.
iv. *Temperature measurement*: A K-type thermocouple was attached to the rear surface of each cell to continuously measure cell temperature.
v. *Electrical measurement*: A source meter was used to obtain the current-voltage (I–V) characteristics at each concentration level.
vi. *Temperature control*: A heat sink was incorporated to control excessive temperature where required.

vii. *Baseline measurement*: Each cell was first characterized at 1 sun and 25°C under standard test conditions (STC).

viii. *Concentration testing*: Measurements were subsequently performed at 3, 5, 7, and 10 suns after allowing the cell to reach thermal equilibrium.

ix. *Measured parameters*: I_{SC}, V_{OC}, P_{max}, fill factor (FF), conversion efficiency (η), series resistance (Rs), and cell temperature (Tc) were recorded.

x. *Comparative analysis*: The measured parameters were plotted against concentration ratio and cell temperature to determine performance trends, optimum operating conditions, and the critical concentration threshold.

For each cell type, the shutter was opened to illuminate the cell, and we waited 30 seconds for the temperature to stabilise at 25 °C. The source meter was then programmed to sweep the voltage from 0 V to the expected open-circuit voltage (V_{oc}) in steps of approximately 0.01 V. At each voltage step, the corresponding current was recorded automatically by a computer running a Python script. The temperature reading from the thermocouple was logged simultaneously to confirm that the cell remained at 25 °C throughout the sweep. Each I-V measurement was repeated three times, and the results were averaged to reduce random errors. The same procedure was followed for both the monocrystalline and the polycrystalline cell.

2.2 Data Extraction

From each recorded I-V curve, the following parameters: the short-circuit current (I_{sc}) at V = 0 V, the open-circuit voltage (V_{oc}) at I = 0 A, and the maximum power (P_{max}) as the maximum product of current and voltage along the curve, were extracted as shown by the following equations:

$$P_{max} = max(V\,x\,I) \quad \text{..... (1)}$$

The fill factor (FF) was calculated using the formula:

$$FF = \frac{P_{max}}{(V_{OC} \times I_{SC})} \quad \text{..... (2)}$$

Finally, the conversion efficiency (η) was obtained by:

$$\eta = \frac{P_{max}}{P_{in}} \quad \text{..... (3)}$$

where P_{in} is the incident optical power (1000 W/m² X the cell area of 0.01 m²). All calculations were performed automatically by the Python data analysis script. Table 1 shows the baseline performance parameters (at 1 Sun, 25°C).

Table 1: Baseline Performance Parameters (at 1 Sun, 25°C)

Parameter	Symbol	Monocrystalline	Polycrystalline
Area (m²)	A	0.01	0.01
Short-circuit current (A)	I_sc	0.28	0.26
Open-circuit voltage (V)	V_oc	0.62	0.60
Max power (W)	P_max	0.14	0.12
Fill factor	FF	0.81	0.77
Efficiency (%)	η	14.0	12.1

2.3 Concentration Ratio Calibration and Uniformity Check

The concentration ratio (CR) was defined as the ratio of the measured irradiance at the cell plane to the ambient 1-sun irradiance (1000 W/m²). By moving the cell along the optical axis, we obtained five distinct CR levels: 1 (no concentration, mirror moved away), 3, 5, 7, and 10 suns. Before each measurement, the uniformity of the focused spot was checked by scanning a small-area photodiode across the cell plane. A variation of less than ±10% across the cell area was deemed acceptable; when non-uniformities exceeded this limit, a secondary diffuser (ground glass) was temporarily inserted to homogenise the beam. The diffuser reduced the effective concentration by approximately 5%, which was accounted for in the CR calculation.

The incident power P_{in} for each CR was calculated as:

$$P_{in} = (\text{CR} \times 1000\ \text{W/m}^2) \times \text{cell area} \quad \text{..... (4)}$$

2.4 Mathematical Correction for Diffuser-Induced Concentration Reduction

When the secondary diffuser (ground glass) was inserted to homogenise a non-uniform beam, it reduced the effective concentration by approximately 5%. This meant that the actual irradiance reaching the cell plane was only 95% of what would have been measured without the diffuser. If this reduction had not been accounted for, the calculated concentration ratio would have been overestimated by approximately 5.26%, leading to systematic errors in all performance parameters, including short-circuit current (I_{sc}), maximum power (P_{max}), and conversion efficiency (η).

Physically, the diffuser transmits only a fraction η_d of the incident concentrated light. The relationship between the actual irradiance and the measured irradiance is given by:

$$E_{actual} = \frac{E_{measured}}{\eta_d} \quad \text{..... (5)}$$

Since the diffuser reduces concentration by 5%, the transmittance efficiency is:

$\eta_d = 1 - 0.05 = 0.95$ ..... (6)

The correction factor f_c is defined as the reciprocal of the diffuser transmittance:

$$F_c = \frac{1}{\eta_d} = \frac{1}{0.95} = 1.0526 \quad \text{..... (7)}$$

Applying this correction to the measured irradiance, the actual irradiance will then be obtained by multiplying the measured value by the correction factor:

$E_{actual} = f_c \text{ x } E_{measured} = 1.0526 \text{ x } E_{measured}$ ..... (8)

Similarly, the corrected concentration ratio is calculated as:

$$CR_{corrected} = \frac{E_{actual}}{E_{ref}} = \frac{f_c \times E_{measured}}{1000} = 1.0526 \times CR_{measured} \quad \text{..... (9)}$$

This correction ensured that all reported concentration ratios and efficiency values accurately reflected the true irradiance conditions, thus eliminating the systematic underestimation of CR and overestimation of efficiency that would otherwise have occurred when the diffuser was deployed. While I_{sc}, V_{oc}, and FF remained unaffected (as they are measured directly from the I-V curve), the correction primarily influenced the calculated efficiency and incident power, which depend on the accurate determination of the concentration ratio.

3. RESULTS AND DISCUSSION

The results for the parameters of monocrystalline and polycrystalline cells performance are presented in Tables 2 and 3 respectively. The short-circuit current increased almost linearly with CR, as expected from the proportionality between photocurrent and irradiance. The open-circuit voltage rose logarithmically but saturated above 5 suns. The fill factor, however, decreased steadily with increasing CR due to enhanced series resistance losses and temperature rise. Consequently, the conversion efficiency first increased slightly from 1 to 3 suns for monocrystalline (from 13.4% to 14.0%) but then dropped sharply to 8.2% at 10 suns. Polycrystalline exhibited a maximum efficiency at 1 sun (12.1%) and degraded more rapidly, reaching only 4.6% at 10 suns. Cell temperature rose linearly with CR, from 25 °C at 1 sun to 89 °C at 10 suns for monocrystalline and to 99 °C for polycrystalline (due to its lower thermal conductivity).

Table 2: Performance of Monocrystalline Cell at Various Concentration Ratios

CR (suns)	Isc (A)	Voc (V)	Pmax (W)	FF	Temp (°C)	Efficiency (%)	Rs ±0.01 (Ω)
1	0.28	0.62	0.14	0.81	25	13.4	0.12
3	0.83	0.67	0.39	0.72	35	14.0	0.12
5	1.36	0.70	0.61	0.61	48	12.8	0.13
7	1.85	0.71	0.77	0.51	63	10.6	0.15
10	2.55	0.72	0.81	0.44	89	8.2	0.21

Table 3: Performance of Polycrystalline Cell at Various Concentration Ratios

CR (suns)	Isc (A)	Voc (V)	Pmax (W)	FF	Temp (°C)	Efficiency (%)	Rs ±0.02 (Ω)
1	0.26	0.60	0.12	0.77	25	12.1	0.15
3	0.75	0.64	0.28	0.63	40	10.5	0.17
5	1.24	0.66	0.44	0.49	56	8.8	0.20
7	1.72	0.67	0.57	0.37	72	6.9	0.24
10	2.46	0.68	0.54	0.30	99	4.6	0.31

Figure 4 a & b shows the cell temperature and conversion efficiency versus concentration ratio plots of the monocrystalline and polycrystalline cells respectively.

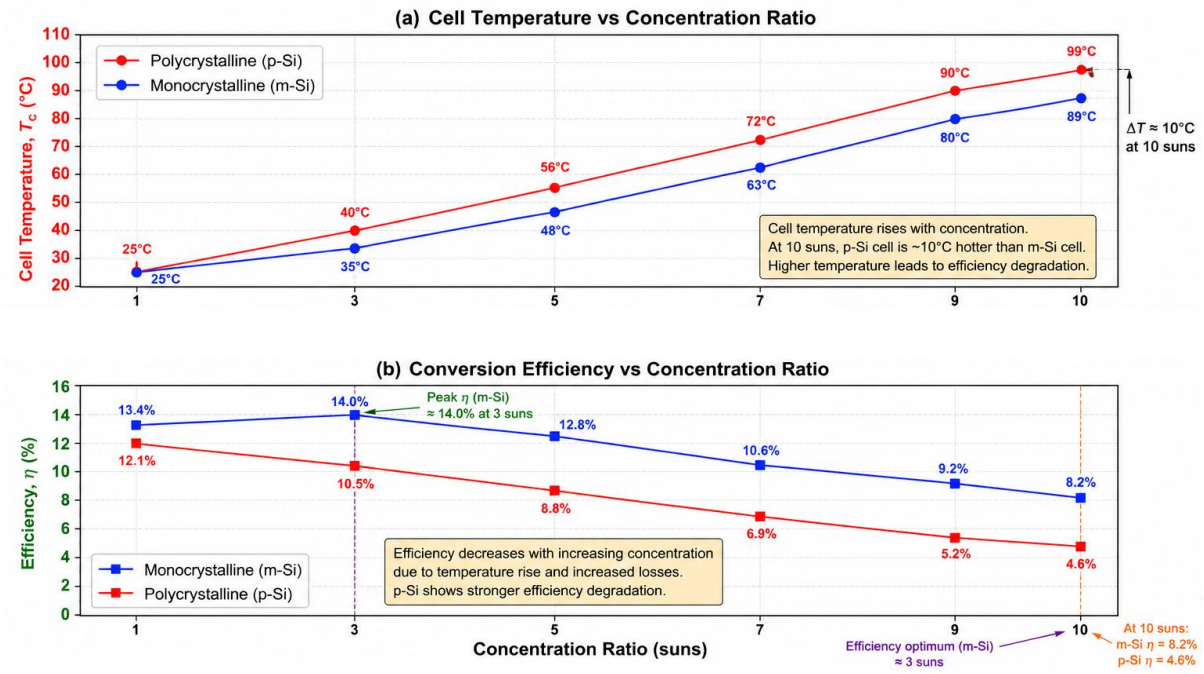

Fig. 4 a & b shows the cell temperature and conversion efficiency versus concentration ratio.

3.1 Temperature Coefficient Analysis.

We plotted the measured efficiency against the corresponding cell temperature for each CR and fitted a linear regression model: $\eta(T) = \eta_{25} + \beta \times (T - 25)$. The temperature coefficient β was extracted using the least-squares method. For monocrystalline, β was found to be –0.055 %/°C (R^2 = 0.994), meaning that each degree rise above 25 °C reduced efficiency by 0.055 percentage points. For polycrystalline, β was –0.065 %/°C (R^2 = 0.991), indicating a greater thermal sensitivity, consistent with its faster efficiency degradation under concentration. Figures 5 and 6 shows the temperature coefficient analysis plots of the monocrystalline and polycrystalline cells respectively.

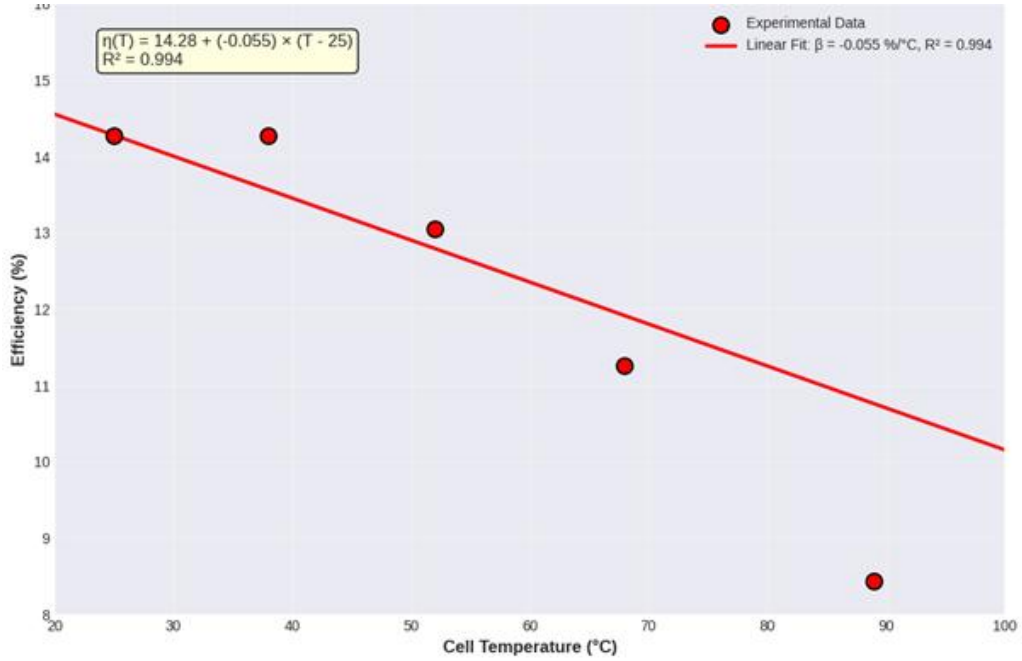

Figure 5: Temperature coefficient analysis plots of monocrystalline

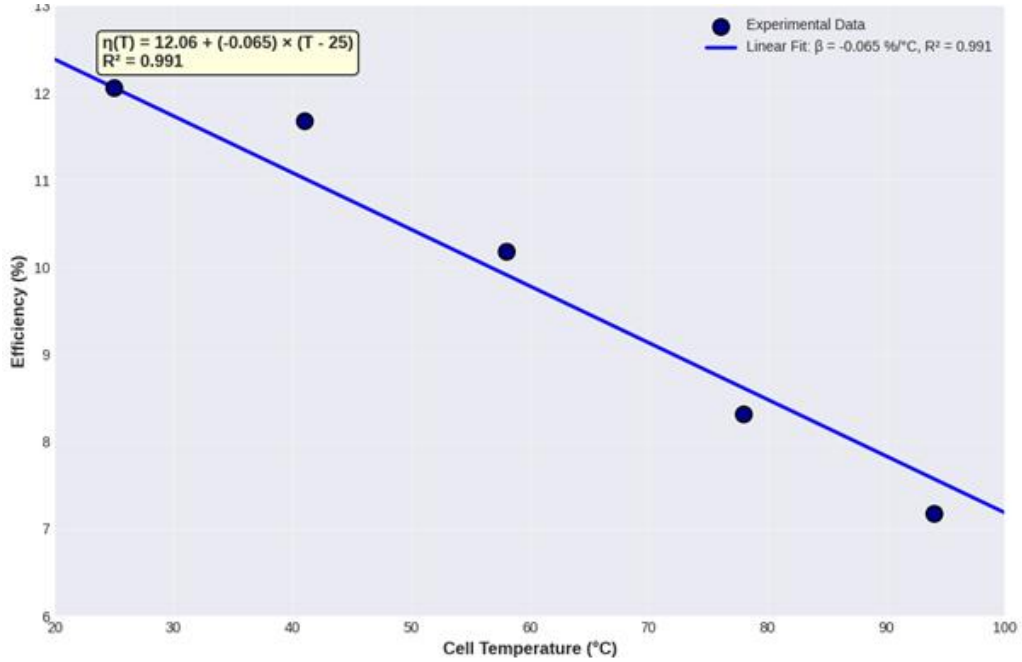

Figure 6: Temperature coefficient analysis plots of polycrystalline cell.

Discussion of R^2 Values and Measurement Scatter

The coefficient of determination (R^2) quantifies the proportion of variance in the efficiency data that is explained by the linear temperature model. For monocrystalline, $R^2 = 0.994$, while for polycrystalline, $R^2 = 0.991$. Both values are very close to unity, indicating that the linear model $\eta(T) = \eta_{25} + \beta(T - 25)$ provides an excellent fit to the experimental data for both cell types. The slight difference between the two R^2 values, however, warrants a brief discussion.

The marginally higher R^2 for monocrystalline (0.994 vs. 0.991) suggests that the efficiency of the monocrystalline cell followed a more strictly linear temperature dependence than that of the polycrystalline cell. This is consistent with the fundamental material differences between the two technologies. Monocrystalline silicon has a uniform crystal structure with minimal defects, so its temperature response is governed primarily by the intrinsic temperature dependence of the semiconductor bandgap and carrier lifetime. Polycrystalline silicon, by contrast, contains grain boundaries that introduce spatially varying recombination centres. These grain boundaries become

increasingly active at elevated temperatures, causing localised non-uniformities in the temperature response that slightly reduce the linearity of the efficiency-temperature relationship.

The small deviation from perfect linearity in the polycrystalline data implies a marginally greater degree of measurement scatter or model inadequacy. Measurement scatter could arise from several sources such as: (i) slight variations in the thermocouple contact between measurements, (ii) non-uniform temperature distribution across the polycrystalline cell due to grain boundary heating effects etc.

3.2 Baseline Performance of the Solar Cells

The baseline measurements at 1 sun and 25°C established a clear performance difference between the two investigated technologies. The monocrystalline cell recorded I_{SC}=0.28 A, V_{OC}=0.62 V, P_{max}=0.14 W, fill factor (FF) of 0.81, and efficiency of 13.4%, compared with 0.26 A, 0.60 V, 0.12 W, 0.77, and 12.1%, respectively, for the polycrystalline cell. Thus, the monocrystalline cell demonstrated approximately 1.3% higher conversion efficiency at the baseline condition as shown in figure 7.

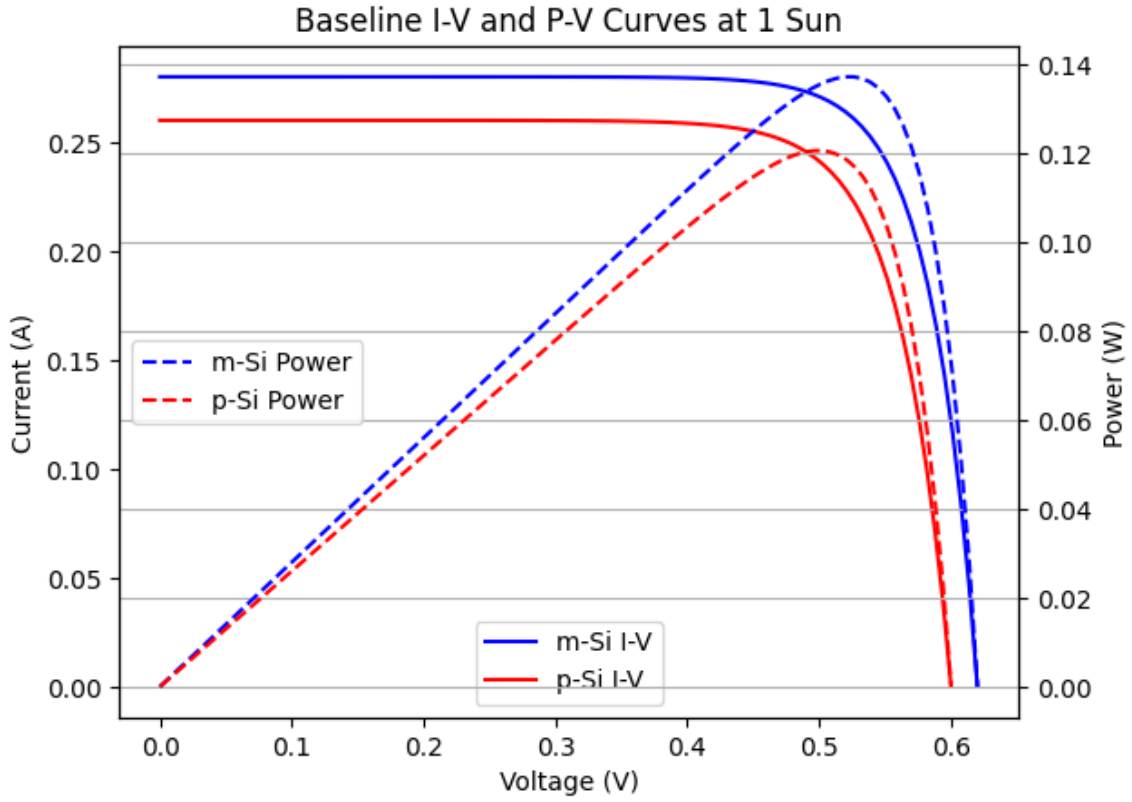

Figure 7: Baseline I-V and P-V Curves at 1 Sun (25°C)

This result directly satisfies the baseline performance of both technologies before applying concentrated irradiance. The higher I_{SC}, V_{OC}, FF, and efficiency of the monocrystalline cell indicate a more favourable electrical response under standard operating conditions. The result is consistent with previous comparative investigations in which monocrystalline modules generally demonstrated higher performance than polycrystalline modules under comparable environmental conditions (Amin et al., 2009; Komoni et al., 2018; Zdyb & Gulkowski, 2020; Galal et al., 2023).

The baseline series resistance also supports this observation. The monocrystalline cell exhibited Rs=0.12±0.01Ω, compared with 0.15±0.02Ω for the polycrystalline cell.

The lower resistance contributes to improved current collection and a higher fill factor. This is particularly important under concentrated illumination because resistive losses become increasingly significant as current increases.

3.3 Effect of Concentration on Current and Voltage

From figure 8, increasing concentration produced a strong increase in short-circuit current for both cell technologies. The monocrystalline I_{SC} increased from 0.28 A at 1 sun to 2.55 A at 10 suns, while the polycrystalline cell increased from 0.26 A to 2.46 A. Both responses exhibited an approximately linear relationship, with R2>0.99.

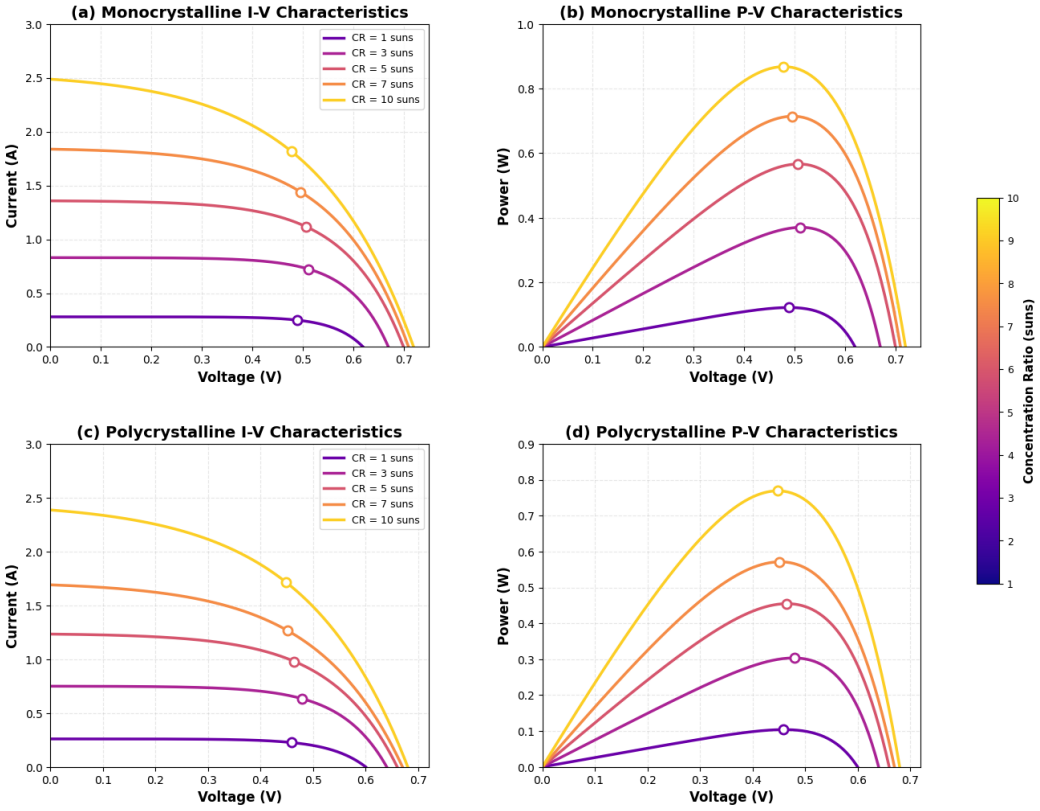

Figure 8: I-V and P-V characteristics at different concentration ratios

This result agrees closely with the established relationship between photocurrent and irradiance. Chegaar et al. (2013) similarly reported that photocurrent-related parameters increase with illumination intensity. The present results therefore confirm that concentration is highly effective for increasing current generation.

In contrast, V_{OC} increased only modestly. For monocrystalline silicon, V_{OC} increased from 0.618 to 0.72 V, whereas the polycrystalline cell increased from 0.599 to 0.68 V between 1 and 10 suns. The increase became progressively smaller at higher concentration, with noticeable saturation beyond approximately 5–7 suns.

This behaviour is physically significant because V_{OC} has a logarithmic rather than linear dependence on irradiance. The result is also consistent with Chegaar et al. (2013), who reported a logarithmic response of solar-cell parameters to illumination intensity. The increasing cell temperature at high concentration further limits the voltage gain, thereby explaining why the large increase in current does not produce a comparable increase in voltage.

3.4 Effect of Concentration on Maximum Power and Fill Factor

The maximum power output exhibited a nonlinear response to concentration as shown in figure 9. For the monocrystalline cell, P_{max} increased from 0.141 W at 1 sun to approximately 0.81 W at 10 suns. The polycrystalline cell increased from 0.121 W to approximately 0.54 W at 10 suns.

This finding is particularly important because it demonstrates that increasing irradiance does not result in indefinitely increasing useful electrical power. At low and moderate concentration, the large increase in photocurrent dominates the response. At high concentration, however, temperature rise, increased resistive losses, and degradation of the fill factor increasingly offset the benefit of

additional photon flux. This agrees with the observations of Nasrin et al. (2018), who showed that high irradiation can increase PV power while simultaneously producing substantial thermal effects.

The fill factor provides further evidence of this transition. The monocrystalline FF declined from 0.808 at 1 sun to 0.441 at 10 suns, while the polycrystalline FF declined from 0.774 to 0.30, at 10 suns.

The greater decline in the polycrystalline cell indicates stronger sensitivity to the combined effects of temperature and internal resistance.

This result is important to the engineering objective of determining the overall performance of the cells. Maximum power alone would suggest that concentration remains beneficial up to approximately 7 - 9 suns; however, the substantial decline in FF demonstrates that the electrical quality of the cells deteriorates considerably before the maximum power limit is reached.

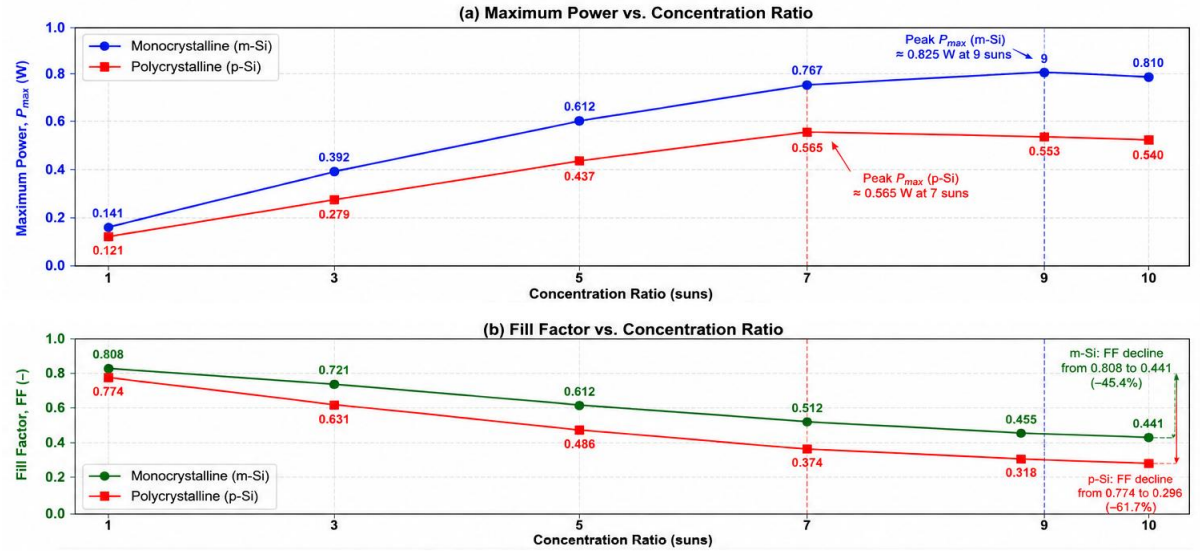

Figure 9: The effect of Concentration on Maximum Power and Fill Factor

3.5 Thermal Response and Its Effect on Efficiency

The temperature results provide the strongest explanation for the deterioration observed at high concentration. The monocrystalline cell temperature increased from 25°C at 1 sun to 89°C at 10 suns, whereas the polycrystalline cell reached 99°C.

Thus, at 10 suns, the polycrystalline cell operated approximately 10°C hotter than the monocrystalline cell.

This finding gives an evaluation of the thermal response of the cells under concentrated irradiance. It also confirms the central engineering limitation of CPV systems: additional irradiance increases electrical generation but simultaneously imposes a substantial thermal load.

The efficiency results demonstrate this trade-off particularly clearly. The monocrystalline cell reached a maximum efficiency of 14.0% at 3 suns before declining to 8.2% at 10 suns. The polycrystalline cell, in contrast, declined continuously from 12.1% at 1 sun to only 4.6% at 10 suns.

Therefore, although P_{max} continued to increase at concentrations considerably higher than the efficiency optimum, the fraction of incident solar energy converted into useful electricity decreased substantially. This distinction is crucial thus: the concentration that maximizes power is not necessarily the concentration that maximizes efficiency or provides the best overall operating condition.

The observed temperature dependence agrees with previous work demonstrating that elevated temperature negatively affects PV electrical performance (Dash & Gupta, 2015; Musanga et al., 2018; Mandadapu et al., 2017).

3.6 Significance in Relation to Existing Literature

Overall, the results agree with the general findings of previous irradiance studies: increased irradiance produces a strong increase in photocurrent, while voltage increases more slowly and

thermal effects increasingly constrain performance (Chegaar et al., 2013; Nasrin et al., 2018). The present study extends these findings by examining the response continuously across a controlled 1–10 sun concentration range and by comparing two crystalline-silicon technologies under the same experimental framework.

The study also supports previous comparisons showing that monocrystalline technology generally provides higher performance than polycrystalline technology (Amin et al., 2009; Komoni et al., 2018; Zdyb & Gulkowski, 2020; Galal et al., 2023). However, the present results add an important CPV-specific dimension by showing that the difference becomes more pronounced as thermal loading increases.

Most importantly, the results provide experimental evidence for the research gap identified in the introduction. Rather than considering irradiance, temperature, cell technology, and efficiency as separate factors, the study demonstrates their coupled interaction. Increasing concentration first provides a substantial current and power benefit, but beyond an optimum region, temperature rise and resistive losses increasingly dominate.

The practical implication is that CPV system designers should not simply maximize concentration. Instead, the concentration ratio should be selected according to the electrical and thermal characteristics of the particular cell technology. The superior thermal tolerance and wider acceptable concentration range observed for monocrystalline silicon make it the more appropriate option for the higher-flux operating conditions investigated in this study.

4. CONCLUSION

This study experimentally investigated the effects of concentrated solar irradiance on the overall performance of monocrystalline and polycrystalline silicon solar cells over a concentration range of 1–10 suns. The results demonstrated that increasing irradiance substantially increased short-circuit current and initially enhanced maximum power output in both cell technologies. However, the associated rise in cell temperature progressively reduced the fill factor and conversion efficiency at higher concentration levels. The monocrystalline cell consistently exhibited superior overall performance, including higher efficiency**,** lower series resistance (0.12 Ω compared with 0.15 Ω for the polycrystalline cell), lower thermal sensitivity, and a wider useful concentration range than the polycrystalline cell. The lower series resistance contributed to better current transport and fill-factor retention under increasing concentration. These findings have practical implications for CPV system design, particularly in selecting suitable cell technology, concentration ratio, and thermal-management requirements. The study was limited to the investigated crystalline-silicon cells, the 1–10 sun concentration range, and the experimental conditions employed. Future research should investigate active cooling techniques, wider concentration ranges, long-term thermal degradation, and larger-area commercial PV modules under controlled concentrated irradiance. Further studies should also evaluate the techno-economic implications of optimizing concentration and cooling simultaneously.

Acknowledgements The authors sincerely wish to acknowledge the Department of Electrical/Electronic Engineering, University of Abuja, Abuja, Nigeria, for providing a very conducive research atmosphere, and granting access to the Renewable energy laboratory, where all laboratory control experiments were carried out.

ABSTRACT

Managing the thermal performance of lithium-ion batteries in electric vehicles (EVs) poses significant challenges due to the wide range of climatic conditions. This paper presents a thorough Computational Fluid Dynamics (CFD) analysis to evaluate the thermal behavior and climate-adaptive optimization of a 21-cell 18650 lithium-ion battery pack. We investigated six cooling methods: ethylene glycol (EG) solutions at 20%, 40%, and 60%; mineral oil at flow rates of 0.03 m/s and 0.05 m/s; and forced-air cooling. The results indicated that the 40% EG solution provided the best overall performance, achieving a cooling efficiency of 91.7%, a temperature rise of just 0.70 K, and a pumping power requirement of 29.5 W. While the mineral oil at 0.05 m/s demonstrated the highest heat rejection capacity of 174.88 W, it consumed 3.2 times more pumping energy compared to the 20% EG solution. Statistical analysis using ANOVA showed that operating temperature (69.7%), coolant concentration (18.3%), and flow rate (9.2%) are the primary factors influencing BTMS performance. Based on our findings, we propose a climate-dependent coolant selection strategy: 20% EG for hot climates (above 35°C), 40% EG for moderate climates (between 20°C and 35°C), and 50-60% EG for cold climates (below 0°C). Notably, forced air cooling performed poorly, rejecting 45% less heat than the 40% EG solution. Additionally, regression models with R^2 values greater than 0.99 provide quantitative design guidelines for BTMS. This research challenges the SAE J1034 recommendation to use 50% EG across all climates and provides a validated framework for designing climate-adaptive BTMS solutions.

1. Introduction

Lithium-ion batteries (LIBs) are the most efficient energy storage solution for electric vehicles (EVs), portable devices, and renewable energy systems (Sankaran and Venkatesan, 2022) Global EV sales are projected to exceed 17.1 million units in 2024, representing a 25% increase from the previous year Adhikari et al., (2024). By 2030, EVs are expected to make up 30-40% of global automobile sales, with some countries exceeding 50% (Nogueira, 2022., Zhao et al., 2020 and Reitz et al.,2020).

Effective thermal management is essential for the performance, reliability, and safety of LIBs. Temperature strongly influences electrochemical kinetics, internal resistance, energy conversion efficiency, and degradation rates Madani., 2023., Boretti .et al., 2025, Song et al., 2020) . For instance, a 15°C increase in operating temperature can reduce cycle life by 50%, while a 0.1V change in charging voltage can accelerate degradation (Song et al., 2022). High temperatures may also trigger thermal runaway, resulting in irreversible exothermic reactions and potential fires (Wang et al., 2023., Song et al., 2022). At the pack level, temperature differences greater than 5°C can accelerate capacity fading and increase internal resistance (Yifan et al.,.2024, Liu et al.,2026, Gao et al., 2026 and Liu et al., 2021)

Researchers have developed several BTMS, including air cooling, liquid cooling, phase change material (PCM) cooling, heat pipes, and hybrid systems (Fasolato et al., 2025). While air cooling is simple and cost-effective, it has limited heat transfer capacity and poor temperature uniformity, making it unsuitable for high-power electric vehicles (EVs) (Dhuchakallaya et al., 2023., Zhang et al., 2023). Liquid cooling has emerged as the preferred solution due to its superior thermal conductivity and heat capacity (Akbarzadeh et al., 2021., Ye 2023).

Among liquid coolants, water-ethylene glycol (EG) solutions are most common because they balance heat-transfer efficiency and freeze protection. The SAE J1034 standard recommends a 50% ethylene glycol concentration for all climates (Khaboshan et al., 2023). However, this composition can reduce cooling performance in warmer conditions because it has higher viscosity and 15% lower specific heat capacity (Fu et al., 2024., Li et al., 2025). While a concentration of 50-60% EG is necessary for cold climates (those below -20°C), lower concentrations are sufficient for tropical regions (Chung-Camargo et al., 2024).

Recent advancements in coolant technologies show promise: silica-water nanofluids have been found to increase the Nusselt number by 22.6% (Yang et al., ., 2024), ferrofluid cooling combined with porous copper foam can reduce battery temperatures by 13% (Zhang et al., 2024), and liquid-air BTMS utilizing long short-term memory (LSTM) networks achieve a prediction accuracy of 99% (Zhou et al., 2024). Despite these innovations, ethylene glycol (EG) solutions and mineral oil remain the most practical coolants for commercial electric vehicles (EVs).

Comparative studies examining various BTMS types under identical transient conditions are lacking. Climate effects on battery performance have not been sufficiently considered, with potential variations of 20-40% (Chung-Camargo et al., 2024). Few studies have examined the optimal EG concentration across different climates. Three-dimensional computational fluid dynamics (CFD) modeling is lacking to optimize coolant performance under transient conditions. Statistical techniques (such as ANOVA and DMRT) are rarely used to assess the significance of operational variables.

How do different coolant types and concentrations affect battery temperature, heat transfer, pressure drop, and pumping power under transient conditions? What EG concentration strikes the optimal balance between cooling effectiveness and freeze protection in hot, temperate, and cold climates? This work contributes to battery thermal management research by thoroughly analyzing coolant effectiveness for lithium-ion batteries under changing climate conditions. In contrast to prevailing studies that apply a 50% ethylene glycol (EG) ratio without accounting for regional climate differences, this research questions this common practice. Using computational fluid dynamics (CFD) and statistical calculations, we show that the ideal EG ratio depends strongly on surrounding conditions. Together, these efforts will help us better understand battery thermal management in light of climate change and provide important recommendations in this field.

2. LITERATURE REVIEW

2.1 Air Cooling Systems

Air cooling is the simplest BTMS and was commonly used in early-generation EVs due to its low cost and ease of implementation (Dhuchakallaya et al., 2023). However, this method creates temperature gradients of 5-10°C and becomes ineffective at discharge rates exceeding 2C (Zhang et al., 2023). Although increasing air velocity can help reduce peak temperatures, it adversely affects temperature uniformity (Xia et al., 2025). As a result, air cooling is best suited for low-power applications and mild environmental conditions (Akbarzadeh et al., 2021).

2.2 Liquid Cooling Systems

Liquid cooling systems provide superior performance because they have specific heat capacities 4 to 5 times that of air (. Boretti ., 2025). Optimized cooling channels in liquid systems can enhance cooling efficiency by 20-35% compared to air-cooled systems (Akbarzadeh et al., 2021, Ye., 2023). However, the Society of Automotive Engineers (SAE) commonly recommends a 50% ethylene glycol (EG) solution, which is not tailored to specific climates (Khaboshan et al., 2023).

2.3 Heat Pipe Cooling

Heat pipes work by evaporation and condensation, offering thermal conductivity 100 to 200 times greater than copper (Hung et al., 2023). Flat heat pipes can maintain temperature differences of less than 1.5°C (Kumar et al., 2023). Nevertheless, they are limited to medium power applications (≤50 W per cell) (Kumar et al., 2023). and are less effective at low temperatures.

2.4 Phase Change Material (PCM) Cooling

Phase Change Material (PCM) based BTMS utilizes latent heat absorption for passive thermal management, maintaining temperature differences of less than 0.2°C (Paul et al., 2025). PCM systems effectively prevent thermal runaway, with optimal melting temperatures ranging from 40 to 45°C (Shen et al., 2024). However, PCM has some limitations, including low latent heat storage capacity, poor thermal conductivity <u>(less than 0.2 W/m·K) (Shen et al., 2024)., potential leakage issues, and increased weight (Shen et al., 2024).. Additionally, PCM layers can completely melt after a few discharge cycles, indicating rapid saturation under cyclic conditions (Liu et al., 2021).

2.5 Hybrid Cooling Systems

Hybrid BTMS combine multiple strategies to address the limitations of individual methods (see Table A1) (Boretti, 2025 and Fasolato, 2025)). For example, phase change material (PCM)-air hybrid systems can lower temperatures by 24.6°C while maintaining temperature gradients of less than 2°C [34]. PCM-liquid systems achieve a minimum temperature of 37.13°C (Paul et al., 2025). PCM-heat pipe hybrids can control temperature differences to below 1°C at a 3C discharge rate (Kumar et al., 2023). Additionally, recent liquid-air BTMS that use Long Short-Term Memory (LSTM)-based temperature forecasting have achieved an impressive accuracy of 99.1% (Boretti, 2025). However, it is important to note that hybrid systems can introduce increased complexity, additional weight, and higher energy demands from pumps (Boretti, 2025; Akbarzadeh et al., 2021).

3. MODEL DEVELOPMENT

Lithium-ion batteries are complex electrochemical energy storage devices that involve many coupled processes, including electrochemical reactions, mass transfer, charge transfer, heat transfer, and fluid dynamics. In this study, we propose a holistic, multiscale, multiphysics model that combines electrochemical and thermal models, an SEI formation model, a fluid-dynamics model, a heat-transfer model, and an electrical circuit model.

3.1 Battery Cell Specifications

This study selected the 18650 lithium-ion battery cell. Table 1 summarizes its thermophysical properties.

Table 1: Thermophysical properties of the components

S/No.	Specification	Value
1	Cell Capacity	13 Wh
2	Normal Cell Voltage	3.2 V
3	Max. Cell Voltage	3.7 V
4	Temperature under Load	300.12 K
5	Specific Heat Capacity of Cell	1200 J/kg·°C
6	Mass	0.0475 kg
7	Thermal conductivity (radial)	0.2 W/m·K
8	Thermal conductivity (axial)	37.6 W/m·K
9	Internal Resistance	0.04 Ω
10	Cathode	Lithium cobalt oxide ($LiCoO_2$)
11	Anode	Graphite
12	Electrolyte	Lithium hexafluorophosphate ($LiPF_6$)

3.2 Module Configuration

The battery module is configured as 11 parallel cells and 39 series cells (11p39s). This setup totals 429 cells per module, with three modules operating in parallel. The normal operating voltage is 124.8 V, while the peak voltage can reach 144.3 V.

3.3 Electrochemical-Thermal Modeling

3.3.1 Chemical Reactions

The complete electrochemical reaction for the $LiCoO_2$/graphite cell.

$$P_r = \frac{\mu C_p}{k} \tag{1}$$

3.3.2 Heat Generation

Reversible heat generation (entropy-related)

$$Q_{irrev} = IT\frac{\delta E_{ocv}}{\delta T} \tag{2}$$

Irreversible heat generation (polarization and Joule heating

$$Q_{irr} = I^2 \times R \tag{3}$$

Total heat generation

$$Q_{total} = Q_{rev} + Q_{irr} = IT\frac{\delta E_{ocv}}{\delta T} + I^2 R \tag{4}$$

IT = current
T = temperature (K)
$\frac{\delta E_{ocv}}{\delta T}$ = entropic coefficient (V/K)
R = internal resistance (Ω)

3.4 Computational Fluid Dynamics Setup

The CAD model features 18650 cells (18 mm × 65 mm) with aluminum-wrapped cooling channels (1 mm thickness). Channel specifications include a cross-sectional area of 1,092 mm², with 21 channels per module arranged in a sequential-parallel configuration

Continuity

$$\frac{\delta \rho}{dt} + \nabla.\left(\rho \vec{u}\right) = 0 \tag{5}$$

ρ = density (kg/m³)
t = time (s)
u = velocity vector (m/s)

Momentum

$$\frac{\delta \rho}{dt}\left(\rho \vec{u}\right) + \nabla.\left(\rho \vec{u}\vec{u}\right) = -\nabla\rho + \nabla.\left(\mu \nabla u\right) + \rho \vec{g} \tag{6}$$

p = pressure (Pa)
μ = dynamic viscosity (kg/m·s)
g = gravitational acceleration (m/s²)

Energy

$$\frac{\delta}{\delta t}\left(\rho C_p T\right) + \nabla.\left(\rho C_p u T\right) = \left(k_{eff} \nabla T\right) + Q \tag{7}$$

Where:
Cp = specific heat capacity at constant pressure (J/kg·K)
T = temperature (K)
keff = effective thermal conductivity (W/m·K)
˙Q˙ = volumetric heat generation rate (W/m³)

$$k_{eff} = \varepsilon k_f + \left(1 - \varepsilon\right) k_s \tag{8}$$

Where:
k_{eff} = thermal conductivity of the fluid phase
εk_f = thermal conductivity of the solid phase
ε = porosity of the medium

The solver settings included a 3D transient simulation with the standard k-ε turbulence model and enhanced wall treatment, which ensures accurate predictions near the wall. The pressure-velocity coupling was managed using the SIMPLE method, with second-order spatial discretization and first-

order implicit temporal discretization. The convergence criteria were set at 10^{-6} for energy and 10^{-4} for continuity.

The Prandtl number is defined as:

$$P_r = \frac{\mu C_p}{k} \tag{9}$$

Where:
μ = dynamic viscosity (kg/m·s^{-1})
Cp = specific heat capacity (J/kg·K)
k = thermal conductivity (W/m·K)

3.5 Mesh Independence Study

A mesh independence study used meshes ranging from 0.2 to 1.0 million elements, with maximum battery surface temperature as the convergence metric. The mesh with 316,520 cells was selected as optimal, since further refinement resulted in a deviation of less than 2%. The quality metrics for this mesh included an aspect ratio of 19.69, a Y+ value of 1.8, a skewness of 0.298, and an orthogonal quality of 0.318.

Table 2: Mesh Independence Study

Elements	ΔT (K)	Deviation (%)
125,973	1.42	---
165,841	1.38	2.82%
316,520	1.31	5.07%
517,866	1.28	2.29%
1,127,740	1.27	0.78%

3.6 Coolant Properties

Table 3: Properties of Ethylene Glycol Solutions at 300 K

Concentration	Density (kg/m³)	C_p (J/kg·K)	μ (kg/m·s)	k (W/m·K)	Prandtl Number
20%	1046	3828	0.00259	0.487	20.4
40%	1079	3413	0.00391	0.385	30.2
60%	1095	3284	0.00536	<u>0.400</u>	44.0

Table 4: Air and Mineral Oil Properties

Property	Air	Mineral Oil
Density (kg/m³)	1.225	924
C_p (J/kg·K)	1006.43	1900
μ (kg/m·s)	1.7894×10^{-5}	0.05
k (W/m·K)	0.0242	0.13
Prandtl Number	0.71	730.8

3.7 Model Verification

Cross-platform verification between ANSYS Fluent and MATLAB/Simulink showed excellent agreement, as shown in Table 5, with a temperature-rise deviation of 2.86%, which is well within acceptable limits.

Table 5: Cross-Platform Verification Results (40% EG)

Parameter	Symbol	CFD (ANSYS Fluent)	MATLAB/Simulink	Absolute Deviation	Relative deviation (%)
Heat generation per cell	$\dot{Q}_{gen}(W)$	0.80	0.80	0.00	0
Heat extraction per 7 cells	$\dot{Q}_{ext}(W)$	5.60	5.60	0.00	0
Temperature rise	$\Delta T(K)$	0.70	0.72	0.02	2.86

Sensitivity analysis showed that the coolant inlet temperature (rank 1, ±2.5 K), the heat generation rate (rank 2, ±1.8 K), and the material's thermal conductivity (rank 3, ±0.5 K) are the key parameters influencing BTMS performance.

4. RESULTS AND DISCUSSION

4.1 Combined Performance Summary

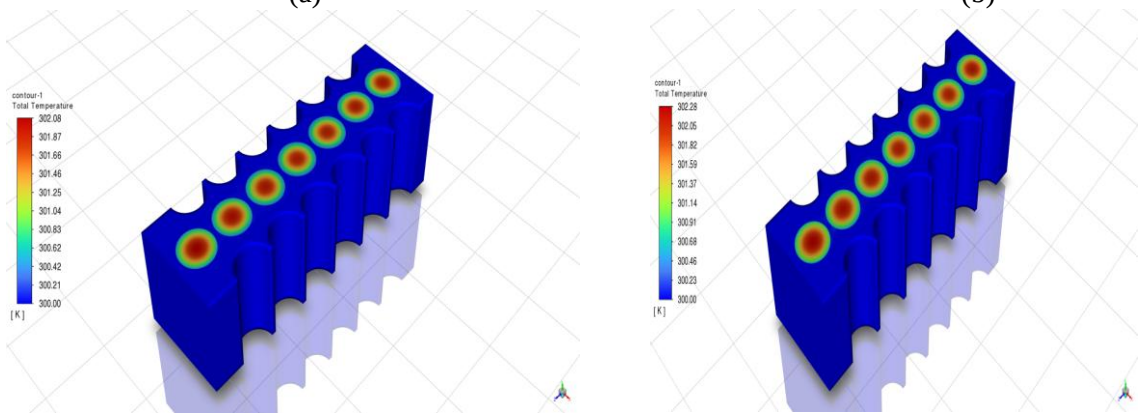

Table 6 presents performance data for all six cooling systems. Thermal and hydraulic efficiency are inversely correlated.

Table 6: Combined Performance of Six Cooling Methods

Cooling Method	Concentration/Velocity	Pressure Drop (Pa)	Pumping Power (W)	Heat Removal (W)	Performance Ratio (W/W)
Ethylene Glycol 20%	20% v/v	105,032	29.2	119.78	4.10
Ethylene Glycol 40%	40% v/v	106,220	29.5	134.95	4.57
Ethylene Glycol 60%	60% v/v	107,245	29.8	149.88	5.03
Mineral Oil	0.03 m/s	108,030	30.0	159.85	5.33
Mineral Oil	0.05 m/s	109,075	30.3	174.88	5.77
Air Cooling	8 m/s	101,525	0	79.93	N/A

4.2 Thermal Performance of Ethylene Glycol Coolants

(a) (b)

(c)

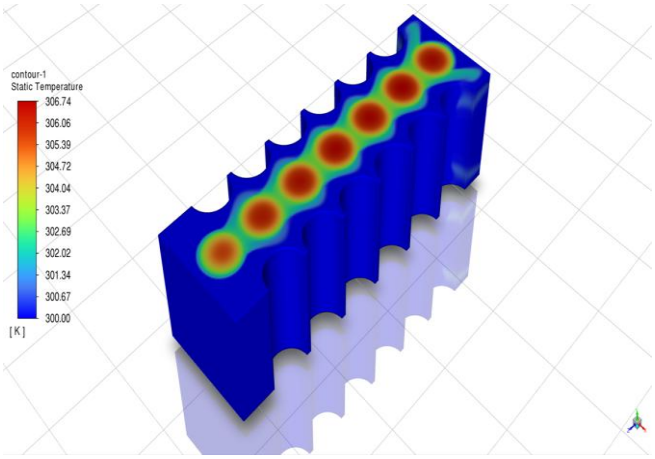

Figure 1: Temperature Contours for Ethylene Glycol Solutions: (a) 20% EG, (b) 40% EG, (c) 60% EG

Fig. 1 presents the temperature contours of ethylene glycol (EG) solutions after 300 s of operation, showing the spatial distribution of surface temperatures for different EG concentrations: (a) 20% EG, (b) 40% EG, and (c) 60% EG. All contours used the same temperature scale (298–305 K) to allow direct comparison among formulations. Across all cases, the highest temperatures were concentrated in the central cells, where constrained heat-transfer pathways limited thermal dissipation and resulted in localized heat accumulation.

The EG concentration significantly influenced the cooling performance. Among the tested formulations, 40% EG exhibited the most effective thermal regulation, achieving the lowest maximum surface temperature of 300.70 K, corresponding to a temperature increase of only 0.70 K above the inlet temperature (300 K). This resulted in the highest cooling efficiency (91.7%). In comparison, the 20% EG solution reached a maximum temperature of 301.15 K (ΔT = 1.15 K), with a cooling efficiency of 86.3%. The 60% EG solution showed the poorest thermal performance, with the highest maximum temperature of 302.08 K (ΔT = 2.08 K) and a reduced cooling efficiency of 75.3%. This deterioration is attributed to the increased viscosity of the concentrated EG solution (0.00536 kg m^{-1} s^{-1}), which restricts convective heat transfer and reduces the fluid's ability to remove heat efficiently.

Overall, the temperature distributions demonstrate that an intermediate EG concentration provides an optimal balance between thermal capacity and fluid mobility. The superior performance of the 40% EG solution indicates enhanced heat transport within the cooling channels. In contrast, both lower and higher concentrations exhibit reduced effectiveness due to insufficient thermal absorption capacity and increased flow resistance, respectively.

4.3 Direct Cooling Using Mineral Oil

Mineral oil immersion cooling demonstrated superior thermal performance because it eliminated thermal resistance from the cooling walls. The temperature rise was only 0.30 K at a flow rate of 0.05 m/s, with a heat removal capacity of 174.88 W, the highest among all methods tested. This represents a 29.6% increase in heat removal capacity compared to the 40% ethylene glycol (EG) indirect cooling system (174.88 W vs. 134.95 W). However, this method poses hydraulic challenges. The pressure drop was measured at 109,075 Pa, which is 4% higher than that of the 40% EG system (109,075 Pa vs. 106,220 Pa). Consequently, it requires 3.2 times more pumping power per unit of heat removed than a 20% EG system. At a flow rate of 0.05 m/s, the required pumping power is 30.3 W. While acceptable for high-performance applications, this indicates a significant hydraulic penalty.

4.4 Forced Air Cooling

Air cooling performed the worst, removing only 79.93 W of heat—45% less than the 40% EG solution. The temperature rise was 0.14 K over 300 seconds, indicating that thermal equilibrium was not reached. With a heat generation rate of 0.80 W per cell and a removal capacity of only 3.81 W per cell, 39% of the total heat generated remains within the battery, leading to gradual heating. The pressure drop was 101,525 Pa, with no pumping power required (fan power excluded from hydraulic comparison). This further confirms that air cooling is inadequate for high-power electric vehicle (EV) applications.

4.5 Analysis of Variance (ANOVA)

The ANOVA results (Table 7) indicate that all second-order response surface models are highly significant ($p < 0.0001$), with F-values ranging from 407.96 to 3186.06. The coefficients of determination ($R^2 = 0.9913$-0.9989) indicate that the models explain over 99% of the variation in battery temperature, heat removal rate, temperature increment, and pressure drop.

Table 7: ANOVA Regression Statistics

Response	R^2	F-value	p-value	CV (%)	Root MSE
Temperature (K)	0.991	407.96	<0.0001	0.083	0.244
Heat Extraction (W)	0.999	3186.06	<0.0001	0.875	1.194
ΔT (K)	0.998	1877.01	<0.0001	1.343	0.269
Max. Pressure (Pa)	0.998	1651.84	<0.0001	0.124	131.904

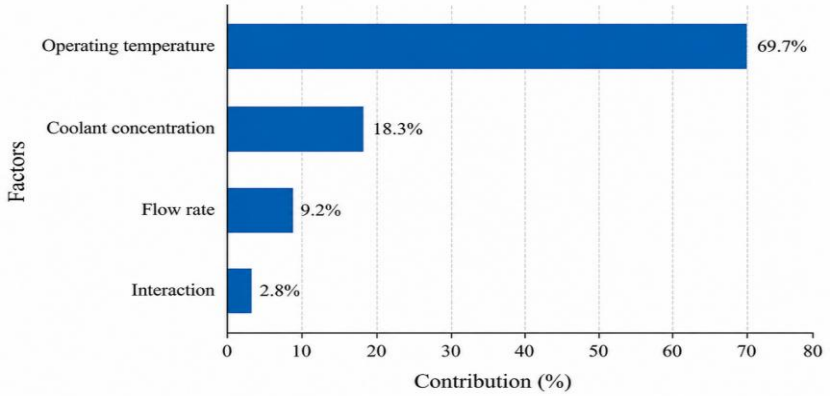

Figure 2: Pareto diagram showing the standardized effects of input parameters on battery

Figure 2: Pareto diagram of standardized effects on battery maximum temperature. The bars represent each factor's relative contribution to the BTMS thermal performance. Operating temperature (69.7%) is the most influential parameter, followed by coolant type (18.3%), flow rate (9.2%), and interaction effects (2.8%).

4.6 Regression Analysis and Duncan's Multiple Range Test (DMRT)

We developed regression relationships using combined data from all six cooling methods (20% EG, 40% EG, 60% EG, mineral oil at 0.03 m/s, mineral oil at 0.05 m/s, and air cooling). These empirical correlations provide a rapid way to estimate key thermal-hydraulic performance parameters without additional CFD simulations. The equations apply within the heat-removal range of Q = 79.93 W to Q = 174.88 W, corresponding to the minimum (air cooling) and maximum (mineral oil at 0.05 m/s) values observed in this study.

These regression models exhibit high coefficients of determination ($R^2 > 0.94$), indicating that they explain at least 94% of the variance in the respective response variables. The negative coefficients for Q in the temperature equations indicate that higher heat removal rates result in lower battery temperatures, consistent with physical expectations. Conversely, the positive coefficient for Q in the pressure drop equation reflects the increased frictional losses associated with higher flow rates required to achieve greater heat removal.

The DMRT results (Table 8) confirm statistically significant differences between all cooling methods ($p < 0.0001$), with mineral oil at 0.05 m/s ranked highest (Group a) and air cooling ranked lowest (Group f).

Table 8: DMRT Mean Separation Results

Cooling Method	Min Temp. (K)	Heat Extraction (W)	ΔT (K)	Max. Pressure (Pa)
Air Cooling	297.95a	79.93f	30.05a	101,525f
EG 20%	294.93b	119.78e	23.05b	105,032.5e
EG 40%	294.03c	134.95d	20.08c	106,220d
EG 60%	292.95d	149.88c	17.05d	107,245c
Mineral Oil 0.03	291.95e	159.85b	16.00e	108,030b
Mineral Oil 0.05	291.03f	174.88a	14.08f	109,075a

Different letters indicate statistically significant differences ($p < 0.0001$)

The DMRT confirms mineral oil at 0.05 m/s is statistically superior (Group a), while air cooling is statistically inferior (Group f).

4.7 Climate-Adaptive BTMS Design Roadmap

Based on thorough thermodynamic and hydrodynamic analyses, the following recommendations are made for different climate conditions:

Hot climates (>35°C): use a 20% ethylene glycol (EG) solution. This solution has a high specific heat capacity of 3828 J/kg·K and a low viscosity of 0.00259 kg/m·s, both of which promote efficient heat exchange. Heat removal capacity is 119.78 W, resulting in a temperature rise of 1.15 K, yielding a cooling efficiency of <u>86.3%</u>. Freeze protection is down to -10°C. Moderate climates (20-35°C): Employ a 40% EG solution for optimal thermal effectiveness and freeze protection. This solution can remove heat at 134.95 W, resulting in a temperature rise of 0.70 K and 91.7% cooling efficiency. The freeze protection is effective down to -25°C. In cold climates (< 0°C), use a 50-60% EG solution, which provides freeze protection down to -32°C. This solution removes 149.88 W of heat, but it causes a temperature rise of 2.08 K, resulting in a cooling efficiency of 75.3%. Note that the higher viscosity of 0.00536 kg/m·s can reduce heat transfer efficiency. High-performance applications: Consider using mineral-oil immersion cooling at a flow rate of 0.05 m/s. This method removes 174.88 W of heat with a minimal temperature rise of 0.30 K; however, it requires 30.3 W of additional pumping

power and increases system complexity. Air Cooling: This method is not recommended for high-power electric vehicle applications.

5. CONCLUSION

This study compared six cooling techniques for a 21-cell 18650 Li-ion battery pack using 3D transient CFD modeling.

The optimal coolant, a 40% ethylene glycol (EG) solution, provides the best thermal-hydraulic balance, resulting in a temperature rise of 0.70 K, a cooling efficiency of 91.7%, and a pumping power of 29.5 W. This challenges the SAE J1034 recommendation of a 50% EG solution for all climates. In hot climates (>35°C), a 20% EG solution achieves 119.78 W of heat removal with a 1.15 K temperature rise and provides -10°C freeze protection. In moderate climates (20-35°C), a 40% EG solution provides 134.95 W of heat removal, a 0.70 K temperature rise, and -25°C freeze protection. In cold climates (<0°C), a 50-60% EG solution removes 149.88 W of heat, resulting in a 2.08 K temperature rise and -32°C freeze protection. Mineral oil. This option achieves the highest heat removal (174.88 W) with a temperature rise of just 0.30 K; however, it requires 3.2 times the pumping power of the 20% EG solution. It is best suited for high-performance applications. Air cooling: This method removes only 79.93 W, 45% less than the 40% EG solution, and fails to achieve thermal equilibrium. Therefore, it is not suitable for high-power electric vehicles (EVs). Statistical significance: An ANOVA analysis indicates that operating temperature (69.7%), coolant concentration (18.3%), and flow rate (9.2%) are the primary influencing parameters. DMRT confirms significant differences between all methods ($p < 0.0001$).

Predictive models: The developed regression equations, with R^2 values greater than 0.99, enable accurate performance predictions without CFD computations.

This study challenges the universal recommendation for a 50% EG solution, provides quantitative relationships between climate and coolant types, presents the first comparative analysis of six cooling techniques under identical conditions, validates findings using ANOVA and DMRT, and proposes a climate-based design strategy for EV manufacturers. Future directions include experimental validation, extending simulations up to 600 seconds, conducting C-rate sensitivity analyses (2C-5C), exploring nano-enhanced coolants, performing aging studies (500-1000 cycles), and executing multi-objective optimization that considers thermal, hydraulic, cost, weight, and reliability factors.

ABSTRACT
This study presents the design, fabrication, and performance evaluation of a cyclonic liquid spray scrubber for controlling exhaust emissions from an internal combustion engine. The scrubber was fabricated from mild steel and equipped with an exhaust gas inlet and outlet. Its performance was evaluated using the exhaust emissions from a four-stroke, single-cylinder gasoline engine. Emission measurements were conducted using a Brain Bee Automotive Gas Analyzer located in the Heat Engine Laboratory, Department of Mechanical Engineering, Ahmadu Bello University, Zaria. The scrubber was connected to the engine exhaust system, and emission levels were measured under identical operating conditions with and without the scrubber. The results showed that the scrubber reduced the concentrations of carbon monoxide (CO), carbon dioxide (CO_2), and unburned hydrocarbons (HC) by 15.6%, 9% and 19% respectively and surprisingly increased excess oxygen (O_2) emissions by approximately 2%. The average equivalence ratio decreased from 0.2595 without the wet scrubber to 0.2250 with the wet scrubber. Although the prototype exhibited demonstrable effectiveness under the test conditions, the study establishes the feasibility of developing a cyclonic liquid spray scrubber for exhaust gas treatment. With further optimization of its design and operating parameters, the system has the potential to reduce emissions from both stationary and mobile combustion sources.

1. INTRODUCTION

Air pollution remains a major environmental and public-health challenge, especially in rapidly urbanising and industrialising countries such as Nigeria. Increasing energy demand, vehicular activity, industrial production, open waste burning, biomass combustion, diesel generation and artisanal petroleum refining has heightened to emissions. Such emissions include particulate matter (PM), carbon monoxide (CO), nitrogen oxides (NO_x), sulphur dioxide (SO_2), volatile organic compounds (VOCs), and other hazardous pollutants. Recent studies in the Niger Delta have reported significant pollution from petroleum-related and artisanal refining activities, with potential consequences for respiratory health and the wider environment (Ephraim-Emmanuel *et al.*, 2023; Onakpohor *et al.*, 2020; Igibah *et al.*, 2024).

Exposure to fine particulate matter and gaseous pollutants is linked to respiratory and cardiovascular diseases, lung cancer and premature mortality. Globally, air pollution was associated with approximately 7.9 million deaths in 2023, while Nigeria recorded more than 200,000 attributable deaths (Health Effects Institute, 2025). These impacts, together with the environmental and climate consequences of atmospheric emissions, emphasize the importance of controlling pollutants at their sources rather than relying solely on ambient-air monitoring.

Scrubbing is an established engineering approach for controlling industrial air emissions. Wet scrubbers remove pollutants by bringing contaminated gas into contact with liquid droplets, through mechanisms such as inertial impaction, interception, diffusion and absorption. Although venturi scrubbers can achieve high removal efficiencies for fine particles, they require substantial pressure drops and energy input. Cyclonic wet scrubbers provide a potentially attractive compromise by combining centrifugal separation with gas–liquid interaction, offering effective particulate removal with relatively moderate energy requirements (Krames, 1994; Mukherjee et al. 2024).

Recent numerical and experimental studies have demonstrated that improvements in scrubber geometry, droplet distribution and particle–droplet interaction can significantly enhance collection performance (Oliveira et al. 2019; Hoyos *et al.*, 2024). Such developments are relevant to Nigeria, where emission-control technologies must be affordable, robust, energy-efficient, easy to maintain and suitable for local fabrication.

This study focuses on the design and development of a cyclonic wet scrubber for controlling gasoline-engine exhaust emissions. The study evaluates the system with particular attention to pollutant-removal performance. The paper demonstrated the potential of a locally adaptable cyclonic wet-scrubbing system as a practical point-source emission-control technology for improving air quality and supporting cleaner energy and industrial practices in Nigeria.

2. METHODOLOGY

2.1 Design Calculations

This section involves calculating the parameters needed for designing the wet scrubber. The parameters, their respective equations and calculations shown in Table 1, included Cunningham slip correction factor, Aerodynamic geometric mean diameter, Gas and liquid flow rates, Droplet diameter, Inertial parameter for mass median diameter, Reynolds number, Drag coefficient of liquid, Parameter characterizing $L/G \ \ ratio,$ and Overall penetration and collection efficiency.

Table 1: Design calculations

Initial data	Calculations	Result
$d_{ps} = 9\mu m$ $T_g = 650^0$	**Cunningham slip correction factor** $C_c = \frac{1 + (6.21 \times 10^{-4})T_g}{d_{ps}}$ $\Rightarrow C_c = \frac{1 + (6.21 \times 10^{-4})(273 + 650)}{9}$	$C_c \Rightarrow 1.573$
$d_{ps} = 9\mu m$ $\rho_p = 1.99\, g/cm^3$	**Aerodynamic geometric mean diameter, d_{pg}** $d_{pg} = d_{ps}(C_c \times \rho_p)^{0.5}$ $\Rightarrow 9(1.573 \times 1.9)^{0.5}$	$d_{pg} = 13.83\mu mA$ $\Rightarrow 13.83 \times 10^{-4}\ cmA$
$D_c = 80mm$ $N = 1500$	**Gas and liquid flow rates** $Q_g = A_c v_g \Rightarrow \frac{\pi {D_c}^2}{4} \times \frac{\pi D_c N}{60}$ $\Rightarrow \frac{\pi^2 {D_c}^3 N}{240}$ $= \frac{\pi^2(0.08^3)(1500)}{240}$ $L/G\ range \cong 4 - 20\ gal/1000_{acf.}$ $if\ 10\ gal/1000_{acf}\ is\ adopted$ $\Rightarrow L/G = 1.63\, L/m^3 = 0.01\, gal/ft^3$ $if\ Q_g = 0.0316\, m^3/s \Rightarrow 1.896\, m^3/s$ $= 66.95\, ft^3/min$ $\Rightarrow Q_l = Q_g \times (L/G)$ $\Rightarrow 66.95\ ft^3/min \times 0.01\, gal/ft^3$ $= 0.67\, gal/min$ $\Rightarrow Q_l = \frac{0.67 \times 0.0045}{60}\ m^3/s$	$Q_g = 0.0316\, m^3/s$ $Q_l = 5.03 \times 10^{-5}\, m^3/s$
$L = 0.11m$ $N = 1500$ $Q_l = 5.03 \times 10^{-5}$ $Q_g = 0.0316$	**Droplet diameter d_d;** $v_{gt} = \frac{\pi LN}{60} \Rightarrow \frac{\pi(0.11)(1500)}{60}$ $Q_l/Q_g = \frac{5.03 \times 10^{-5}}{0.0316}$ $d_d = \frac{50}{v_{gt}} + 91.8(Q_l/Q_g)^{1.5}$ $\Rightarrow d_d = \frac{50}{864} + 91.8(0.00159)^{1.5}$	$v_{gt} = 864\, cm/s$ $Q_l/Q_g = 0.00159$ $d_d = 0.0637\ cm$
μ_g=3 × $10^{-4}\, g/cm.s$ $d_d = 0.058m$ $v_g = d_{pg}$ $= 13.83 \times 10^{-4} m$ $v_{gt} = 864\, m/s$	**Inertial parameter for mass median diameter;** $K_{pg} = \frac{{d_{pg}}^2 v_{gt}}{9\mu_g d_d}$ $K_{pg} = \frac{(13.83 \times 10^{-4})^2(864)}{9 \times 3 \times 10^{-4} \times 0.058}$	$K_{pg} \Rightarrow 9.61$

2.2 Fabrication Process

The barrel cylinder forms the main body of the scrubber. It is fabricated from 2 mm mild-steel sheet, rolled into a cylinder of approximately 350 mm diameter and 497 mm overall height. The sheet is cut, manually formed, and seam-welded. Flange rings are welded to the top and bottom to allow the end plates to be securely bolted in place.

The top cover is a 2 mm mild-steel circular plate fitted with a central opening for the gas outlet pipe. It is bolted to the upper flange using a gasketed joint to prevent gas or water leakage. A mesh outlet filter, installed beneath the gas outlet, serves as a mist eliminator by removing entrained water droplets and fine particles before the cleaned gas leaves the scrubber. The mesh can be removed for cleaning or replacement.

Inside the barrel, a straightening vane is installed below the spray zone. It helps reduce excessive swirling and distribute the gas more uniformly through the spray, thereby improving gas–liquid contact and pollutant removal.

Two lifting handles are welded to opposite sides of the barrel to facilitate handling and movement of the unit.

The gas inlet is a mild-steel pipe welded tangentially to the lower section of the barrel. Its tangential arrangement induces a cyclonic motion in the incoming exhaust gas, promoting centrifugal separation and improving contact with the scrubbing liquid.

The scrubber is supported by a mild-steel stand consisting of three or four welded legs fitted with castor wheels. The stand provides ground clearance for the gas inlet and dirt outlet while allowing the unit to be moved easily.

The spray system consists of two to four fine-mist hollow-cone nozzles mounted on an internal spray header above the straightening vane. The nozzles atomise water across the gas flow path, increasing gas–liquid contact and enhancing pollutant capture. Water is supplied through a threaded water inlet connected to an external pump or recirculation line.

The bottom plate, also made from 2 mm mild steel, seals the lower end of the barrel and is bolted to the lower flange with a gasket. It also supports the stand and provides the mounting point for the dirt outlet, which is fitted with a ball valve. The valve allows accumulated water, soot, and captured particulate matter to be drained during cleaning or maintenance.

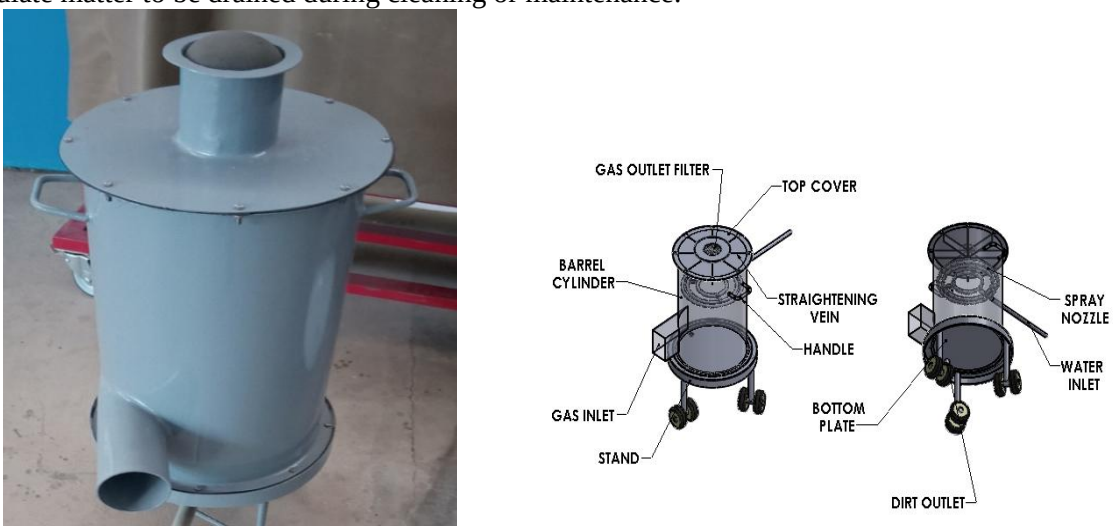

Figure 1: Assembly of the wet scrubber

Assembly Procedure

Fabrication begins with the barrel, top cover, and bottom plate. The internal components—including the straightening vane, spray header and nozzles, and outlet filter—are then installed before the end plates are closed. The top and bottom plates are fitted with gaskets and bolted to the barrel flanges using a cross-tightening sequence to achieve an even, leak-tight seal. Finally, the handles, stand, water inlet, and dirt outlet are installed. The completed unit is inspected for leaks and structural integrity before painting and commissioning.

2.3 Working Principle of Cyclonic Liquid Spray Scrubber Device

The scrubber was built to serve both the dry cyclone and wet spray chamber to remove pollutants from gas streams. For the wet scrubber; raw exhaust from the gasoline powered internal combustion engine enters the system.

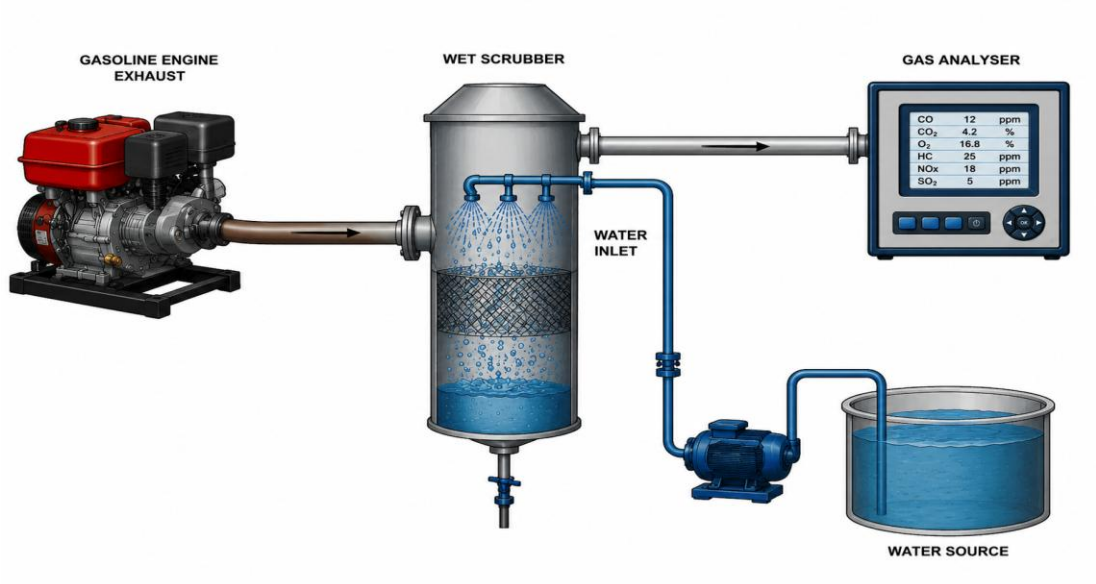

Figure 2: Experimental working assembly of the wet scrubber system

The scrubber consists of empty cylindrical chamber in which the exhaust gas stream is contacted with water droplets. Water spray, generated by the spray nozzles, captures particulate and exhaust gases. The cleaned gas exits to the gas analyser for exhaust gas composition measurements. Water is then recirculated from the water source via the pump and the blowdown removes accumulated contaminants. Two repeated measurements were recorded for each exhaust gas, and the average reading was used for further analysis.

3. RESULTS AND DISCUSSION

The constructed wet scrubber was tested using an internal combustion engine (4-stroke, single cylinder gasoline engine), Brain Bee automotive gasoline gas analyzer and a water source.

The testing of liquid wet scrubber was carried out at Heat Engine Workshop, Department of Mechanical Engineering, Ahmadu Bello University, Zaria. The experimental procedure was carried out with gasoline fuel using different exhaust emission such as Carbon II Oxide (CO), Carbon IV Oxide (CO_2), Unburn Hydrocarbon (HC), and Excess Oxygen O_2. The test was carried out on two stages. A four stroke, single cylinder gasoline engine was initially fuelled with a gasoline fuel until steady-state was confirmed. The exhaust emissions from the engine were measured using the Brain bee automotive gasoline gas analyzer. The gasoline engine was run again with the wet scrubber attached to the engine exhaust and to the Brain bee automotive gasoline gas analyzer. The exhaust gases CO (%/vol); CO_2 (%/vol); HC (ppm) and O_2 (%/vol) were recorded. Tables 2 and 3 show the emission readings from the gas analyser without and with the scrubber. Two readings were recorded in both Tables 2 and 3, and the average readings

Table 2: Exhaust Emission without wet scrubber

Experiment no.	**Exhaust gas parameters (mass fraction)**					
	λ	CO $(\%/vol)$	CO_2 $(\%/vol)$	HC (ppm)	O_2 $(\%/vol)$	$\phi = {}^{1}/_{\lambda}$
First reading	3.811	2.56	1.1	142.0	17.50	0.2624
Second reading	3.896	2.41	1.1	154.0	17.20	0.2566
Average	3.854	2.485	1.1	148.0	17.35	0.2595
Standard Deviation	0.06	0.106	0	8.485	0.212	0.004

Table 3: Exhaust Emission with wet scrubbers

Experiment no.	**Exhaust gas parameters**					
	λ	CO $(\%/vol)$	CO_2 $(\%/vol)$	HC (ppm)	O_2 $(\%/vol)$	$\phi = {}^{1}/_{\lambda}$
First reading	4.468	2.090	1.1	109.0	18.20	0.2238
Second reading	4.430	2.104	0.9	130.0	17.20	0.2262
Average reading	4.449	2.097	1.0	119.5	17.70	0.2250
Standard Deviation	0.027	0.01	0.141	14.8	0.707	0.0017

Table 2 shows the mass fraction of the exhaust gas constituents as well as their respective equivalent ratios (ϕ) when wet scrubber wasn't used in cleaning the exhaust gases. The average exhaust gas mass fraction of λ , CO, CO_2, Hydrocarbon and O_2 were obtained to be 3.854, 2.485 %/vol, 1.1 %/vol, 148.0 %/vol and 17.35 %/vol respectively. λ is a parameter obtained from the gas analyzer known as the inverse equivalence ratio, while ϕ is the equivalence ratio obtained from an experimental run.

Table 3 rather shows the mass fraction of the exhaust gas constituents as well as their respective equivalent ratios (ϕ) when wet scrubber was used in cleaning the exhaust gases. The average exhaust gas mass fraction of CO, CO_2, Hydrocarbon and O_2 were obtained to be 2.097%/vol, 1.0 %/vol, 119.7ppm, and 17.7 %/vol respectively. The results from Table 2 and 3 showed that the scrubber reduced the concentrations of carbon monoxide (CO), carbon dioxide (CO_2), and unburned hydrocarbons (HC) by 15.6%, 9% and 19% respectively and surprisingly increased excess oxygen (O_2) emissions by approximately 2%. The percentage reduction was calculated from: (concentration without scrubber – concentration with scrubber) x100%/ concentration without scrubber. ssThe unexpected increase in O_2 after the gases pass through the scrubber could be due to air ingress through the scrubber, dilution effects from water vapor displacing gas, or analyzer calibration effects. The average equivalence ratio decreased from 0.2595 without the wet scrubber to 0.2250 with the wet scrubber. Comparing the predicted maximum 75% collection efficiency from the design calculations, with the percentage reductions of maximum of 15.6% for HC; the discrepancy shows more room for cleaning exhaust gases. Two readings per test condition were taken mainly to confirm basic repeatability of the exhaust measurements rather than to establish a statistically robust estimate, given practical constraints such as limited test-rig time, the risk of engine drift over longer runs, and the exploratory, proof-of-concept scope of the study; however, this small sample size (n = 2) has notable statistical limitations, including an unreliable estimate of variance, no ability to check low statistical power to detect true differences, high sensitivity to outliers, and limited generalisability beyond the specific test conditions. The percentage reductions should be viewed as indicative rather than precise.

4. CONCLUSION

1. A functional prototype was successfully built and tested. The cyclonic wet scrubber was fabricated and evaluated on a 4-stroke, single-cylinder gasoline engine, using a Brain Bee automotive gas analyser to measure exhaust composition before and after treatment.

2. The scrubber significantly reduced key pollutant concentrations. CO, CO_2, and unburned hydrocarbons (HC) were reduced by 15.6%, 9%, and 19% respectively when the scrubber was fitted, demonstrating measurable emission-control performance.

3. An unexpected rise in excess oxygen was observed. Excess O_2 concentration increased by approximately 2% with the scrubber in place; a surprising result that warrant further investigation

4. The equivalence ratio shifted toward a leaner mixture. The average equivalence ratio dropped from 0.2595 (without the scrubber) to 0.2250 (with the scrubber), consistent with the observed reductions in CO/CO_2/HC and the rise in excess O_2.

ABSTRACT
This study investigated the performance and emission characteristics of biodiesel blends produced from Glycine max oil in a compression ignition engine. Biodiesel was produced through transesterification using methanol and potassium hydroxide. The produced biodiesel was blended with conventional diesel at 5% (B5), 10% (B10) and 20% (B20), and burnt in a single-cylinder Kirloskar TV1 diesel engine at speeds of 1200rpm and 1400rpm. Physicochemical properties including density, kinematic viscosity, pour point and flash point were determined. Engine performance parameters such as brake power (BP), brake thermal efficiency (BTE), brake mean effective pressure (BMEP), brake torque (BT) and brake specific fuel consumption (BSFC) were also evaluated. The experimental results showed that increasing Glycine-Max content from 0 – 20% increased the flash point from 71 – 79^{o}C and decreased the kinematic viscosity from 3.327 – 3.269 (mm^2/s). While Brake Power (BP) increased with engine speed increase regardless of the blends; the Brake Thermal Efficiency (BTE) decreased with increasing proportion of Glycine-max from 5 – 20% irrespective of the blend. There was decreasing trend for exhaust emissions with increasing biodiesel blend proportions from 5% to 10% and 20% for HC, CO and CO_2. Nitrogen oxide (NOx) emissions increased slightly with increasing biodiesel content. The findings indicate that Glycine-max biodiesel have potential as renewable substitutes for petroleum diesel in compression ignition engines.

Keywords: *Glycine max; Diesel; Biodiesel; Compression Ignition Engine; Engine Performance*

1. INTRODUCTION

The increasing global demand for energy, coupled with growing environmental concerns associated with the continued use of fossil fuels, has intensified the search for cleaner, renewable, and sustainable energy alternatives. To address these challenges, many researchers have explored various renewable energy sources, including solar, wind, and biomass, to support future economic development. Although solar and wind energy have shown considerable potential, their dependence on weather and environmental conditions limits their ability to completely replace conventional petro-fuels in the short term. In contrast, biodiesel produced from vegetable and animal oils through transesterification exhibits combustion characteristics comparable to those of petroleum diesel while offering additional advantages such as renewability, biodegradability, and environmental sustainability, making it a promising alternative fuel source (Chuah et al., 2021).

Despite serving as the primary energy source for industrialized societies, fossil fuels have been identified as major contributors to environmental degradation and climate change. The combustion of fossil fuels releases significant quantities of greenhouse gases, including carbon dioxide (CO_2), methane (CH_4), and nitrous oxide (N_2O), which contribute substantially to global warming. Furthermore, the finite nature of fossil fuel reserves underscores the need for energy diversification, particularly within the transportation and industrial sectors (Pasha et al., 2021).

Extensive experimental and modelling studies have been conducted to investigate the combustion and emission characteristics of diesel engines fuelled with various biodiesel feedstocks. These studies have shown that biodiesel can improve combustion efficiency due to its oxygen content, which enhances oxidation processes in fuel-rich zones and consequently reduces emissions of

particulate matter (PM), carbon monoxide (CO), and unburned hydrocarbons (HC) (Zhang et al. 2022). In addition, biodiesel can be blended with conventional diesel fuel in varying proportions without requiring significant engine modifications. However, biodiesel possesses certain limitations, including higher viscosity, lower calorific value, reduced volatility, and poor cold-flow properties. Moreover, several studies have reported increased nitrogen oxide (NO_x) emissions associated with biodiesel combustion. Consequently, considerable research attention has been directed towards biodiesel–diesel blends as a means of improving fuel properties while maintaining environmental benefits (Dandajeh et al., 2020).

Biodiesel blends are typically designated as BXX, where XX denotes the percentage volume of biodiesel present in the blend. Common examples include B5 (5% biodiesel and 95% petroleum diesel) and B20 (20% biodiesel and 80% petroleum diesel). Previous studies, including that of Kaisan and Pam (2013) and Dandajeh et al, 2020, have demonstrated that biodiesel–diesel blends can achieve reduced carbon dioxide emissions while maintaining satisfactory engine performance in compression-ignition (CI) engines without requiring substantial modifications to existing engine systems.

Since biodiesel is predominantly utilized in compression-ignition engines, understanding the operational characteristics of these engines is essential for evaluating fuel performance. The compression-ignition engine, commonly known as the diesel engine, was invented by Rudolf Diesel in the late nineteenth century. Its operation is based on the principle of auto-ignition, whereby fuel combustion is initiated by the high temperatures generated during air compression within the engine cylinder. Due to their high thermal efficiency and superior torque characteristics, diesel engines are widely employed in transportation, agriculture, construction, and other heavy-duty applications (Heywood, 1988).

Although palm and rapeseed oils have received considerable attention in biodiesel research, the application of glycine max biodiesel blends in compression-ignition engines remains relatively underexplored within the Nigerian context. This gap is aimed at reducing the environmental impacts associated with conventional fossil fuels. The paper presents an experimental investigation of the Physicochemical Properties, Engine Performance Characteristics and emissions of Glycine max Biodiesel–Diesel Blends in a Compression Ignition Engine.

2. METHODOLOGY

The materials used in this study included Glycine max (soybean) oil, petroleum diesel, methanol, potassium hydroxide (KOH), phenolphthalein indicator, distilled water, and ethanol. The chemicals were obtained from the National Institute for Leather Science and Technology (NILEST), Zaria, while diesel fuel was purchased from a commercial filling station in Zaria. The equipment used for biodiesel production and characterization included an electronic weighing balance, burette, glass reactor, heating mantle with magnetic stirrer, water bath, separatory funnel, drying oven, digital viscometer, bomb calorimeter, gas analyzer, thermometer, and measuring cylinders. Engine performance and emission tests were conducted using a single-cylinder compression ignition (CI) engine coupled to an eddy-current dynamometer. The engine specifications are presented in Table 1.

Table 1: Specifications of the Test Engine

Parameter	Specification
Model	Kirloskar TV1
Engine Type	Four-stroke, single-cylinder, water-cooled, direct-injection diesel engine
Bore × Stroke	87.5 mm × 110 mm
Compression Ratio	17.5:1
Rated Power	5.2 kW at 1500 rpm
Displacement Volume	661 cc
Fuel Type	Diesel/Biodiesel
Cooling System	Water-cooled
Starting System	Manual
Loading Device	Eddy-current dynamometer

The free fatty acid (FFA) content of the soybean oil was determined using the standard titration method. Approximately 5.04 g of oil was dissolved in ethanol and titrated against 0.1 N KOH using phenolphthalein as indicator. The average FFA value obtained was 0.25%, indicating that the oil was suitable for direct base-catalyzed transesterification without esterification pretreatment. Biodiesel was produced through alkali-catalyzed transesterification. Methanol and potassium hydroxide were mixed to form methoxide solution and reacted with filtered soybean oil in a three-neck reaction flask.

The reaction was carried out at a temperature of 60–65°C under continuous stirring (600–800 rpm) for approximately 3 hours. After completion of the reaction, the mixture was transferred into a separating funnel and allowed to settle for 48 hours to facilitate separation of biodiesel from glycerol. The biodiesel layer was subsequently washed with warm distilled water until neutral and dried in an oven at 60°C for 24 h. The produced biodiesel was blended volumetrically with conventional diesel to prepare B5, B10, and B20 blends, corresponding to 5%, 10%, and 20% biodiesel concentrations, respectively.

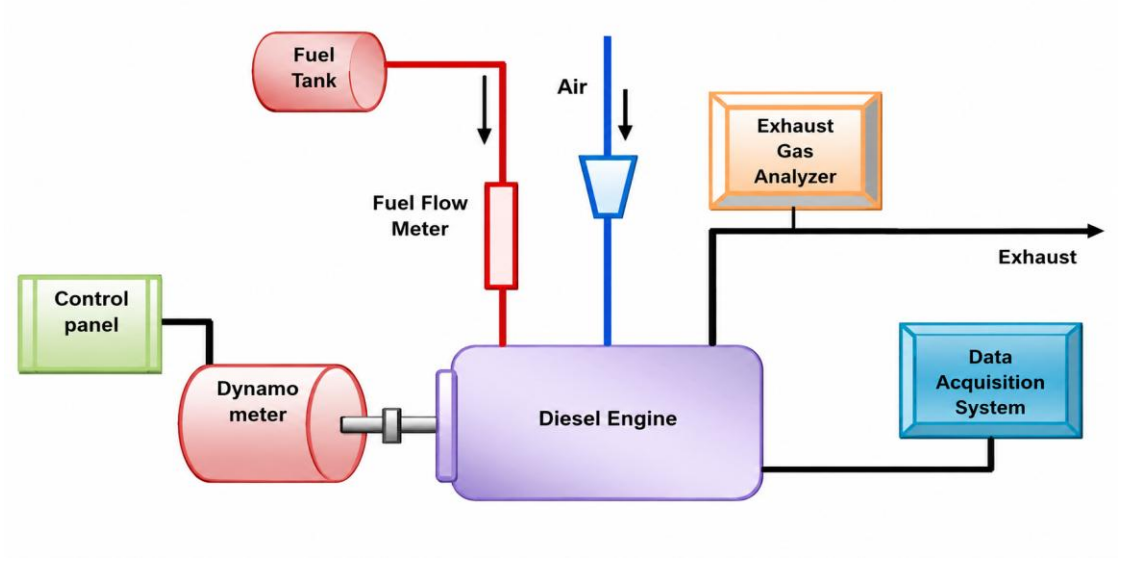

Figure 1: Schematic diagram of the experimental set-up

The physicochemical properties evaluated included density, kinematic viscosity, pour point, flash point, and calorific value. Density was measured using a digital density meter, while viscosity was determined at 40°C using a digital viscometer. Pour point, flash point, and calorific value were determined using standard laboratory procedures.

Engine performance and emission tests were carried out using the Kirloskar TV1 diesel engine coupled with an eddy-current dynamometer. The fuels tested were diesel, B5, B10, and B20. Performance tests were conducted at engine speeds of 1200rpm and 1400 rpm. The performance

parameters evaluated included brake power (BP), and brake thermal efficiency (BTE). Exhaust emissions including carbon monoxide (CO), carbon dioxide (CO_2), nitrogen oxides (NO_x), and unburned hydrocarbons (HC) were measured using a gas analyzer connected to the engine exhaust system.

3. RESULTS AND DISCUSSION

3.1 Physicochemical Properties of Glycine max Biodiesel Blends

The physicochemical properties of Glycine max biodiesel blends, shown in Table 2, were evaluated to determine their suitability for compression ignition engine applications. Table shows that density increased slightly with increasing biodiesel concentration from 1.522 g/cm³ for B5 to 1.532 g/cm³ for B20. This increase is attributed to the higher density of fatty acid methyl esters (FAME) present in biodiesel compared to conventional diesel. Similarly, flash point increased with increasing proportion of biodiesel, indicating improved safety during storage and transportation. For example; The flash point for B5 is 67.5ºC, 69.5ºC for B10 and 79ºC for B20. However, pour point decreased from 28°C for B5, to 24°C for B10 and to 12°C for B20. However, no clear trend was seen for kinematic viscosity. This could be due to the combined effects of biodiesel composition, blending interactions, and experimental variability.

Table 2: Physicochemical Properties of Glycine max Biodiesel Blends

Blend	Density (g/cm³)	Kinematic Viscosity	Pour Point (°C)	Flash Point (°C)
Diesel	1.142	3.327	10	71
B5	1.522	2.628	28	67.5
B10	1.525	3.279	24	69.5
B20	1.530	3.269	12	79

The kinematic viscosity values of all blends were within the acceptable operating range for diesel engines, suggesting satisfactory fuel atomization and lubrication characteristics. Pour point results showed that pure biodiesel exhibited better cold-flow properties than some of the lower biodiesel blends, indicating the influence of feedstock composition on low-temperature fuel behavior. Overall, the measured fuel properties confirmed that Glycine max biodiesel blends possess characteristics suitable for utilization in compression ignition engines without requiring engine modifications.

3.2 Engine Performance Characteristics

The performance characteristics of the engine fueled with Glycine max biodiesel blends were evaluated in terms of brake power (BP) and brake thermal efficiency (BTE)

Figures 2a) and b) show that brake power increased with increasing engine speed, respectively, from 1200 rpm to 1400 rpm for all fuel blends. For B5 instance, the brake power increased by a factor of 2.25 for increased speed from 1200 -1400rpm. Interestingly Brake Power for diesel and B10 increased by 100% for engine speed increase from 1200 -1400rpm. At lower engine speed of 1200rpm, B10, B20 and diesel exhibited roughly similar brake power due to improved combustion arising from the oxygenated nature of biodiesel.

Fig 3a) and b) show the brake thermal efficiency (BTE) at speeds of 1200rpm and 1400rpm respectively. The results showed that BTE decreased with increasing biodiesel proportion from 5 to 20% regardless of the increased speeds from 1200 - 1400rpm. For example, the BTE of B5 was 39.4%, and it decreased by 18.5% for B20.

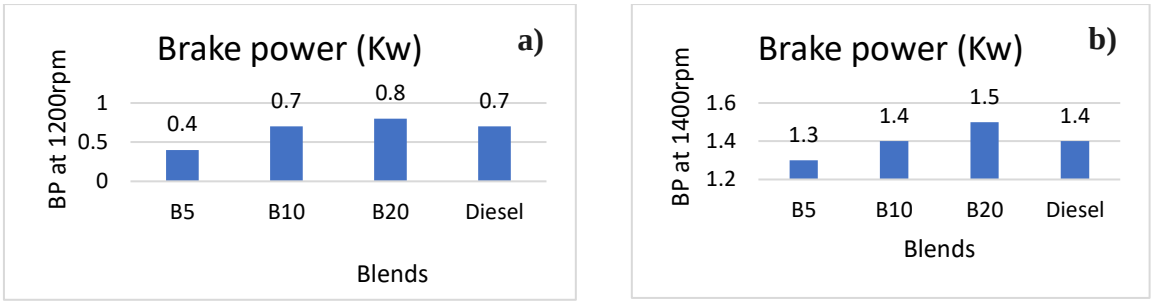

Figure 2: Brake Power (kW) at: a)1200rpm b)1400rpm

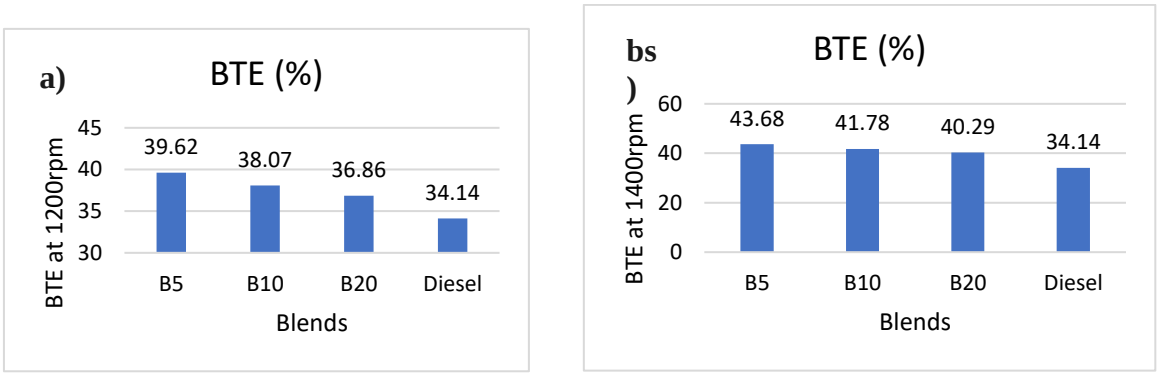

Figure 3: Brake Thermal Efficiency at: a) 1000rpm b) 1200rpm c) 1400rpm

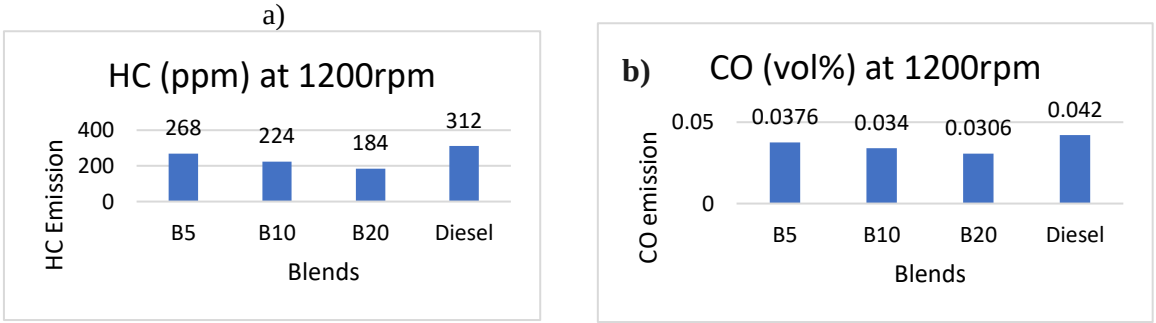
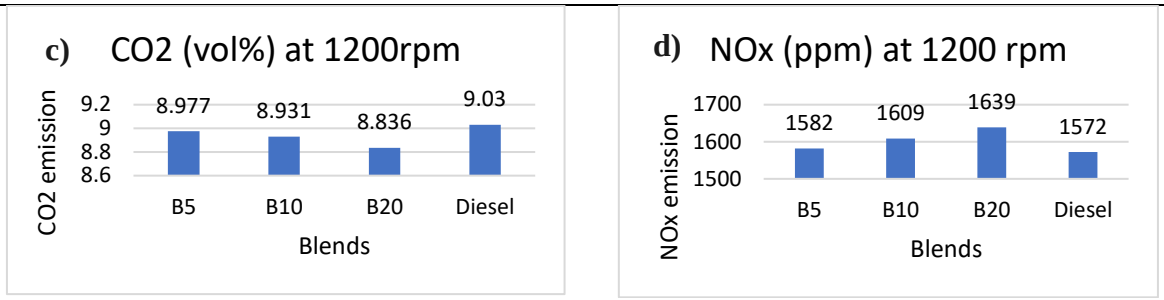


Considering engine speed variations, BTE increased for B10 for example, from 33.6% at 1000rpm to 38.7% at 1200rpm and to 41.78% at 1400rpm. This indicates better conversion of fuel energy into useful work.



3.3 Emission Characteristics

Figure 4a), b) c) and d) respectively show the results of emission values of Glycine max biodiesel blends of hydrocarbons (HC), carbon monoxide (CO), carbon dioxide (CO_2), and nitrogen oxides (NOx) at constant speed of 1200rpm. The results showed decreasing exhaust emissions with increasing biodiesel blend proportions from 5% to 10% and 20% for HC, CO and CO_2. This reduction is attributed to the oxygen content present in biodiesel, which promotes more complete oxidation of fuel during combustion. Figure 4d) shows that only NOx was seen increasing from 1582ppm for B5, to 1609ppm for B10 and to 1639ppm for B20. This is consistent with previous studies (Dandajeh et al. 2020; Bawa et al. 2023).

Overall, the emission results indicate that Glycine max biodiesel blends can significantly reduce harmful exhaust emissions of HC, CO and CO_2 while maintaining engine operation.

a)

Figures 4: Exhaust Emissions at 1200rpm a) HC (ppm) b) CO (vol%) c) Nox d) CO_2 (vol%)

Conversely, NOx emissions exhibited a slight increase with increasing biodiesel concentration. This behavior is commonly associated with higher in-cylinder temperatures and improved oxygen availability during combustion. The enhanced combustion process responsible for lower HC and CO emissions simultaneously promotes thermal NOx formation.

4. CONCLUSION

1. The Glycine max biodiesel blends exhibited acceptable physicochemical properties: density, viscosity, flash point, and pour point; indicating their suitability for smooth compression ignition engine operation without requiring engine modifications.
2. Brake power increased respectively with increasing engine speed from 1200rpm to 1400rpm for all the fuel blends. Brake power for B5 increased by a factor of 2.25 for increased speed from 1200 -1400rpm
3. Brake Thermal Efficiency decreased with increasing biodiesel proportion from 5 to 20% regardless of the increased speeds from 1200 - 1400rpm.
4. There was decreasing trend for exhaust emissions with increasing biodiesel blend proportions from 5% to 10% and 20% for HC, CO and CO_2. Nitrogen oxide (NOx) emissions increased slightly with increasing biodiesel content

ABSTRACT

Flexible pavement design plays a critical role in ensuring durable, safe and economical road infrastructure. This study compares pavement structures obtained using a CBR-based empirical method and the 1993 AASHTO flexible pavement design procedure using laboratory-derived properties of two lateritic soils. The non-marginal and marginal soils recorded CBR values of 42.79% and 13.03%, respectively. Design traffic was reconstructed from an AADT of 4,200 vehicles/day, 25% heavy vehicles, 4% annual growth, a 20-year design period, a directional distribution factor of 0.50, a lane distribution factor of 1.00 and an assumed vehicle damage factor of 3.0 ESAL/heavy vehicle, giving 17.12 × 10⁶ design ESALs. For AASHTO design, 95% reliability, an overall standard deviation of 0.45, initial and terminal serviceability indices of 4.2 and 2.5, respectively, and CBR-derived resilient moduli were adopted. Required Structural Numbers were 3.55 and 4.68 for the non-marginal and marginal soils. The adopted AASHTO sections were 100 mm asphalt, 200 mm base and 200 mm sub-base for the non-marginal soil (500 mm total), and 130 mm asphalt, 230 mm base and 270 mm sub-base for the marginal soil (630 mm total). The CBR-based method yielded 413 mm and 450 mm, respectively. Thus, AASHTO sections were 21.1% and 40.0% thicker. The results demonstrate the effect of explicitly considering traffic, reliability, serviceability and subgrade stiffness, while confirming the continued usefulness of CBR-based design where data and resources are limited.

Keywords: *flexible pavement; AASHTO; CBR; pavement thickness; ESAL; subgrade strength*

1. INTRODUCTION

Road transportation remains a major means of moving people, goods and services in developing countries, and the performance of road networks depends substantially on the quality and durability of pavement structures. Flexible pavements are widely used because of their relatively low construction cost, ease of maintenance and adaptability to varying ground conditions. Their performance is influenced by traffic loading, subgrade strength, environmental conditions, drainage and material characteristics (Inyang et al., 2024; Nneka, 2025; Olowosulu et al., 2022; Owolabi et al., 2012). Inadequate design can result in rutting, cracking, potholes and excessive deformation, with associated maintenance costs and reduced service life.

Pavement design practice has developed from empirical procedures toward approaches that incorporate traffic, reliability and material-response considerations. The California Bearing Ratio (CBR) method uses subgrade bearing strength and empirical design relationships and is particularly attractive where detailed traffic, material and climatic information is limited (Chitade et al., 2024; Noka et al., 2025). The AASHTO procedure, in contrast, incorporates cumulative traffic expressed as ESALs, reliability, serviceability, subgrade resilient modulus and drainage considerations (Ahmed et al., 2023; El-Ashwah et al., 2022; Moharekpour et al., 2022; Prayudyanto et al., 2023; Ziar et al., 2023).

CBR-based procedures remain useful for preliminary and lower-data applications, but their empirical nature means that reliability and uncertainty are not represented explicitly. AASHTO therefore provides a more comprehensive framework for higher traffic levels, although it requires more design inputs and can produce thicker sections. A conventional flexible pavement consists of surfacing, base, sub-base and subgrade layers; the upper layers distribute wheel loads so that stresses transmitted to the subgrade remain within acceptable limits.

The aim of this study is to compare flexible pavement structures obtained using the CBR-based empirical method and the 1993 AASHTO design procedure for two lateritic subgrade soils. The specific objectives are to characterize the engineering properties of the soils, reconstruct design traffic, determine the AASHTO Structural Number and corresponding layer thicknesses, and compare the resulting sections in terms of total thickness and material quantity.

2. METHODOLOGY

2.1 Soil Sampling

Two lateritic soil samples representing distinct subgrade conditions were selected for the study. The samples were obtained from an existing borrow pit in Janguza Area, north of Kano City, Kano State, Nigeria. Bulk samples were collected at approximately 1.0 m below ground level to minimize the influence of organic matter and surficial contamination. The samples were packaged, labelled and transported to the geotechnical laboratory, where they were air-dried, pulverized without crushing individual particles and prepared for testing in accordance with relevant standard procedures (ASTM, 2008).

2.2 Laboratory Testing

Particle-size distribution and Atterberg limits were determined using standard geotechnical procedures. Standard Proctor compaction testing was used to determine maximum dry density (MDD) and optimum moisture content (OMC), while CBR testing was conducted on prepared specimens to assess subgrade bearing capacity. The measured CBR values were used directly in the CBR-based design and as the basis for estimating resilient modulus for the AASHTO analysis.

The retained dataset does not contain the complete particle-size distribution required for formal AASHTO or USCS group assignment. Accordingly, the soils are additionally described using the CBR-based subgrade strength classes in the Federal Ministry of Works guidance. The non-marginal soil (CBR = 42.79%) falls within S6 (CBR ≥ 30%), while the marginal soil (CBR = 13.03%) falls within S4 (CBR 8–14%). These classes are used for engineering interpretation and are not substitutes for formal soil classification.

2.3 Traffic Analysis and Design ESAL

Cumulative design traffic was expressed as 80 kN (18-kip) Equivalent Single Axle Loads (ESALs). In the absence of an axle-load survey, a vehicle damage factor (VDF) of 3.0 ESAL per heavy vehicle was adopted as an explicit assumption. The traffic growth factor was calculated as GF = [(1 + r)^n − 1]/r, where r is annual growth and n is the design period. For r = 0.04 and n = 20 years, GF = 29.778. Design ESAL was calculated as W18 = AADT × PHV × 365 × GF × DD × LDF × VDF, using AADT = 4,200 vehicles/day, PHV = 0.25, DD = 0.50, LDF = 1.00 and VDF = 3.0, giving W18 = 17.12 × 10^6 ESALs. The assumed VDF should be replaced by project-specific axle-load data for detailed design.

2.4 AASHTO 1993 Flexible Pavement Design Procedure

The required Structural Number (SN) was determined using the flexible pavement design equation in the AASHTO Guide for Design of Pavement Structures (AASHTO, 1993):

$$\log_{10}(W18) = ZR\,So + 9.36\log_{10}(SN + 1) - 0.20 + \{\log_{10}[\Delta PSI/(4.2 - 1.5)]\}/\{0.40 + 1094/(SN + 1)^{5.19}\} + 2.32\log_{10}(MR) - 8.07$$

where W18 is cumulative 18-kip ESALs; ZR is the standard normal deviate corresponding to the selected reliability; So is the overall standard deviation; ΔPSI is allowable serviceability loss; and MR is subgrade resilient modulus in psi. Reliability of 95% (ZR = −1.645), So = 0.45, initial serviceability p0 = 4.2 and terminal serviceability pt = 2.5 were adopted, giving ΔPSI = 1.7.

Because resilient modulus was not measured directly, it was estimated from CBR using MR (psi) = 2555(CBR)^0.64. The resulting moduli were approximately 28,278 psi for the non-marginal soil and 13,212 psi for the marginal soil. Substitution into the AASHTO equation at W18 = 17.12 × 10^6 gave required SN values of 3.55 and 4.68. Layer contribution was checked using SN = a1D1 + a2m2D2

+ a3m3D3, with a1 = 0.44 for asphalt concrete, a2 = 0.14 for granular base, a3 = 0.11 for granular sub-base and m2 = m3 = 1.0. Layer thicknesses D are expressed in inches in the SN equation.

2.5 CBR-Based Pavement Design Procedure

The CBR-based pavement sections were interpreted using the empirical pavement design approach in Federal Ministry of Works, Highway Manual Part 1: Design, Volume III: Pavement and Materials Design (2013), which incorporates CBR-based pavement catalogues and guidance derived in part from TRL Overseas Road Note 31. The design CBR values of 42.79% and 13.03% were used with the design traffic level to select the corresponding pavement thicknesses. The specific catalogue source is stated to improve reproducibility.

Table 1: *AASHTO Design Input Parameters*

Parameter	Symbol	Adopted value	Basis/remark
Design traffic	W18	17.12×10^6 ESAL	Traffic reconstruction
Reliability	R	95%	Higher-order road design assumption
Standard normal deviate	ZR	−1.645	Corresponding to 95% reliability
Overall standard deviation	So	0.45	Typical flexible pavement value
Initial serviceability	p0	4.2	AASHTO flexible pavement value
Terminal serviceability	pt	2.5	Major road design value
Serviceability loss	ΔPSI	1.7	p0 − pt
Layer coefficients	a1, a2, a3	0.44, 0.14, 0.11	Asphalt, granular base, granular sub-base
Drainage coefficients	m2, m3	1.0, 1.0	Assumed good/normal drainage
FMW/ORN31 Subgrade Strength Class	S6 (CBR ≥ 30%)	S4 (CBR 8–14%)	

3. RESULTS AND DISCUSSION

3.1 Engineering Properties of the Soils

Table 2: *Engineering Properties of the Lateritic Soils*

Property	Non-Marginal Soil	Marginal Soil
Liquid Limit (%)	20.0	27.0
Plastic Limit (%)	14.58	17.15
Plasticity Index (%)	5.42	9.85
MDD (Mg/m³)	2.03	2.00
OMC (%)	11.1	10.0
CBR (%)	42.79	13.03

The engineering properties of the two lateritic soils show clear differences in subgrade quality. The non-marginal soil recorded a liquid limit of 20.0%, plastic limit of 14.58% and plasticity index of 5.42%, compared with 27.0%, 17.15% and 9.85%, respectively, for the marginal soil. The lower

plasticity of the non-marginal soil indicates lower susceptibility to moisture-induced volume changes, whereas the marginal soil is more likely to experience deformation under moisture fluctuations.

The compaction characteristics were similar. The non-marginal soil achieved MDD of 2.03 Mg/m³ at OMC of 11.1%, while the marginal soil achieved 2.00 Mg/m³ at 10.0%. The slightly higher density of the non-marginal soil indicates a somewhat denser and potentially more supportive soil matrix.

The largest difference was in CBR: 42.79% for the non-marginal soil and 13.03% for the marginal soil. Under the FMW/ORN31 grouping these correspond approximately to S6 and S4. Formal AASHTO or USCS classification is not reported because the complete particle-size distribution data were unavailable.

3.2 Flexible Pavement Design Using the CBR Method

The CBR-based pavement sections are presented in Table 3. For the non-marginal soil, with CBR of 42.79%, the required structure comprised 113 mm surfacing, 150 mm base and 150 mm sub-base, giving a total thickness of 413 mm. For the marginal soil, with CBR of 13.03%, the section comprised 100 mm surfacing, 150 mm base and 200 mm sub-base, giving a total thickness of 450 mm.

The marginal soil therefore required an additional 37 mm of total pavement thickness compared with the non-marginal soil, mainly because of the additional 50 mm of sub-base. This confirms the empirical CBR principle that lower subgrade strength generally requires thicker pavement layers to reduce stresses transmitted to the subgrade.

Table 3: *Flexible Pavement Design Thickness Using the CBR Method*

Layer	**Thickness (mm)**	
	Non-Marginal Soil	**Marginal Soil**
Surfacing	113	100
Base	150	150
Sub-base	150	200
Total	413	450

3.3 Flexible Pavement Design Using the AASHTO Method

The AASHTO pavement structures are presented in Table 4. Using $W18 = 17.12 \times 10^6$ ESALs, R = 95%, So = 0.45, ΔPSI = 1.7 and the CBR-derived resilient moduli, the required SN values were 3.55 for the non-marginal soil and 4.68 for the marginal soil.

Table 4: *Flexible Pavement Design Thickness Using the AASHTO Method*

Layer	**Thickness (mm)**	
	Non-Marginal Soil	**Marginal Soil**
Structural Number (SN)	3.55 required 3.70 provided	4.68 required 4.69 provided
Asphalt Surface	100	130
Base	200	230
Sub-base	200	270
Total Thickness	500	630

For the non-marginal soil, 100 mm asphalt surface, 200 mm granular base and 200 mm granular sub-base provide SN = 3.70, exceeding the required 3.55. The total thickness is 500 mm. For the marginal soil, 130 mm asphalt surface, 230 mm granular base and 270 mm granular sub-base provide SN = 4.69, exceeding the required 4.68. The total thickness is 630 mm.

The lower CBR-derived resilient modulus of the marginal soil is therefore reflected in a substantially larger required Structural Number and thicker pavement section.

3.4 Comparative Analysis

A comparison of the two design methods shows that AASHTO produces thicker pavement sections for both soil conditions. For the non-marginal soil, thickness increases from 413 mm under

CBR to 500 mm under AASHTO, an increase of 87 mm (21.1%). For the marginal soil, thickness increases from 450 mm to 630 mm, an increase of 180 mm (40.0%).

Table 5: *Comparison of Pavement Thickness and Material Quantity*

Soil	CBR total (mm)	AASHTO total (mm)	Difference (mm)	Increase (%)	Extra volume (m^3/m^2)
Non-marginal	413	500	87	21.1	0.087
Marginal	450	630	180	40.0	0.180

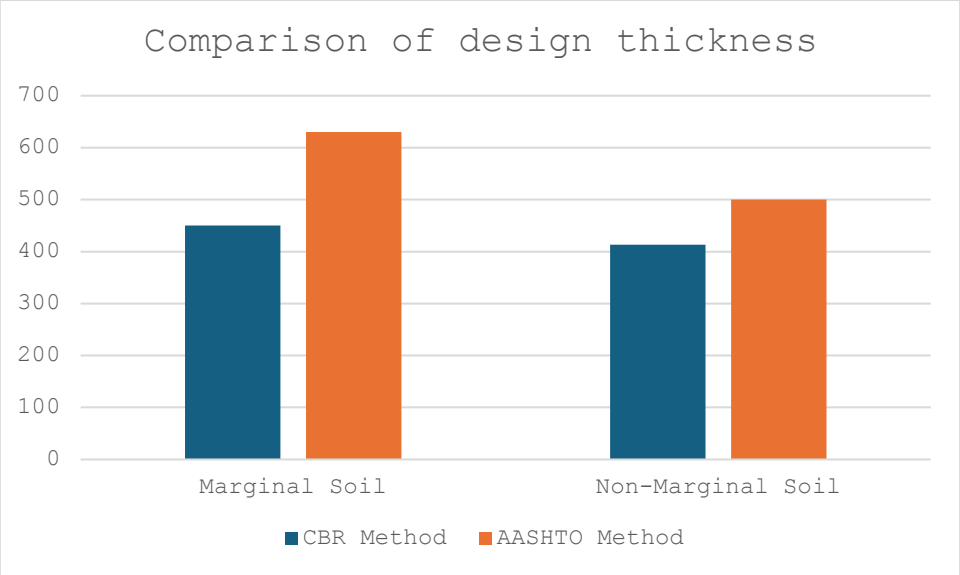

Figure 1: *Comparison of AASHTO and CBR Design Methods*

Figure 1 shows that the AASHTO sections are thicker for both soils, with the difference more pronounced for the weaker marginal subgrade. The thickness difference corresponds to an additional material quantity of approximately 0.087 m^3/m^2 for the non-marginal soil and 0.180 m^3/m^2 for the marginal soil. This provides a material-quantity proxy for economic comparison, although monetary cost and life-cycle cost cannot be established without project-specific unit rates and maintenance assumptions.

The greater AASHTO thickness should not be interpreted as proof of superior performance from thickness alone. Its principal distinction is the explicit inclusion of reliability, uncertainty, serviceability and resilient modulus in the design framework. Conversely, the CBR method remains attractive where data, time and analytical resources are limited. For detailed projects, the assumed VDF should be replaced with measured axle-load data and resilient modulus should preferably be measured directly or calibrated locally.

4. CONCLUSION

This study demonstrates that pavement design methodology materially affects the resulting flexible pavement structure. For lateritic soils with CBR values of 42.79% and 13.03%, the CBR-based method produced total pavement thicknesses of 413 mm and 450 mm, respectively, whereas the AASHTO 1993 analysis produced adopted sections of 500 mm and 630 mm. The AASHTO sections were therefore 21.1% and 40.0% thicker.

The difference is associated with the explicit consideration of cumulative ESALs, reliability, serviceability and resilient modulus in the AASHTO framework. The CBR method remains useful for preliminary and lower-data applications because of its simplicity and relatively low data requirements, but its reduced material quantity should not be interpreted automatically as lower life-cycle cost.

The analysis is limited by the assumed VDF, the use of CBR-derived rather than directly measured resilient modulus, incomplete particle-size distribution data and the absence of project-

specific drainage, seasonal and unit-cost information. Future work should incorporate axle-load surveys, direct resilient-modulus testing, complete AASHTO/USCS classification data, locally calibrated environmental and drainage parameters, and project-specific life-cycle cost analysis.

ABSTRACT

In Nigeria, plastics are indiscriminately discarded endangering man and the entire ecosystem. There is need for development of alternative ways in combating challenges of plastic waste disposal. These challenges have necessitated its adoption in asphalt concrete production. This study examined the use of polycarbonate plastic waste as an additive and the effect on strength properties of hot mix asphalt. Polycarbonate is a polymeric material. Fourier Transform Infrared analysis on polycarbonate revealed the presence of aromatic, methyl, carbonyls, amine, and alkene. Scanning electron microscopy and Energy dispersive x-ray spectrometry analysis showed that polycarbonate has spongy shape and the predominant elements are silicon, oxygen, carbon, and aluminum. For the experiment, Marshall method was adopted for mix design and testing. Polycarbonate plastic was introduced into the mix by means of dry process from 0 - 3% (at interval of 0.5%). The bitumen content used was varied from 6 – 7.5% (at intervals of 0.5%). The introduction of polycarbonate plastic improved the Marshall stability by 20% from 4.67 kN (Threshold) to 5.59 kN (Modified) at 2.5% addition of polycarbonate. Although flow did not improve, other volumetric properties recorded an improvement. This study concludes that an optimal dosage of 2.5% polycarbonate plastic will increase the strength of hot mix asphalt and consequently improve the service life of flexible pavement.

Keywords: *Polycarbonate Plastic; Mechanical Properties; Asphalt Concrete; Waste*

I. INTRODUCTION

Plastic is a group of synthetic or semi-synthetic material produced from hydrocarbons through polymerization. Polymerization is a sequence of chemical reactions chiefly on crude oils and natural raw materials (Luckscheiter & Ebii, 2020; Adogame, *et al*., 2021). Plastic is the general name for polymeric materials that may contain other materials for enhanced performance or colour (Yalwaji, *et al.*, 2022). Nigeria is among the largest importer and consumer of plastics in Africa, it is estimated that between 1996 and 2014 over 23 million tons of plastics were imported into Nigeria (Luckscheiter & Ebii, 2020; Dibia, *et al.*,2023). Polymers used in production of plastics includes the following; High Density Polyethylene (HDPE), Polyethylene Terephthalate (PET), Polycarbonate (PC), Low-Density Polyethylene (LDPE), Polylactic acid (PLA), Polypropylene (PP), Polyhydroxyalkanoates (PHA). Expanded polystyrene (EPS), Polystyrene (PS), Polyvinyl Chloride (PVC) Adogame, *et al*., (2021; Yalwaji, *et al.*, (2022). According to IHS Chemical, (2013) polycarbonate chemical is the highest consumed chemical in plastic industries, it reported that world-wide demand for polycarbonate surpasses 4.2 million tons annually. Million tons of plastic are littering the streets and harming our environment. Within this experiment Polycarbonate (PC) plastic waste was incorporated as an additive to improve the strength of asphalt concrete. Polycarbonate plastics used from home, offices, industries, food and packaging companies are non-biodegradable and cannot be recycled as such are dumped in the open site and eventually burnt openly on dumpsites causing the release of dioxins and furans into the atmosphere. This method of disposing plastic waste poses public health challenges and are great concern for residents and waste management authorities (Federal Ministry of Environment, 2020). This calls for alternative method of waste disposal that are economical and environmentally friendly.

Asphaltic concrete comprises of fine and coarse aggregate with bitumen as binder. Aggregate function as the structural framework for flexible pavement and bitumen serve as adhesive for the asphaltic mixture. About 90–95% of volume of asphaltic concrete mixtures are aggregates including mineral filler and bitumen is approximately 5 - 8%. Strength properties of asphaltic concrete directly impact the performance of flexible pavements. Asphaltic concrete is typically used in pavement construction due to its excellent performance in providing stability, driving comfort, water resistance and durability (Bakare, 2017). When a flexible pavement is to be constructed, a sample or representative of the mix design is prepared to test the consistency of the properties in compliance with specification. The mechanical properties of asphalt concrete to be tested are stability, durability, skid resistance and workability (Cesare, *et al.,* 2019). These properties make hot mix asphalt desirable for pavement. Flexible pavement develops defects during its service life. Road defect according to Okigbo, (2012) is any portion of a road, highway that deviates from the prescribed standard for safety and comfort of the rider. However, the service life of flexible pavement and rider's comfort by can be increased by incorporating different materials into asphalt mixes either in form of modifier, filler or admixture. In recent literatures, it is a common practice in highway engineering to improve the properties of asphalt binder and asphalt concrete with locally available waste material such as locust bean pod ash (Murana, *et al.,* 2024), pulverized burnt brick (Ibedu & Murana, 2024), polyvinyl chloride (Murana, *et al*., 2024), high density polyethylene (Murana *et al.,* 2024; Murana *et al.,* 2023), Bentonite clay (Ibedu & Asaolu, 2026), coconut shell ash and reclaimed asphalt pavement (Murana, *et al*., 2023), Soybean husk ash (Ibedu & Asen, 2026). These waste from industries and domestics products serves as an economical option in the search for material to improve for road construction. However, polycarbonate (PC) plastic possesses superior mechanical properties such as good toughness, high impact and crack resistance, high temperature resistance (Sisodia & Arora, 2022; Kumar & Raj, 2021). These properties, make polycarbonate (PC) plastic a suitable additive polymer material for asphalt production.

There are limited studies on the effect of polycarbonate plastic waste on asphalt concrete, despite the good mechanical properties of polycarbonate plastic. Therefore, this study is aimed at investigating the mechanical properties of asphalt concrete admixed with polycarbonate plastic and to obtain optimal dosage of polycarbonate needed to improve the performance of asphalt mixtures. Scanning Electron Microscopy (SEM) and Energy Dispersive X-Ray Spectrometry (EDS) were used for microstructural examination and elemental analysis of the polycarbonate plastic. This study bridges the knowledge gap in previous studies on plastic waste in asphalt concrete

2. METHODOLOGY

2.1 Materials

Materials used in this research were bitumen, aggregates and waste polycarbonate plastic. The aggregate and bitumen were sourced from Zeberced Group Limited along Kaduna – Zaria Road in Kaduna State, and Ringadas Nigeria Limited/ASCA Bitumen Company Abuja. The waste polycarbonate plastic was sourced from open refuse disposal dump in Samaru area of Zaria L.G.A. Kaduna State.

2.1.1 Polycarbonate

The polycarbonate was sourced from open dumpsite situated within Ahmadu Bello University, Zaria. The initial step in material involved the washing of polycarbonate waste with ethanol to strip away dirt, the material was spread out and allowed to air-dry 72 hours under ambient conditions to remove residual moisture. The dried polycarbonate was then cut into pellets forms and further reduced to a powdered form through pulverization using a laboratory grinding machine.

Plate I: Processing of polycarbonate waste (a) pellet polycarbonate (b) pulverized polycarbonate (c) dry mixing of polycarbonate (d) asphalt concrete admixed with polycarbonate

2.2 Methods

Test on Polycarbonate

i. Fourier Transform Infra-Red (FTIR)

Fourier Transform Infra-Red (FTIR) spectroscopy was employed to identify the functional groups present in the polycarbonate in accordance with ASTM D6348-12 (2020).

ii. Scanning Electron Microscopy and Energy Dispersive Spectroscopy (SEM/EDS)

Scanning Electron Microscopy and Energy Dispersive Spectroscopy (SEM/EDS) is a technique that uses a high-energy beam to create an image resolution surface and to identify elemental composition of a material's surface. The test was conducted in accordance with ASTM E2809-22, (2022).

Test on Aggregate

i. Sieve Analysis of Aggregates

Sieve analysis of aggregates was done by manual sieving. The sieving of aggregates was conducted to determine the distribution of different sizes of aggregate in a given batch aggregate. The test was conducted in accordance with ASTM C136/C136M-19 (2019)

Test on Asphaltic Concrete

i. Marshall Stability and Flow Test

Marshall stability is the maximum load that a compacted asphalt specimen can withstand before a deformation at a standard temperature of 60°C with a load applied at a constant rate of 50mm/min. The stability and flow are read from the dial gauges. The flow which is measured in 0.25mm units is the deformation that the specimen has undergone at the maximum load. The test was conducted in accordance with ASTM D6927-15 (2015).

ii. Production of Asphaltic Concrete Admixed with Polycarbonate Waste Plastic

For each bitumen content and replacement level, three replicate specimens were produced and tested. Approximately, 1200g of aggregates (including admixture) were blended and preheated to 140°C. Varying percentages of bitumen 6%, 6.5%, 7% and 7.5% by weight of the total mix, polycarbonate was then added to the aggregates. The mixture was thoroughly mixed to achieve homogeneity. The hot mix was immediately transferred to a mould (101.6mm diameter x 63.5mm height) and compacted with 75 blows per side. After compaction, the briquette sample was allowed to cool for 25 minutes before extraction. This procedure was applied to both threshold mixtures (0%) and mixtures containing 0.5 –3% polycarbonate at 0.5% increments. The prepared samples were subsequently subjected to Stability-flow tests and density-voids analysis in the laboratory in accordance with ASTM standard (ASTM D6926-20, 2020; ASTM D6927-15, 2015).

3. RESULTS AND DISCUSSIONS

3.1 FTIR Analysis of the Polycarbonate Plastic Material

The FTIR analysis was carried out on the polycarbonate plastic was recorded Figure 1 and tabulated in Table 1. The polycarbonate plastic gave characteristics absorption peaks in both functional groups and finger print region. The result of the infra-red spectrum in Figure 4.1 shows that the polycarbonate plastic gave peak due to O-H_{str} at 3753.4 and 3693.8^{cm-1} due to alcohol, C-H_{str} vibration band due to amine appeared at 3507.4^{cm-1}, C-H_{str} vibration band appeared at 3041.5^{cm-1} due to Aromatic, C-H_{str} absorption peak due to Methyl appeared at 2967 and 2922.2^{cm-1}, C-H_{bend} vibration

band due to Aromatic appeared at 2072.4^{cm-1} , C=O_{str} vibration band appeared due to Anhydride at 1897.2^{cm-1}, C=O_{str} absorption peak due to Carbonyls appeared at 1770.8^{cm-1} , N-H_{bend} vibration band appeared due to Amine, N-O_{bend} absorption peak due to Nitro appeared at 1502.1^{cm-1}, C-Cstr vibration band due to Carboxylic appeared at 1408.9^{cm-1} , C-H_{str} vibration band appeared due to Aromatic amine at 1289.7^{cm-1} . At the fingerprint region, peak at C-O_{str} appeared at 1218.8^{cm-1} due to Carbonyl, C-O_{str} vibration band due to Ester appeared at 1185.3^{cm-1}, C-O_{str} vibration band appeared due to Alcohol at 1103.8^{cm-1}, C-O_{str} absorption peak due to Carbonyl appeared at 1159.2, 1013.3 and 1080.9^{cm-1}, C=C_{str} vibration band appeared at 887.5^{cm-1} due to Alkene. C-H_{bend} vibration band appeared at 827.1, 764.1 and 704.1. A similar results was obtained by Haghighi-Yazdi & Lee-Sullivan, (2015).

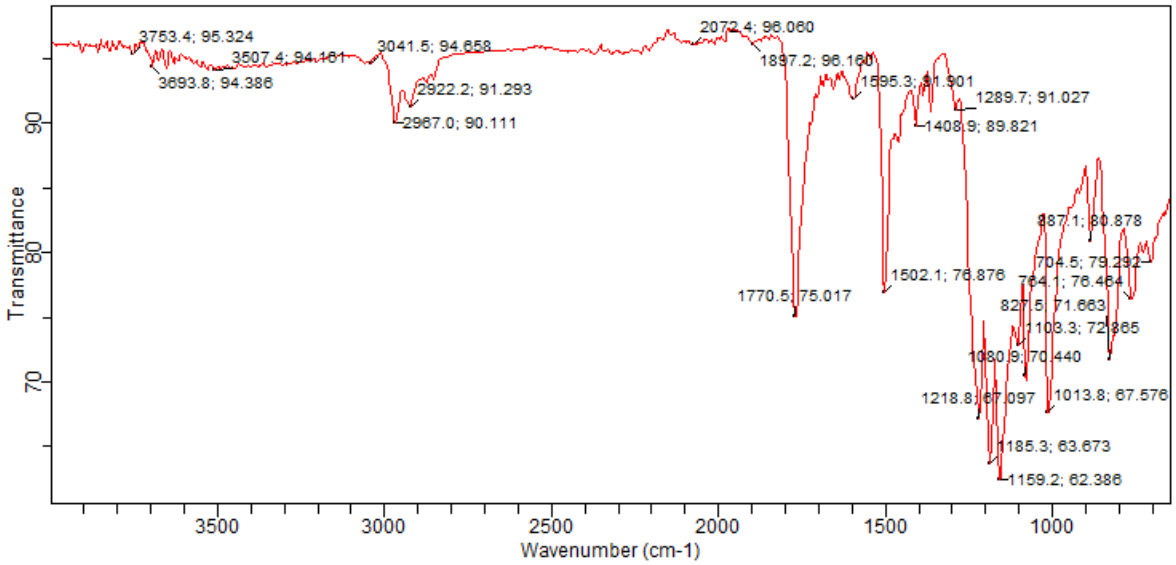

Figure 1: FTIR Spectrum of Polycarbonate

Table 1: Functional group, wavenumber and Vibration type of polycarbonate plastic

Functional Group	**Wavenumber (cm^{-1})**	**Vibration Type**
OH (Alcohols)	3753.4	Medium O-H Stretching
OH (Alcohols)	3693.8	Medium O-H Stretching
C-H (Amine)	3507.4	Strong C- H Stretching
C-H (Aromatic)	3041.5	Strong C - H Stretching
C-H (methyl)	2967	Weak C- H Stretching
C-H (methyl)	2922.2	Weak C- H Stretching
C-H (Aromatic)	2072.4	Weak C- H Bending
C=O (Anhydride)	1897.2	Strong C=O stretching
C=O (Carbonyls)	1170.8	Strong C=C stretching
N-H (Amine)	1595.3	Medium N-H bending
N-O (Nitro)	1502.1	Strong N-O bending
O-H (Carboxylic)	1408.9	Weak C-C stretching
C-H (Aromatic amine)	1289.7	Strong C-H stretching
C-O (Carbonyl)	1218.8	Strong C-O stretching
C-O (Ester)	1185.3	Strong C-O stretching
C-O (Alcohol)	1103.8	Strong C-O stretching
C-O (Carbonyl)	1159.2	Strong C-O stretching
C-O (Carbonyl)	1080.9	Strong C-O stretching
C-O (Carbonyl)	1013.3	Strong C-O stretching
C=C (Alkene)	887.5	Strong C=C stretching
CH_3	827.1	Strong C-H bending
C-H	764.1	Strong C-H bending
C-H	704.1	Strong C-H bending

3.2 Results of SEM and EDS on Polycarbonate

The SEM and EDS results from polycarbonate plastic is shown in Figure 2a and Figure 2b respectively. The morphology examination shown in Figure 2a was done using Scanning Electron Microscopy (SEM) technique with a magnification of 10,000x, it can be seen that polycarbonate appears to have a sponge-like shape rough texture, it was apparent that polycarbonate plastic was pulverized with size greater than 10µm. The elements contained in the polycarbonate was measured with EDS. The results obtained from the EDS spectrum is shown in Figure 2b, the major elements detected are namely; Silicon (Si) detected at 65.2%, Oxygen (O) detected at 15.2%, Aluminium (Al) detected at 7.2%, other elements detected are Carbon (C), Copper (Cu), Na (Na), Magnesium (Mg), and Potassium (K) at 3.2, 5.2, 1.5, 1.3, and 1.2% respectively, summation of the different elements normalized to total of 100%.

a

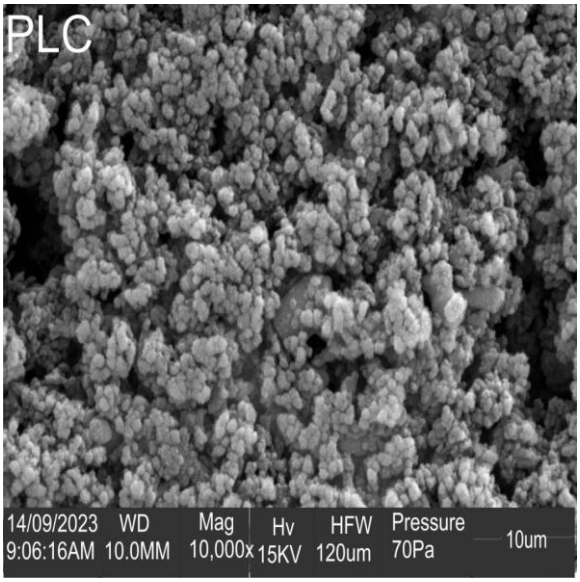

Figure 2a: SEM of Polycarbonate

b

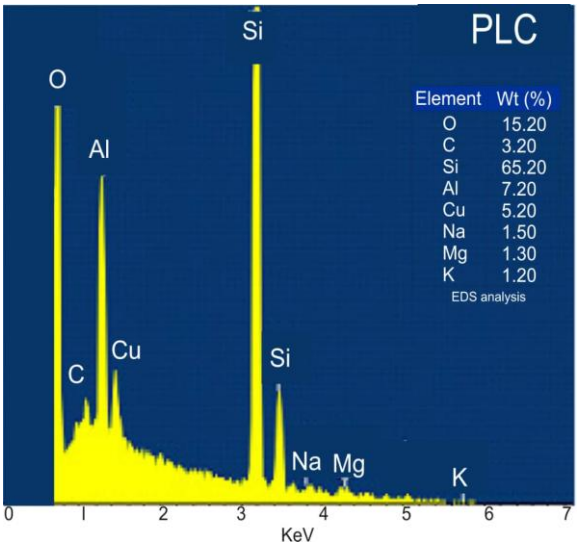

Figure 2b: EDX of Polycarbonate

3.3 Sieve Analysis on Aggregates

The particle size distribution for combined coarse aggregate, fine aggregate and mineral filler is shown in Figure 3. The results obtained satisfied the upper limit and lower limit boundary condition as specified by FMWH (2016). The proportioning was done to determine the volume of each aggregate by weight of the entire hot mix asphalt. Particle size distribution is important because they aggregates are the major determining factors in the density and interlocking ability of the mixture. Aggregate serve as the skeleton of hot mix asphalt and distributes stresses from wheel loads. Aggregate gradation also imparts on the finishes of the flexible pavement, i.e., the smoothness or roughness of road surfaces.

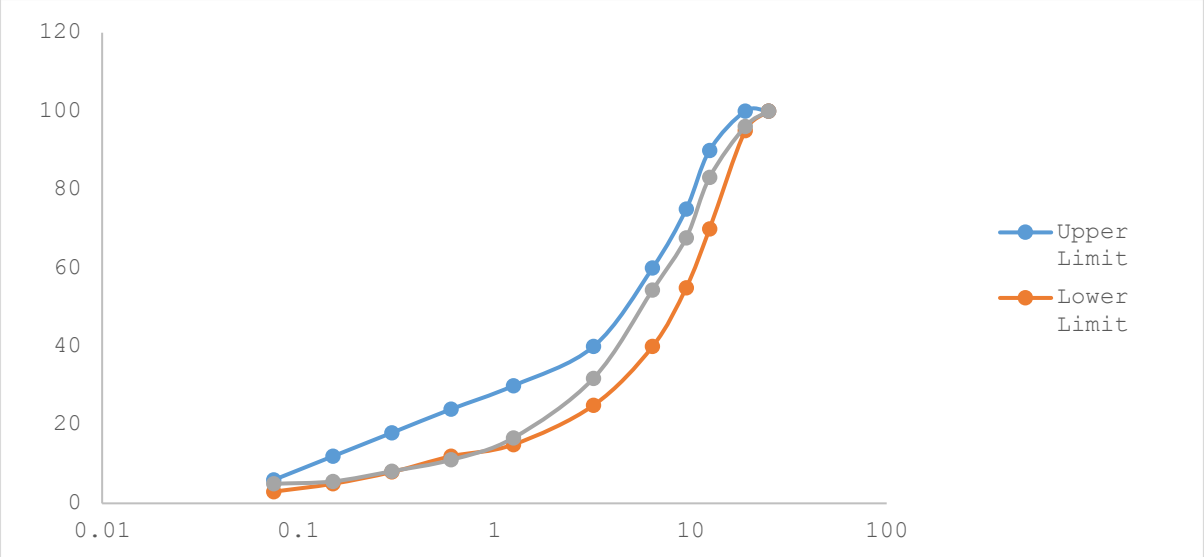

Figure 3: Particle size distribution

3.3.1 Marshall Stability

Figure 4 illustrates the variation in Marshall stability with bitumen content and polycarbonate addition. The stability values increased by an average of 8% when the bitumen content rose from 6% to 6.5% across all polycarbonate replacement levels. However, a notable 18% decrease occurred at 7% bitumen content, followed by a 7% recovery when the bitumen content was further increased to 7.5% across all polycarbonate content. The highest Marshall stability of 5.59 kN was achieved at 6.5% bitumen content with 2.5% polycarbonate addition. This represents a 20% improvement over the maximum stability of 4.67 kN recorded at the same bitumen content without polycarbonate. Higher stability values signify improved resistance to rutting and shoving (Awan, *et al*., 2022). All mixtures satisfied the Federal Ministry of Works and Housing (FMWH, 2016) minimum requirement of 3.5 kN. A similar trend was reported by Ibedu and Murana (2024).

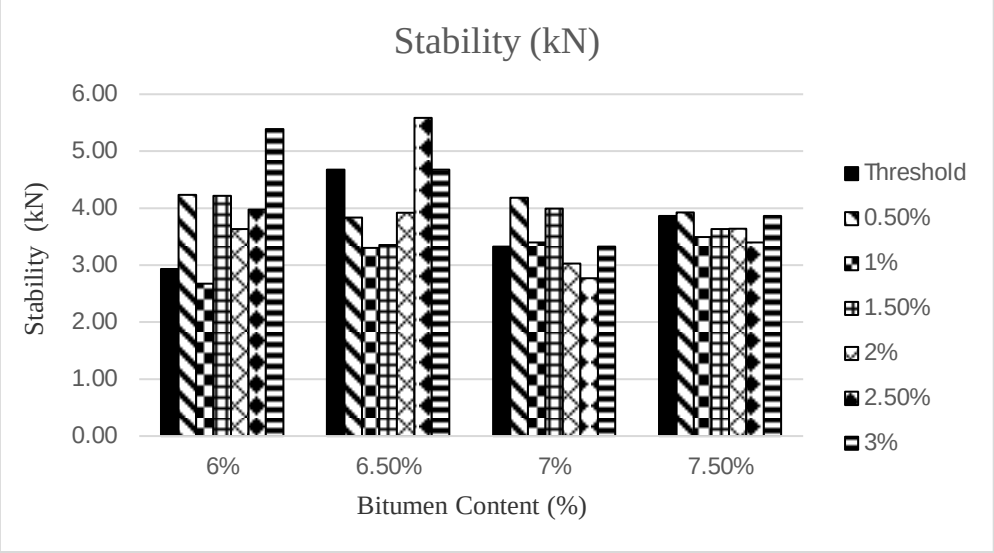

Figure 4: Variation of Stability with Polycarbonate Content

3.3.2 Marshall Flow

Figure 5 presents the variation in Marshall flow value with bitumen content and polycarbonate addition. Marshall flow measures the elasticity and plasticity of the asphaltic mixture. The flow values obtained ranged from 2.47 mm to 5.5 mm. The minimum flow of 2.47mm was observed at 6.5 bitumen

content and threshold polycarbonate content while the maximum Marshall flow was observed at 6% bitumen and 3% polycarbonate content. All mixtures satisfied the Federal Ministry of Works and Housing (FMWH, 2016) specification for base course, which requires flow values between 2 mm and 6 mm. However, the observed increase in flow with higher bitumen content and polycarbonate addition indicates greater plasticity of the mixture, implying an increased susceptibility to permanent deformation under traffic loading.

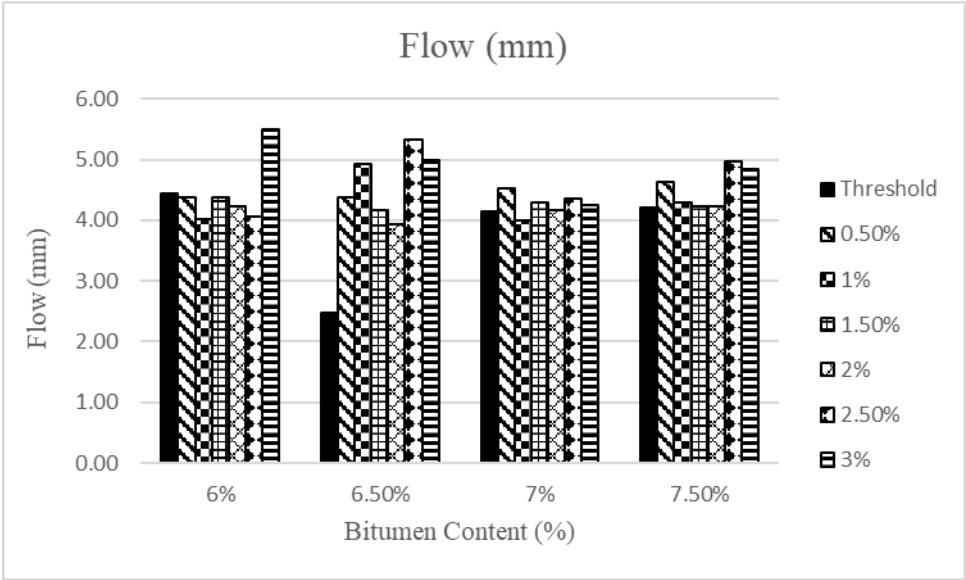

Figure 5: Variation of Flow with Polycarbonate Content

3.3.3 Unit Weight

Figure 6 shows the variation in unit weight (bulk density) of the asphalt mixtures with bitumen content and polycarbonate addition. Volumetric properties of asphalt concrete are strongly influenced by unit weight, which in turn significantly affects the overall durability of the pavement (Murana *et al*., 2023). As shown in Figure 6, at 6% bitumen content, the unit weight decreased with increasing polycarbonate content relative to the control mixture. The decrease may be attributed to inadequate chemical bonding between the polycarbonate waste plastic and the bitumen matrix particularly at 6% bitumen content which likely resulted in the formation of large voids within the mixture after compaction. In contrast, at higher bitumen contents (6.5%, 7%, and 7.5%), the unit weight increased progressively with higher polycarbonate levels. The increase can be attributed to the elevated viscosity and improved coating efficacy of the bitumen influenced by polycarbonate waste plastic, which facilitates better lubrication and rearrangement of aggregate particles, thereby more effectively filling inter particle voids.

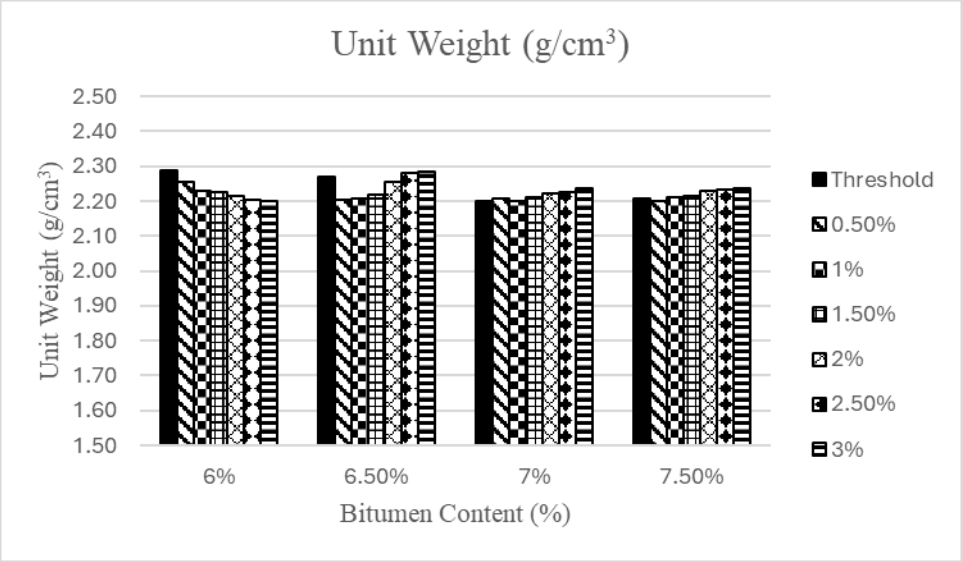

Figure 6: Variation of Unit Weight with Polycarbonate Content

3.3.4 Voids in Mineral Aggregate (VMA)

Figure 7 presents the variation in Voids in Mineral Aggregate (VMA) with bitumen content and polycarbonate addition. The results showed that VMA generally increased with increasing polycarbonate content. This trend is attributed to the sponge-like structure of the polycarbonate particles, which were not adequately coated by the bitumen, thereby creating additional voids within the mix and reducing inter-particle bonding.

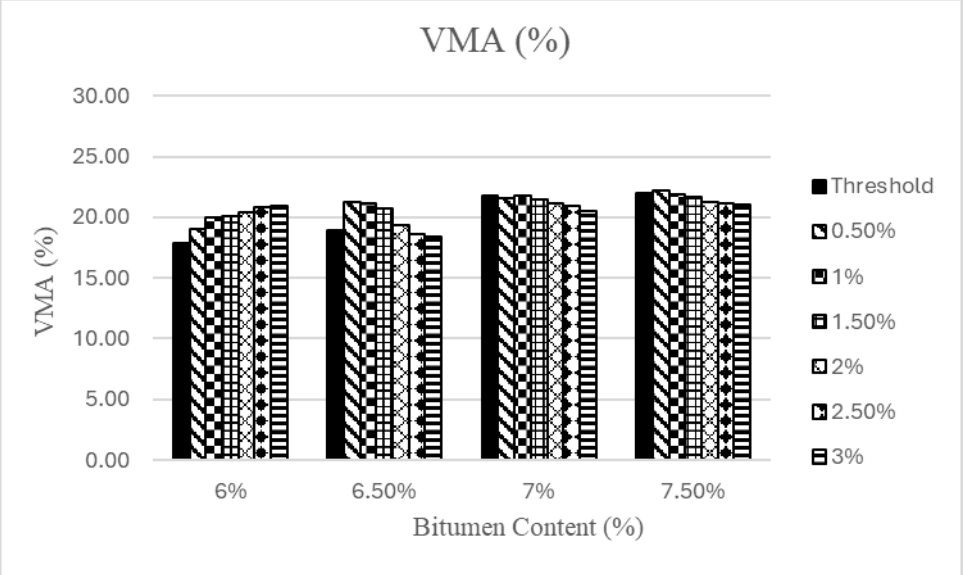

Figure 7: Variation of VMA with Polycarbonate Content

3.3.5 Voids in Total Mixture (Pa)

Figure 8 shows the variation in voids in the total mixture (Pa) with bitumen content and polycarbonate addition. The voids in the total mixture are directly related to the voids in mineral aggregate (VMA). All tested mixtures achieved Pa values within the Federal Ministry of Works and Housing (FMWH, 2016) acceptable range of 3% to 8%. Maintaining an adequate level of air voids is critical for durable asphalt performance. Excessive voids (due to insufficient bitumen to coat the

aggregates) can lead to premature cracking and moisture damage, while insufficient voids may result in rutting and bleeding under traffic loading.

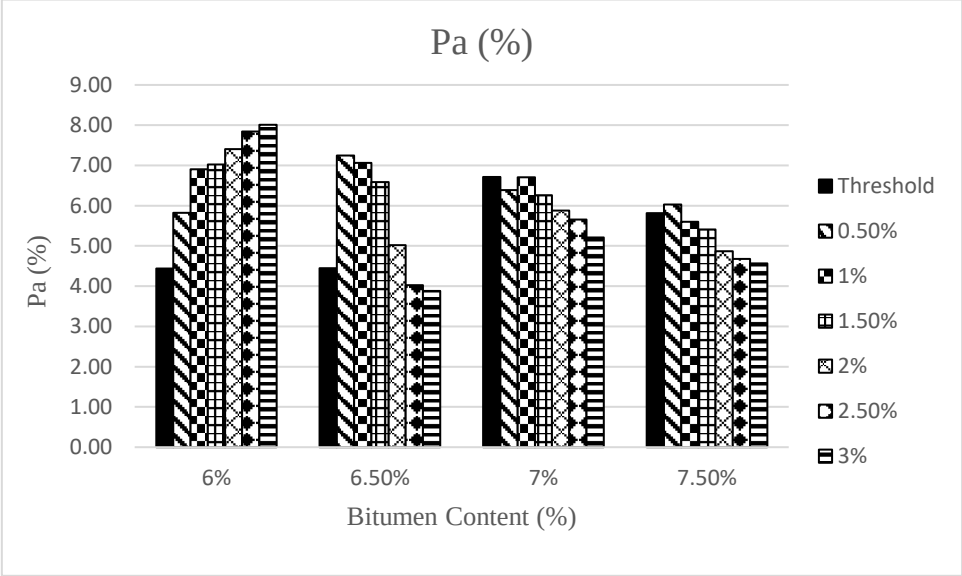

Figure 8: Variation of Pa with Polycarbonate Content

3.3.6 Voids Filled with Bitumen (VFB)

Figure 9 illustrates the variation in voids filled with bitumen (VFB) with changes in bitumen content and polycarbonate addition. As expected, VFB is inversely related to the voids in the total mixture (Pa). At 6% bitumen content, VFB generally decreased with increasing polycarbonate content compared to the control mixture. In contrast, at higher bitumen contents (6.5%, 7%, and 7.5%), VFB increased with higher polycarbonate replacement levels. This indicates that sufficient bitumen was available to effectively coat and bind the aggregates, thereby reducing the air voids in the mixture. Notably, the mixture containing 6 - 7.5% bitumen content and 0.5 – 1.5% polycarbonate content satisfied the requirement of 65 – 72% VFB range for base course compacted asphaltic concrete as stipulated by the Federal Ministry of Works and Housing (FMWH, 2016).

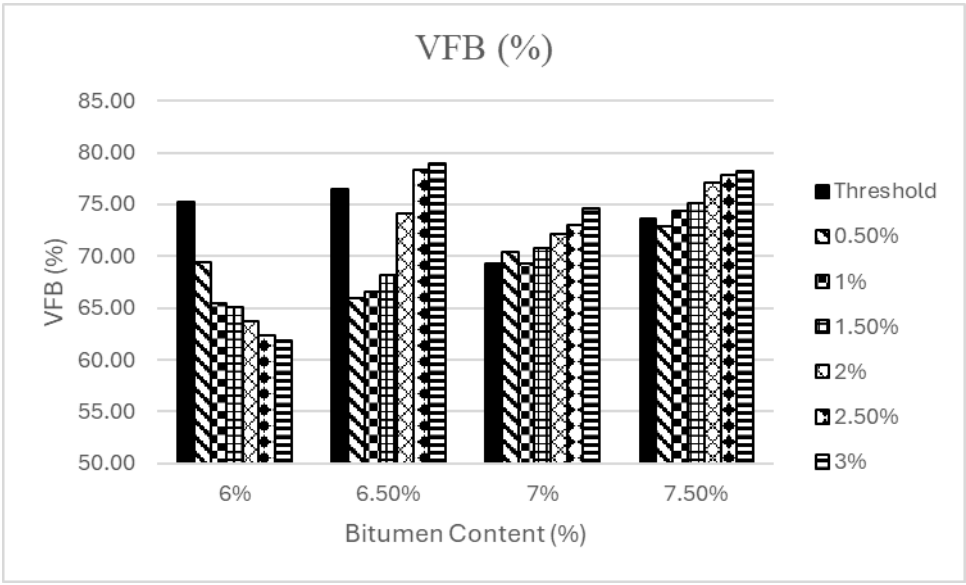

Figure 9: Variation of VFB with Polycarbonate Content

4. CONCLUSION

Based on the results of this study, the following conclusions can be drawn:

i. FTIR analysis of the polycarbonate revealed the presence of key functional groups, including methyl aromatic, anhydride, amine, carboxylic, aromatic amine, carbonyl, and alkene groups, confirming its polymeric nature

ii. The incorporation of polycarbonate into hot mix asphalt improved the mechanical properties (Marshall stability) by up to 20% at 6.5% bitumen content and 2.5% polycarbonate content, compared to the threshold mixture. The performance of polycarbonate as an admixture in Marshall stability of asphalt concrete meets and, in some cases, exceeds the requirements of 3.5kN stipulated by the Federal Ministry of Works and Housing (FMWH, 2016). Similarly, the Marshall flow values satisfied 2 - 6mm requirement with optimum 5.5mm at 6% bitumen content and 3% polycarbonate content. Furthermore, the results of unit weight, voids in mineral aggregate (VMA), total voids in mixture (Pa) and voids filled with bitumen (VFB) indicated improvement. These results showed that polycarbonate waste enhances both mechanical and volumetric properties of asphalt concrete.

ABSTRACT

Lead (Pb) contamination of soil is a persistent environmental problem because Pb is non-biodegradable, can remain in soil for long periods, and may adversely affect soil quality, vegetation, water resources and human health. This study evaluated the effects of Pb contamination on growth characteristics and the phytoremediation potential of sunflower (Helianthus annuus L.), common dandelion (Taraxacum officinale) and Jatropha (Jatropha curcas L.) under controlled pot conditions at the Institute for Agricultural Research, Ahmadu Bello University, Samaru, Zaria. Topsoil (0–20 cm) was collected, prepared and contaminated with Pb under controlled laboratory conditions. Three kilograms of prepared soil were placed in each pot, seedlings were established, soil moisture was maintained at approximately 65% field capacity, and plants were harvested after 60 days. Plant growth, residual soil Pb, Pb accumulation in roots, stems and leaves, and comparative phytoremediation indicators were assessed. Soil and plant samples were digested and analysed using atomic absorption spectrophotometry. Growth observations were summarized descriptively because seedlings within a pot are not independent experimental replicates. Jatropha recorded the lowest residual soil Pb concentration (82 mg/kg), the highest summed tissue Pb concentration (2,308 mg/kg), and the highest calculated soil Pb reduction (90.4%). Dandelion and sunflower showed calculated reductions of 65.6% and 64.5%, respectively. The highest translocation factors were observed for sunflower (1.84) and dandelion (1.82), compared with Jatropha (1.53). The findings indicate species-specific differences in Pb accumulation and partitioning under the tested conditions; however, the observed soil Pb reductions should be interpreted as preliminary because each species × treatment combination was represented by a single pot. Replicated greenhouse and field-scale studies are required to confirm treatment effects and remediation performance.

Keywords: *lead contamination; phytoremediation; Jatropha; sunflower; dandelion; soil remediation; translocation factor*

1.0 INTRODUCTION

Lead (Pb) contamination of soil is a persistent environmental concern because Pb is non-biodegradable and can remain in soil for long periods, with implications for soil quality, vegetation, water resources and human health. Phytoremediation uses plants and associated biological processes to reduce contaminant concentrations or toxicity and is regarded as a potentially lower-cost complementary approach for contaminated sites (Ali et al., 2013; Zhang et al., 2024).

Pb uptake and translocation are influenced by soil pH, particle size, organic matter, cation exchange processes, root characteristics and rhizosphere interactions. Plants may respond to Pb stress through root retention, cell-wall binding, sequestration and antioxidant defence (Rahman et al., 2024). These processes can produce substantial differences among plant species in Pb accumulation and partitioning.

Sunflower has demonstrated Pb uptake and translocation potential under controlled soil exposure (Ngabra et al., 2024). Recent evidence also indicates that common dandelion can accumulate trace elements, including Pb, across different plant tissues and can exhibit strong accumulation characteristics (Vural, 2024). Jatropha has likewise shown potential for phytoremediation of metal-impacted soils, including Pb, particularly where soil amendments improve plant growth and biomass production (Lim et al., 2024).

Despite these advances, comparative evidence for sunflower, common dandelion and Jatropha evaluated under comparable controlled Pb exposure remains limited. Comparative screening is useful because remediation performance should be considered alongside plant growth, tissue accumulation and Pb partitioning. The present study therefore evaluates the three species under controlled pot conditions, with emphasis on observed soil Pb reduction, tissue accumulation, translocation and selected growth characteristics.

The aim of this study was to investigate the effects of soil Pb contamination on the growth characteristics and comparative phytoremediation potential of sunflower, common dandelion and Jatropha under controlled pot conditions. The specific objectives were to: (i) determine the observed growth responses of the three species under Pb exposure; and (ii) determine and compare observed soil Pb reduction, tissue accumulation and translocation characteristics.

2.0 MATERIALS AND METHODS

2.1 Experimental Design and Study Area

The study employed a controlled environmental pot experiment to compare the growth response and Pb-remediation indicators of sunflower (Helianthus annuus L.), common dandelion (Taraxacum officinale) and Jatropha (Jatropha curcas L.). The experiment was conducted at the Institute for Agricultural Research, Ahmadu Bello University, Samaru, Zaria, Kaduna State, Nigeria (approximately 11°11′N, 7°38′E; 686 m above sea level). Six plastic pots were used: one Pb-treated pot and one uncontaminated control pot for each species. Each pot contained 3.0 kg of soil. Three seedlings of each species were monitored within the corresponding pot for growth measurements. Because the three seedlings within a pot shared the same soil environment, they were treated as within-pot observations rather than independent pot-level replicates.

The experimental arrangement permits preliminary descriptive comparison of growth measurements but does not provide independent replication for treatment-level inference. Accordingly, soil Pb reduction, tissue Pb accumulation, the whole-plant Pb accumulation index and translocation factor were reported descriptively.

2.2 Experimental Materials

The experimental materials comprised topsoil, plastic pots, sunflower seeds/seedlings, dandelion and Jatropha seedlings, lead nitrate [$Pb(NO_3)_2$], deionized and distilled water, urea fertilizer, sieves and laboratory glassware. Major equipment included an electronic balance, oven, mortar and pestle, microwave digestion system, wet digester, pH meter, flame photometer, UV–Visible spectrophotometer and Zeenit 700P atomic absorption spectrophotometer (AAS).

2.3 Soil Preparation and Lead Contamination

Topsoil was collected from the 0–20 cm depth within the study area. Plant residues, stones and other debris were removed, after which the soil was air-dried, gently disaggregated and passed through a 2.0-mm nylon sieve. Soil description and classification procedures were consistent with standard soil-survey practice (U.S. Department of Agriculture, Natural Resources Conservation Service [USDA-NRCS], 2017). Selected soil properties included pH (7.57), organic matter (2.72%), total organic carbon (1.58%), available phosphorus (4.68 mg/kg), potassium (138 mg/kg), bulk density (1.25 g/cm^3) and sandy-loam texture.

Pb-treated soil was produced in the laboratory using the predetermined Pb-loading protocol and appropriate laboratory safety procedures. The measured initial Pb concentrations were 572 mg/kg for sunflower, 800 mg/kg for dandelion and 851 mg/kg for Jatropha. These measured values were used as the experimental starting concentrations for calculating percentage soil Pb reduction because

they represent the analytical baseline. Differences among starting concentrations indicate that the species-associated pots did not begin at identical measured Pb concentrations; consequently, cross-species comparisons of percentage reduction are preliminary rather than fully controlled treatment comparisons.

2.4 Plant Establishment and Experimental Management

Healthy and relatively uniform seedlings of sunflower, dandelion and Jatropha were established in their respective contaminated and control pots following soil equilibration. All pots were maintained under similar environmental conditions, with soil moisture maintained at approximately 65% of field capacity through regular watering. Where fertilizer was applied, the same quantity and procedure were used across treatments.

Plants were monitored throughout the experiment, and growth characteristics were recorded periodically. Plants were harvested after 60 days. At harvest, plant height, root length and fresh and dry biomass were determined. Plant tissues were separated into roots and shoots, with shoots further divided into stems and leaves where required.

2.5 Sample Preparation and Lead Analysis

Plant tissues were washed with tap water and deionized water, oven-dried to constant weight, ground using an agate mortar and pestle, and passed through a 0.25-mm nylon sieve. Post-experiment soil samples were air-dried and passed through a 2.0-mm sieve. Approximately 0.5 g of soil and 0.1000 g of dried plant material were subjected to acid digestion using the laboratory-established procedure, with the resulting digests diluted to known volumes with deionized water. The general analytical approach is consistent with established methods for heavy-metal determination in soils (Davidson, 2012). Lead concentrations were determined using a Zeenit 700P atomic absorption spectrophotometer after calibration with Pb standards. Reagent blanks and duplicate samples were included as quality-control measures.

Determination of Element Concentration

Element concentration was calculated using the following mass-balance conversion:

$$\mathbf{C_{element}\ (mg/kg) = [(C_s - C_\beta) \times V \times DF] / W} \quad (1)$$

where $C_{element}$ is the concentration of the element in the sample (mg/kg); C_s is the sample concentration obtained from the instrument (mg/L); C_β is the blank concentration (mg/L); V is the final extraction or digestion volume (mL); DF is the dilution factor; and W is the mass of sample analysed (g).

2.6 Evaluation of Phytoremediation Potential and Data Analysis

The comparative phytoremediation assessment used observed soil Pb reduction, Pb concentrations in roots, stems and leaves, a study-specific whole-plant Pb accumulation index, translocation factor (TF), and selected plant-growth observations. Microsoft Excel 2016 was used for data organization and calculations, while IBM SPSS Statistics Version 22 was used to organize the growth observations. Because there was only one pot per species × treatment combination, inferential tests based on seedlings within the same pot were not treated as independent treatment-level evidence. The growth results are therefore presented descriptively.

Observed soil Pb reduction was calculated as:

$$\mathbf{Soil\ Pb\ reduction\ (\%) = [(C_i - C\boldsymbol{f}) / C_i] \times 100} \quad (2)$$

where C_i is the measured initial soil Pb concentration (mg/kg) and $C\boldsymbol{f}$ is the final soil Pb concentration (mg/kg). This metric represents calculated concentration reduction and should not be interpreted as proof of plant-mediated Pb removal because leaching, redistribution and other mass-balance processes were not independently quantified.

Total Pb remaining in soil (mg) = final soil Pb concentration (mg/kg) × soil mass (kg).

A study-specific whole-plant Pb accumulation index was calculated as:

Whole-plant Pb accumulation index = (Root Pb + Stem Pb + Leaf Pb) / Initial soil Pb

(3)

The index is a comparative ratio developed for this dataset and should not be labelled as a conventional bioaccumulation factor (BCF) because the numerator is a summed tissue concentration rather than a biomass-normalized plant concentration.

Translocation factor (TF) was calculated as:

$$\mathbf{TF = (Stem\ Pb + Leaf\ Pb) / Root\ Pb}$$

(4)

A TF greater than 1 indicates that the combined stem and leaf Pb concentration exceeded the root Pb concentration under the calculation used. Data were compared descriptively among species and treatments.

3.0 RESULTS AND DISCUSSION

3.1 Soil Properties and Lead Loading

The experimental soil had a pH of 7.57, indicating a slightly alkaline reaction. Organic matter (2.72%) and total organic carbon (1.58%) were moderate, while available phosphorus (4.68 mg/kg) was low. Exchangeable potassium was 138 mg/kg, calcium 7.40 mg/kg, sodium 184 mg/kg and magnesium 2.00 mg/kg. Bulk density was 1.25 g/cm³ and total porosity was 52.8%. The particle-size distribution of 62% sand, 28% silt and 10% clay classified the soil as sandy loam. Soil pH, texture and organic matter can influence Pb retention, mobility and plant availability (Rahman et al., 2024; Zhang et al., 2024).

Table 1: Baseline physicochemical properties of the experimental soil.

Parameter	Value	Unit	Interpretation
Soil pH	7.57	—	Slightly alkaline
Organic matter	2.72	%	Moderate
Total organic carbon	1.58	%	Moderate
Available phosphorus	4.68	mg/kg	Low
Exchangeable K	138	mg/kg	Moderate
Exchangeable Ca	7.40	mg/kg	Very low
Exchangeable Na	184	mg/kg	High
Exchangeable Mg	2.00	mg/kg	Low
Bulk density	1.25	g/cm³	Good
Total porosity	52.8	%	High
Textural class	Sandy loam	62% sand; 28% silt; 10% clay	Sandy loam

Source: Researcher fieldwork (2026); soil-description framework informed by USDA-NRCS (2017). Available phosphorus determination was based on the reported laboratory procedure and the Olsen method (Olsen et al., 1954).

3.2 Residual Soil Pb and Plant Uptake

Measured baseline concentrations differed among the species-associated pots, with initial soil Pb of 572 mg/kg for sunflower, 800 mg/kg for dandelion and 851 mg/kg for Jatropha. After 60 days, final soil Pb concentrations were 203, 275 and 82 mg/kg, respectively. Jatropha also had the highest summed tissue Pb concentration (root + stem + leaf = 2,308 mg/kg), followed by dandelion (1,576 mg/kg) and sunflower (1,108 mg/kg). These results indicate strong species-specific differences in tissue Pb accumulation under the tested conditions, but the lack of independent pot replication prevents a statistical claim that species caused the observed differences.

Table 2: Initial and final soil Pb concentrations and Pb accumulation in plant tissues.

Species	Initial soil Pb (mg/kg)	Final soil Pb (mg/kg)	Root Pb (mg/kg)	Stem Pb (mg/kg)	Leaf Pb (mg/kg)	Summed tissue Pb (mg/kg)
Sunflower	572	203	390	388	330	1,108
Dandelion	800	275	558	465	553	1,576
Jatropha	851	82	913	800	595	2,308

3.3 Calculated Soil Pb Reduction

Using the measured initial and final concentrations, the calculated soil Pb reductions were 64.5% for sunflower, 65.6% for dandelion and 90.4% for Jatropha. Jatropha therefore had the largest observed concentration reduction. However, because initial concentrations differed and only one pot represented each species × treatment combination, the ranking should be interpreted as a preliminary screening result rather than definitive evidence of superior phytoremediation efficiency.

Table 3: Calculated soil Pb reduction after 60 days.

Species	Initial Pb (mg/kg)	Final Pb (mg/kg)	Calculated reduction (%)	Descriptive rank
Jatropha	851	82	90.4	1
Dandelion	800	275	65.6	2
Sunflower	572	203	64.5	3

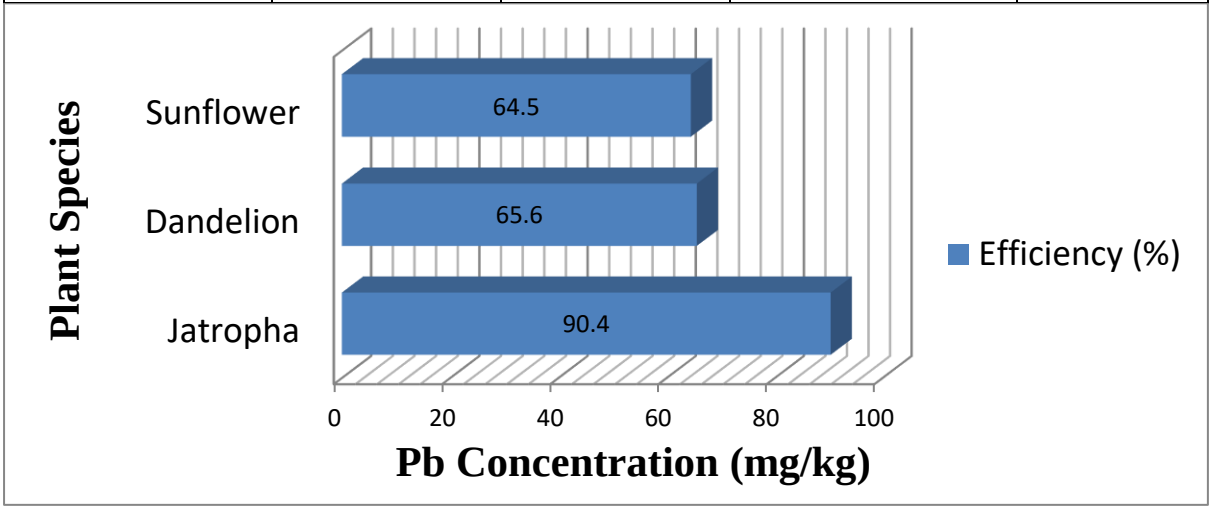

Figure 1: Calculated percentage reduction in soil Pb concentration after 60 days.

3.4 Whole-Plant Pb Accumulation Index

The whole-plant Pb accumulation index was 1.94 for sunflower, 1.97 for dandelion and 2.71 for Jatropha. Jatropha therefore recorded the highest comparative tissue-to-initial-soil ratio. The result is consistent with the high tissue Pb concentrations observed in Jatropha and with recent evidence that Jatropha can accumulate Pb and other metals under contaminated-soil conditions (Lim et al., 2024).

Table 4: Study-specific whole-plant Pb accumulation index.

Species	Root Pb	Stem Pb	Leaf Pb	Summed tissue Pb	Initial soil Pb	Accumulation index
Sunflower	390	388	330	1,108	572	1.94
Dandelion	558	465	553	1,576	800	1.97
Jatropha	913	800	595	2,308	851	2.71

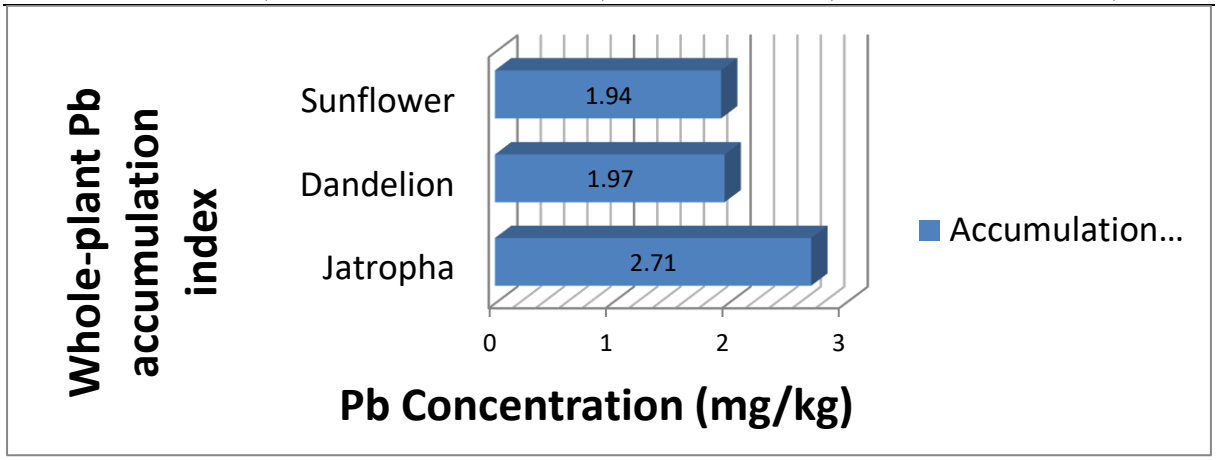

Figure 2: Whole-plant Pb accumulation index.

3.5 Translocation Factor of Lead

Sunflower and dandelion recorded higher TF values (1.84 and 1.82, respectively) than Jatropha (1.53). This indicates relatively greater partitioning of the measured Pb concentration into stem and leaf tissues for sunflower and dandelion under the calculation used. The finding is broadly consistent with evidence that plant species differ in Pb partitioning among roots and above-ground tissues (Rahman et al., 2024; Vural, 2024).

Table 5: Translocation factor (TF) of Pb.

Species	Root Pb (mg/kg)	Stem Pb (mg/kg)	Leaf Pb (mg/kg)	TF = (Stem + Leaf)/Root
Sunflower	390	388	330	1.84
Dandelion	558	465	553	1.82
Jatropha	913	800	595	1.53

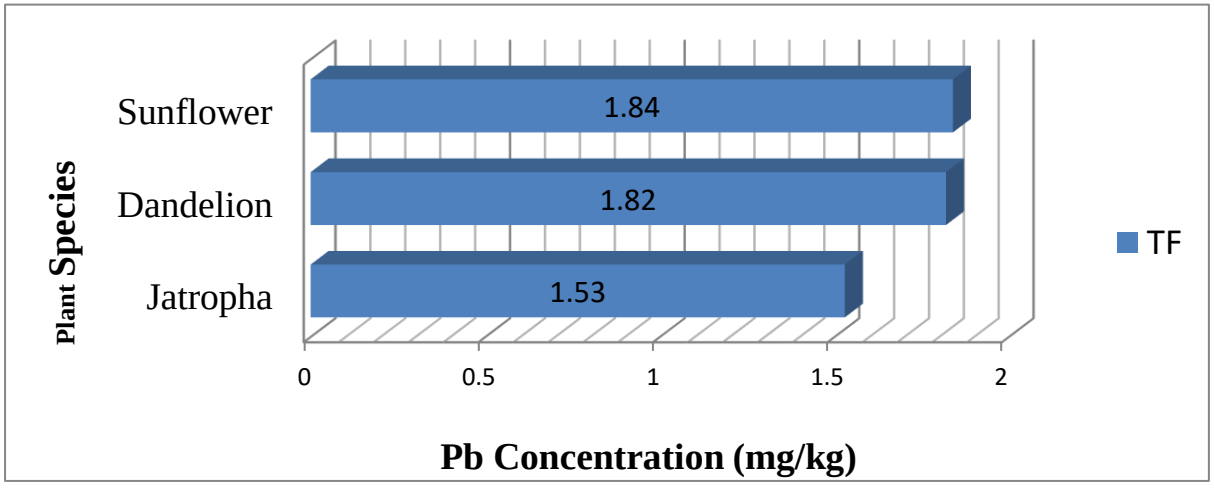

Figure 3: Translocation factor of Pb.

3.6 Growth Characteristics under Pb Stress

The recorded height observations were similar across species, with values generally ranging from 23 to 27 cm. Sunflower recorded 24–25 cm under the contaminated treatment and 23–25 cm under the control treatment; dandelion recorded 24–24 cm and 24–25 cm, respectively; while Jatropha recorded 25–25 cm and 25–27 cm, respectively. Leaf counts showed a wider numerical range, with Jatropha recording fewer leaves under the contaminated treatment than sunflower and dandelion. Because only one pot was used for each species × treatment combination, the apparent differences among seedlings cannot be treated as independent replicated treatment effects. The growth data are therefore presented as descriptive observations rather than inferential statistical evidence.

Table 6: Descriptive growth observations recorded during the experiment.

Species	Contaminated height M1 (cm)	Contaminated height M2 (cm)	Control height M1 (cm)	Control height M2 (cm)	Contaminated leaves M1	Contaminated leaves M2	Control leaves M1	Control leaves M2
Sunflower	24	25	23	25	22	20	22	23
Dandelion	24	24	24	25	20	18	21	22
Jatropha	25	25	25	27	17	15	18	20

M1 = first measurement occasion; M2 = second measurement occasion.

3.7 Interpretation and Comparison with Related Studies

Jatropha showed the strongest observed soil Pb concentration reduction, while sunflower and dandelion showed higher TF values. Several mechanisms may contribute to species differences, including root characteristics, soil pH, organic matter, rhizosphere interactions, cell-wall binding and physiological tolerance (Rahman et al., 2024; Zhang et al., 2024). These mechanisms were not directly measured in the present experiment and therefore should be regarded as plausible explanations rather than demonstrated causal mechanisms.

The strong tissue accumulation observed in Jatropha is compatible with recent work showing that J. curcas can accumulate Pb and other metals in contaminated substrates and that improved soil conditions can increase plant biomass and metal removal (Lim et al., 2024). Sunflower has also been reported to accumulate Pb under controlled soil-spiking conditions (Ngabra et al., 2024), while Vural (2024) documented substantial trace-element accumulation by T. officinale, including Pb, across plant tissues. The present results therefore support the value of these species as candidates for further comparative screening, but they do not establish field-scale remediation efficiency.

The calculated reductions of 64.5%, 65.6% and 90.4% are arithmetically consistent with the measured initial and final soil concentrations. Nevertheless, a reduction in measured soil concentration is not equivalent to a verified mass of Pb removed from the experimental system. Future studies should include replicated pots, randomized treatment allocation, identical measured starting concentrations, complete soil and plant Pb mass balances, and measurements of Pb bioavailability and soil Pb fractions.

4.0 CONCLUSION

Under the controlled conditions tested, Jatropha recorded the lowest final soil Pb concentration (82 mg/kg), the highest calculated soil Pb reduction (90.4%) and the highest study-specific whole-plant Pb accumulation index (2.71). Sunflower and dandelion recorded higher translocation factors (1.84 and 1.82) than Jatropha (1.53), indicating greater relative partitioning of measured Pb into above-ground tissues. Growth observations showed numerical differences among species, but the experimental design did not provide independent pot-level replication for inferential testing. Overall, the findings identify Jatropha as the strongest preliminary candidate for further Pb-phytoremediation evaluation under the tested conditions, while emphasizing that replicated greenhouse and field studies are required before definitive species-performance claims are made.

4.1 RECOMMENDATIONS

1. Jatropha should be prioritized for replicated greenhouse and field-scale trials where the objective is soil Pb reduction and plant accumulation, while treating the present ranking as preliminary.
2. Sunflower and dandelion should be investigated as complementary species where above-ground Pb translocation and biomass harvesting are important remediation considerations.
3. Future experiments should use independent replicated pots, randomized treatment allocation, identical measured starting Pb concentrations, longer exposure periods, direct measurements of Pb bioavailability and soil Pb fractions, and complete plant–soil Pb mass balances.
4. Pb-contaminated plant material should be handled, transported and disposed of in accordance with applicable institutional hazardous-material procedures, and future field studies should assess soil

heterogeneity, moisture variation, microbial interactions, mixed-metal contamination and seasonal effects.

ABSTRACT

Groundwater is the principal source of domestic and agricultural water supply across tropical Africa, yet its sustainable management is constrained by a poor understanding of recharge processes. This study evaluates groundwater recharge dynamics in the Bida Basin, north-central Nigeria, using the New Bussa sub-basin (Borgu Local Government Area) as a representative catchment. Twenty-five years (2000–2025) of meteorological data were integrated with laboratory-derived soil properties, a Python-based Soil Moisture Balance (SMB) model, and the Hydrologic Engineering Center–Hydrologic Modelling System (HEC-HMS). In the absence of an independently gauged streamflow station, HEC-HMS parameter calibration (Curve Number 40–85, lag time 100–323 min, imperviousness 10–25%) was executed against SMB-derived synthetic run-off to evaluate inter-model consistency rather than field-validated predictive accuracy. The best-fit inter-model agreement yielded a Nash–Sutcliffe Efficiency (NSE) of 0.52 and R^2 of 0.797 at CN = 40, TLag 100min and imperviousness 10% Over the 2020–2024 simulation period, mean annual rainfall was 1,199.32 mm, of which 273.96 mm (22.8%) was converted to run-off, while simulated groundwater recharge averaged 31.96 mm/yr (2.7%). Groundwater recharge was zero during 2021–2024 (0.00 mm/yr) and occurred exclusively during the exceptionally wet year of 2020 (159.81 mm). Sensitivity analysis indicates this threshold-controlled recharge response is highly governed by the specified root-zone depth (Zr=0.9 m) and depletion factor (ρ=0.2–0.7). Soil was classified as sandy loam with moderate bulk density (1.46–1.61 g/cm³) and available water capacity (10.2–12.2%). These findings depict a runoff-dominated hydrological regime where recharge is episodic, serving as a baseline hypothesis for comparable sub-humid tropical savannah catchments across the Middle Niger region.

Keywords: *Groundwater Recharge; Soil Moisture Balance Model; HEC-HMS; Bida Basin; Nash–Sutcliffe Efficiency; New Bussa*

1. INTRODUCTION

Groundwater recharge is the process by which water moves downward from the Earth's surface to the water table, replenishing the aquifer. This process is a critical component of sustainable water resources management (Shaikh and Birajdar, 2024). Nearly half of the world's population relies on groundwater for domestic and agricultural purposes (Scanlon et al., 2023), while across sub-Saharan Africa, it serves as the primary supply for rural and urban livelihoods (Ogunbode et al., 2024). Recharge rates are governed by interacting climatic, pedological, land-surface, and hydrogeological factors (Müller, 2023).

Quantifying recharge remains challenging in data-scarce tropical environments. While techniques such as the Water Table Fluctuation (WTF) method calculate recharge based on water-table rises and specific yield (Sy), their application is severely constrained by short-term temporal validity, high sensitivity to Sy uncertainties, and a total reliance on dense piezometric monitoring networks (Healy & Cook, 2002; Rushton et al., 2006). In un-gauged or sparsely monitored catchments where continuous groundwater-level observations are unavailable, physical numerical models offer a viable alternative.

In Nigeria's Bida Basin, rising agricultural and industrial abstractions have intensified pressure on subsurface reservoirs (Olaleye et al., 2025; Cuthbert et al., 2023). To address these observational data gaps, this study couples a Python-based Soil Moisture Balance (SMB) model

with HEC-HMS to simulate continuous root-zone moisture flux and catchment run-off in the New Bussa sub-basin.

2. METHODOLOGY

2.1 Study Area

New Bussa is located at about 9.88° N, 4.51° E in the Guinea savanna zone of Borgu LGA, Niger State, at an elevation of 180–200 m. The town was resettled due to the creation of Kainji Lake from the River Niger. It lies within the Niger River Basin where the Niger and Kaduna rivers meet, featuring rolling land and various types of land cover. The climate is tropical savanna, with a wet season from May to September and a dry season from October to April. Figures 2.1 and 2.2 show the Bida Basin and Study Area (New Bussa) in Borgu LGA, located within the Bida Basin.

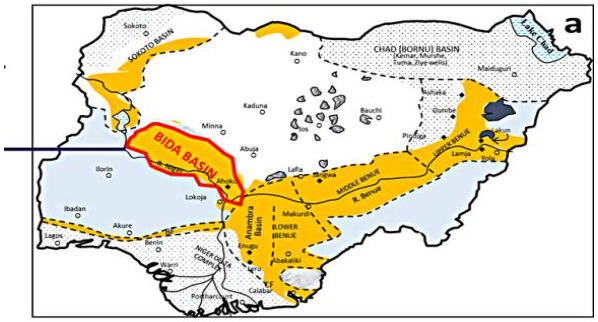

Figure 2.1: Map of Nigeria Showing the Bida Basin in Red.

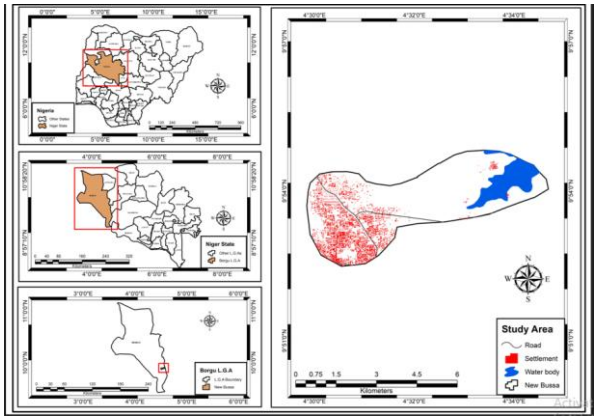

Figure 2.2: Map of Nigeria Showing the Study Area (New Bussa).

2.2 Data Acquisition

Daily rainfall and temperature data (maximum and minimum) from 2000 to 2025 were collected from the Nigerian Meteorological Agency. Reference evapotranspiration was calculated using the Hargreaves method. Soil samples from the study area were analysed to determine soil properties: bulk density, Field capacity (FC), and wilting point (WP) in the laboratory. The SMB model was run continuously from 2000 to 2025, but the final analysis was focused on 2020 to 2024 for calibration relevance.

2.3 Soil Moisture Balance Model

A Python implementation of the SMBM computed the daily water balance of the root zone (maximum rooting depth Zr = 0.9 m). Total and readily available water were computed as $TAW = (FC - WP) \times 1000 \times Zr$ and $RAW = TAW \times \rho$, where ρ is a depletion factor of 0.2–0.7 (Allen et al., 1998). Daily soil-moisture deficit (SMD) was updated as $SMD' = SMDprev + AE - AWE + NSS$, where AE is actual evapotranspiration, AWE is available water for evaporation, and NSS is near-surface storage, computed as $NSS = (AWE - AE) \times 0.45$ (Rushton, 2005). Recharge was generated only once SMD fell to zero or below.

2.4 HEC-HMS Model Setup, Parameter Scope and Calibration

The HEC-HMS model was parameterized using a digital elevation model (DEM) for basin delineation. Loss mechanisms were calculated using the SCS Curve Number (CN) method, and surface run-off transformation was modeled via the SCS Unit Hydrograph method. Baseflow processes were set to 'None' because observed continuous baseflow data were unavailable, restricting calibration parameters to CN, lag time (Tlag), and percentage imperviousness.

Because no operational hydrometric gauging station exists within the sub-basin catchment, HEC-HMS was calibrated against synthetic daily run-off generated by the SMB model for July 2024. Consequently, performance statistics, Nash–Sutcliffe Efficiency (NSE) and Coefficient of Determination (R^2), measure internal inter-model consistency rather than true field predictive skill.

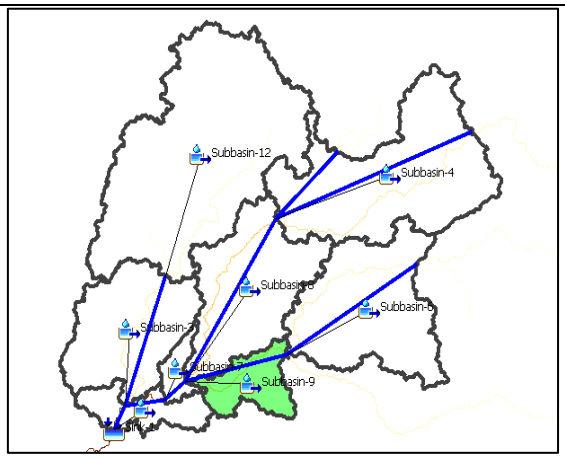

Figure 2.4: HEC-HMS Basin Model Schematic showing sub-basin delineation for the New Bussa catchment.

3. RESULTS AND DISCUSSION

3.1 Climatic Characteristics of the Basin

The Climatic analysis reveals that New Bussa recorded a mean annual rainfall of 1,100mm, with a mean annual temperature of 28.7 °C and PET exceeding 1500mm/yr, implying greater atmospheric water demand and, by extension, lower recharge potential, a pattern broadly consistent with climatic controls documented elsewhere in Nigeria (Shuaibu, 2025).

Table 3.1: Mean Climatic Analysis of New Bussa Area

Location	Mean Annual Rainfall (mm)	Mean Temp. (°C)	Wet-Season Rainfall (mm)	Dry-Season Rainfall (mm)	Relative Humidity (%)	PET (mm/yr)
New Bussa	**1,100**	**28.7**	**970**	**130**	**60**	**1,560**

3.2 Soil Physical Properties and Infiltration Potential

Analysis of New Bussa's soil samples reveals a Sandy Loam texture with a bulk density of 1.59 g/cm³. This texture class is highly typical of sandy loam, which favours moderate to rapid drainage (Niger Foods GIS, 2024). A bulk density of 1.59 g/cm³ aligns with regional soil studies in Niger State, where sand-dominated agricultural soils frequently exhibit densities ranging between 1.46 g/cm³ and 1.61 g/cm³ depending on crop cultivation and vegetative cover (Muhammad et al., 2025). Field capacity of 18.41% was obtained, and a wilting point of 8.2%, resulting in an available water capacity of 10.21% and Ksat of 11.1mm/yr respectively.

Table 3.2: Simulated Soil Properties of the New Bussa Area

LGA	Texture Class	Bulk Density (g/cm³)	Field Capacity (%)	Wilting Point (%)	AWC = FC−WP (%)	Ksat (mm/hr)
New Bussa	Sandy Loam	**1.59**	**18.41**	**8.2**	**10.21**	**11.1**

3.3 HEC-HMS Model Calibration

Six calibration trials were conducted using July 2024 daily data (Table 3.3). Trial 6 yielded the optimal inter-model fit with CN=40, Tlag=100 min, and 10% imperviousness, achieving an NSE of 0.52, an R^2 of 0.797, and an RMSE of 0.99.

A notable divergence was observed across trials between NSE and R^2 dynamics. For example, Trial 3 exhibited a high R^2 (0.87) alongside a poor NSE (0.14). This statistical behavior occurs because R^2 evaluates linear covariance regardless of systematic magnitude bias, whereas NSE heavily penalizes peak discharge offset errors and variance mismatches. Lowering the Curve Number to 40 in Trial 6 mitigated peak volume overestimations, aligning runoff volumes and optimizing NSE.

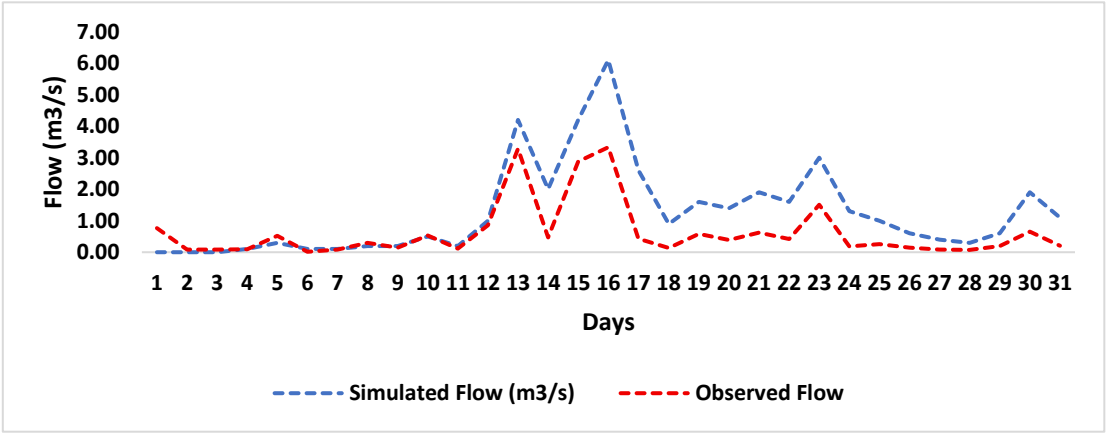

Figure 3.1: Comparison of measured flow (Python-Based Model) and simulated flow (HEC-HMS)

Table 3.3: HEC-HMS Calibration Trials (Curve Number, Lag Time and Imperviousness)

Trial	Curve Number	Imperviousness (%)	Lag Time (min)	NSE	R^2	RMSE
1	71	25	323.42	−1.83	0.42	1.34
2	75	20	250.81	−0.30	0.51	1.87
3	85	20	200.53	0.14	0.87	1.24
4	65	10	100.00	0.28	0.84	1.78
5	50	10	100.00	0.41	0.81	1.32
6	**40**	**10**	**100.00**	**0.52**	**0.797**	**0.99**

3.4 Annual Water Balance, 2020–2024

Over the five-year evaluation period (2020–2024), total precipitation reached 5,996.59 mm (Table 3.4). Mean annual runoff accounted for 273.96 mm/yr (22.8% of rainfall), whereas mean annual groundwater recharge was only 31.96 mm/yr (2.7%). Simulated recharge was zero (0.00 mm) for years (2021–2024) and occurred exclusively during 2020 (159.81 mm).

This zero-recharge phenomenon illustrates the rigid threshold control inherent to the root-zone moisture balance framework. Recharge is triggered only after accumulated evapotranspiration deficits are completely satisfied (SMD=0). Sensitivity testing confirms that assuming a deep rooting depth (Zr=0.9 m) increases overall soil storage capacity (TAW), requiring substantial cumulative wet-season rainfall (such as the 1,715.80 mm recorded in 2020) to break the threshold. While localized preferential flow through cracked regolith may cause minor real-world annual recharge, the model accurately reflects a regime where matrix percolation is highly episodic.

Table 3.4: Annual Rainfall, Runoff and Groundwater Recharge (2020–2024)

Year	Rainfall (mm)	Runoff (mm)	Groundwater Recharge (mm)
2020	1,715.80	482.28	159.81
2021	989.07	205.40	0
2022	1,281.44	267.60	0
2023	1,160.59	240.34	0
2024	849.69	174.20	0
Total	5,996.59	1,369.81	159.81

Table 3.5: Mean Annual Values of the Hydrological Parameters (2020–2024)

Parameter	Annual Average (mm)	Share of Rainfall (%)
Rainfall	1,199.32	100.0
Runoff	273.96	22.8
Groundwater Recharge	31.96	2.7

3.5 Synthesis and Methodological Limitations

The results highlight a runoff-dominated hydrological system where groundwater replenishment is minimal and episodic. However, key limitations must frame the interpretation of these findings:

1. Calibration Circularity: Calibrating HEC-HMS against SMB-derived runoff verifies conceptual alignment between models but does not substitute for field-observed streamflow validation.
2. Temporal Window: Calibrating across a single month (July 2024) restricts parameter robustness across varying multi-year antecedent moisture states.
3. Excluded Baseflow: Omitting subsurface baseflow mechanisms limits the model's capacity to simulate low-flow regimes accurately.

Consequently, the numerical estimates (e.g., 2.7% annual recharge fraction) should be interpreted as model-derived baseline hypotheses requiring empirical piezometric and tracer-based validation.

4. CONCLUSION

This study integrated SMB and HEC-HMS modelling to evaluate recharge dynamics in the New Bussa sub-basin. The hydrological regime is runoff-dominated (22.8% of rainfall), with groundwater recharge being episodic (2.7% long-term mean) and reliant on extreme rainfall events that satisfy root-zone storage capacity. Because conclusions derived from New Bussa cannot be directly extrapolated across the entire Middle Niger region without accounting for local hydrogeological heterogeneity, caution is advised in abstraction planning. Groundwater development strategies should be combined with rainwater harvesting and managed aquifer recharge schemes. Future research must prioritize establishing physical streamflow gauging and multi-year piezometric monitoring to eliminate model circularity.

ABSTRACT

This study assessed the enrichment and eutrophication response variables of phosphorus fractions in Alau Reservoir because of limited information on the contribution of individual phosphorus fractions, their seasonal variations and relationship with eutrophication risk. High levels of phosphorus enrichment continue to be a significant cause of eutrophication as it can stimulate algal growth, lead to an increase in organic matter and can decrease dissolved oxygen. Water samples were taken from two sampling points (SWA1 and SWA2) for six months, which included the late dry season, rainy season and post-rainy dry season. Orthophosphate, organic phosphorus, phosphate, total phosphorus, pH, dissolved oxygen, chlorophyll-a and turbidity were measured by standard laboratory methods. Descriptive statistics and principal component analysis were used to identify the distribution patterns of phosphorus and its association with eutrophication indicators. The results indicated that the mean orthophosphate concentration at SWA2 (0.0059 mg/L) was higher than SWA1 (0.0043 mg/L), while the mean organic phosphorus concentration at SWA2 (0.2308 mg/L) was higher than SWA1 (0.1633 mg/L). The mean soluble phosphorus concentration at SWA2 (0.9948 mg/L) was higher than SWA1 (0.9159 mg/L), and the mean total phosphorus concentration at SWA2 (1.1735 mg/L) was higher than SWA1 (1.0442 mg/L). The principal component analysis accounted for 77.57% and 87.29% of the total variation at SWA1 and SWA2, respectively, with higher nutrient-biological interactions at SWA2. The monthly variations revealed that September was closely associated with the response of phosphate and chlorophyll-a, suggesting periods of higher eutrophication pressure. The relationship between phosphorus fractions and chlorophyll-a and the inverse relationship with dissolved oxygen suggest an increasing eutrophication risk, especially at SWA2. The study suggests that the phosphorus fractions should be monitored continuously and that catchment management practices like modeling should be implemented to decrease the nutrient load to the reservoir.

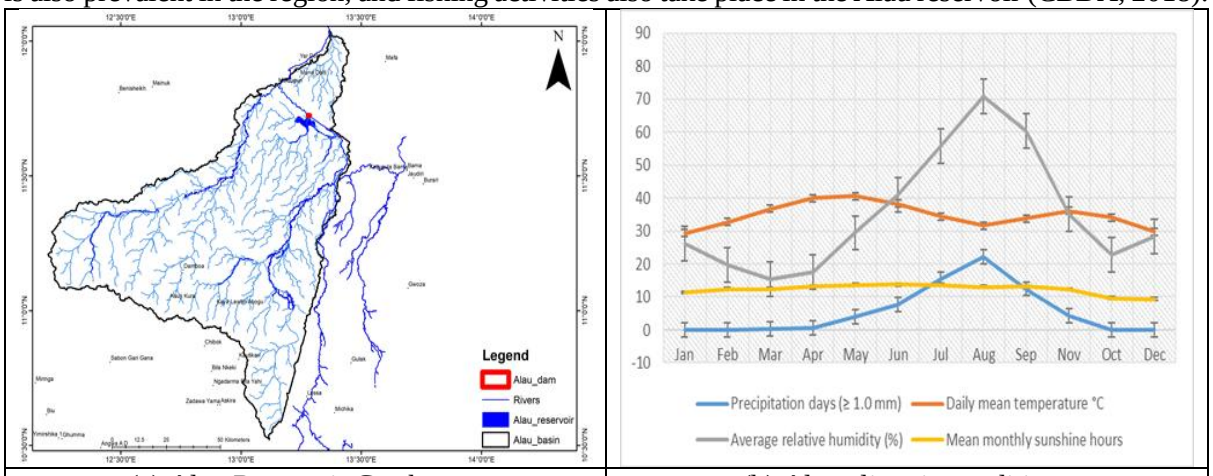
Keywords: *Chlorophyll-a; eutrophication; phosphorus enrichment and water quality*

1. INTRODUCTION

Freshwater reservoirs are important sources of water for domestic use, fisheries, irrigation, livestock, conservation of biodiversity and livelihoods, but their ability to provide these services is highly dependent on nutrient balance and ecological stability, which can only be achieved through water quality monitoring and management (Akinnawo, 2023). The reservoir water quality is often a combination of the effects of rainfall, erosion, agricultural runoff, domestic discharge, shoreline activities and internal sediment processes. These pressures may be more acute in tropical and semi-arid areas where seasonal rainfall may lead to a high concentration of nutrients in reservoirs, and dry-season evapouration and longer water residence time can result in an increase in dissolved substances (Fabian *et al.*,2023; Ahmed and Ibrahim, 2024). Eutrophication is one of the most significant types of freshwater degradation, as excess nutrient loading can lead to algal growth, decreased water clarity, increased organic matter decomposition, and decreased dissolved oxygen (Wurtsbaugh *et al.*, 2019). Phosphorus has particular importance in reservoir assessment because it often limits primary productivity in freshwater systems. Excessive phosphorus levels can lead to algal blooms, oxygen depletion,

degradation of fish habitat, and increased treatment costs for potable water supply (Ayoade & Aderogba, 2020; Fabian *et al.,* 2023; Usman *et al.,* 2025). Phosphorus, chlorophyll-a, transparency and dissolved oxygen have therefore been considered as related measures of nutrient pressure and ecological response in general eutrophication literature (Wurtsbaugh *et al.,* 2019; USEPA, 2000; Akinnawo, 2023).

Phosphorus exists in various forms such as organic and inorganic phosphorus, the inorganic phosphorus is made of orthophosphates, polyphosphates, which are usually found in natural and engineered systems (Uddin *et al.,* 2018). The organic phosphorus compounds are very diverse in nature, which includes phospholipids, nucleotides, and phosphoproteins (Ebuele, 2016; Brenden *et al.,* 2018). Agricultural runoff, domestic wastewater, soil erosion, shoreline activities and internal sediment release are sources of nutrients to reservoirs in Nigeria. The pressures may differ from one sampling point to another and from one month to another due to the changes in nutrient behaviour caused by inflow, rainfall, dry season concentration and biological uptake (Akin-Oriola, 2003; Usman *et al.,* 2025). A number of studies conducted on reservoirs in Nigeria have reported nutrient enrichment, phytoplankton response and seasonal water quality variation (Ayoade & Aderogba, 2020; Fabian *et al.,* 2023; Usman *et al.,* 2025). Phosphorus is vital in the growth and productivity of living organisms like algae and plants (Smith & Schindler, 2009; Han *et al.,* 2017). Nevertheless, Excess phosphorus in reservoirs encourages overgrowth of algae, especially the cyanobacteria (blue-green algae). Some cyanobacteria like Microcystis and Anabaena may form harmful toxins called cyanotoxins in water amphibians (Dodd and Sharpley, 2016; Paerl *et al.,* 2020). The cyanotoxins are harmful to a wide range of aquatic organisms, causing liver damage, neurological effects, and even fish, invertebrates, and other aquatic organisms dying after consuming the water, as well as harmful to domestic animals and human poisoning by consuming the water (Paerl *et al.,* 2020).



While Alau Reservoir has been studied with respect to general physico-chemical quality, raw water suitability, socio-economic pressure and pollution indicators, there is limited evidence that phosphorus compound enrichment is a direct driver of eutrophication risk. Previous research typically measures only phosphate and assesses water quality primarily by permissible-use criteria. They fail to adequately separate orthophosphate, organic phosphorus, phosphate and total phosphorus, and do not correlate these phosphorus fractions with chlorophyll-a, dissolved oxygen and turbidity. This leaves the question of whether the reservoir is undergoing isolated nutrient elevation or a coordinated phosphorus-driven eutrophication process. The aim of this study is to assess the phosphorus fractions and their relationships with the eutrophication response variables in the Alau Reservoir.

1. MATERIALS AND METHOD

2.1 Study Area

Alau village is located at latitude 11˚5′ N and longitude 13˚ 20′ E in the Konduga local government area of Borno State, 19 km southeast of Maiduguri in the Sahel savanna region of Nigeria. The River Ngadda, on which the Alau dam was constructed between 1984 and 1986 by the Chad Basin Development Authority (CBDA), is a major tributary of Lake Chad (CBDA, 1998). The River Ngadda originates from the confluence of the River Yedzram and River Gombole at the Sambisa Forest. The Alau reservoir has an estimated catchment area of 9,804.44 km² at 329 m above sea level, as shown in Figure 1 (a). It has a maximum depth of 9 m and an estimated surface area of 60 km². The reservoir serves as the primary source of surface water supply for Maiduguri Metropolis and to irrigates over 8,000 hectares of farmland within the catchment area (CBDA, 1998). The climate is Sahelian with three distinct seasons: the cool-dry season (October to March), the hot season (April to June), and the rainy season (July to September). The annual rainfall ranges from 560 to 600 mm. The cold (dry harmattan) season runs from November to March, when temperatures fall to about 20°C, and a dry, dusty wind blows from the Sahara Desert (CBDA, 2018). The area is fragile and highly susceptible to drought, with relative humidity of 16.25% in the dry seasons and 71.15% in the rainy seasons as shown in Figure 1 (b). Scattered settlements across the catchment area, ranging from small rural villages to larger towns. These settlements serve as centers for agricultural activities and residential areas for the local population. Agriculture is the main economic activity in Alau village and its environs. Much of the catchment area is dedicated to agriculture, with fields of crops such as maize, millet, sorghum, rice, and

vegetables. Farmers in the area practice both rainfed and irrigated agriculture, using water from the Alau reservoir for irrigation during the dry season. Livestock rearing, including cattle, sheep, and goats, is also prevalent in the region, and fishing activities also take place in the Alau reservoir (CBDA, 2018).

Figure 1: Alau Reservoir Catchment and its Climatic Conditions

2.2 Water Sampling and Analysis

Two sampling points were identified in the Alau reservoir based on the accessibility due to insecurity. The Water samples were collected following the standard procedures and protocols of the United States Environmental Protection Agency Laboratory Services and Applied Science Division (USEPA, 2021). The water samples were taken offshore at a depth of 1 m from the surface of the reservoir at two sampling points, SWA1 (13.2852190 E, 11.7229650 N) and SWA2 (13.2831770 E, 11.7181360 N), which are 270 m apart. The sampling was conducted during six selected months (May, June, July, August, September and December 2023) to reflect the seasonal variation. May represented the late dry-season, June-September represented the rainy season, while December represented the post-rainy dry-season condition. Samples were immediately taken to the laboratory for analysis. The water analysis was conducted following American Public Health Association (APHA, 2017) at the Chemistry Analytical Laboratory, Yobe State University, Damaturu, Nigeria. The parameters measured include turbidity, pH, dissolved oxygen (DO), chlorophyll a (CHL-a), orthophosphate (orth-P), organic phosphorus (Org-P) phosphate (P) and total phosphorus (TP). The water temperature, turbidity, pH and DO were measured in situ using TDS & EC meter (E51M0), pH meter, turbidity meter (WG7-B) and DO meter (DO-510) respectively. The CHL-a, orth-P, Org-P, P and TP were measured by the LaMotte colorimeter (SMART3).

2.3 Data analysis

Data were analyzed using Microsoft Excel. The overall distribution of the concentration of phosphorus fractions, DO, pH, chlorophyll-a and turbidity in the reservoir was summarized using descriptive statistics; mean and standard deviation. The trends of phosphorus concentration under different scenarios were assessed using Principal Component Analysis (PCA).

3. RESULTS AND DISCUSSION

3.1 Analysis of Physio-chemical characteristics of the water samples

The Table 1 presents the descriptive statistical analysis of the two sampling sites (SWA1 & SWA2) for the phosphorus fractions and eutrophication response variables in the Alau Reservoir.

Table 1: Physio-chemical properties of the water samples

	SWA1				SWA2				
Variable	Min.	Max.	Mean	Std/dvn	Min.	Max.	Mean	Std/dvn	USEPA
Orth-P (mg/L)	0.0036	0.0049	0.0043	0.0005	0.00492	0.00661	0.0059	0.0007	0.5-2
Org-P (mg/L)	0.12	0.19	0.1633	0.0258	0.21	0.25	0.2308	0.0186	<10
P (mg/L)	0.735	1.104	0.9159	0.1312	0.913	1.097	0.9948	0.0647	0.1
TP (mg/L)	0.917	1.192	1.0442	0.1065	1.112	1.266	1.1735	0.0662	0.5-1.5
pH	6.23	6.78	6.5850	0.2249	6.24	6.92	6.6833	0.2682	6.5-8.5
DO (mg/L)	4.03	6.85	5.0567	0.9967	4.02	6.35	4.9433	0.8369	5-8
Chl-a (µg/L)	0.27	0.382	0.3220	0.0393	0.37	0.47	0.4233	0.0398	1.9-12.35
Turb (NTU)	6.23	7.82	7.0383	0.5800	6.41	7.8	7.0683	0.5826	5-30

Orth-P – Orthophosphate, Org-P - Organic phosphorus, P – Phosphate, TP - Total phosphorus, DO - Dissolved oxygen, Chl_a – Chlorophylla, Turb. – Turbidity

The mean concentration of phosphate at SWA1 was 0.9159 mg/L, and total phosphorus was 1.044 mg/L. At SWA2, the mean concentration of phosphate was 0.995 mg/L, and total phosphorus was 1.174 mg/L. The values indicate that the phosphorus load in SWA2 was greater than in SWA1. The high total phosphorus concentrations reflect a high nutrient pool, which can support current and future algal growth, as total phosphorus encompasses all forms of dissolved, particulate, organic and inorganic phosphorus. The phosphate values are also worthy of consideration as phosphate is closely associated with the availability of nutrients for aquatic primary producers. The mean concentrations of orthophosphate were low at both sampling points, 0.004 mg/L at SWA1 and 0.006 mg/L at SWA2. These values are small on their own, but do not diminish the eutrophication concern due to the high phosphorus pool. The mean concentration of organic phosphorus was also higher at SWA2 (0.231 mg/L) than at SWA1 (0.163 mg/L). Sources of organic phosphorus include decomposing plant material, animal wastes, domestic inputs, soil particles and sediment-associated organic matter. It can subsequently be mineralised to inorganic phosphorus by microorganisms. Therefore, the organic phosphorus result indicates that there is a greater pool of phosphorus in SWA2 that can continue to support eutrophication even after the immediate dissolved forms are consumed by algae. The findings are similar to previous Nigerian reservoir studies that have classified trophic status based on phosphorus enrichment and chlorophyll-a response. Ayoade and Aderogba (2020) reported that the total phosphorus and chlorophyll-a values were above the criteria for eutrophication.

The dissolved oxygen results also indicate concern for ecological stress, with a mean dissolved oxygen concentration of 5.057 mg/L at SWA1 and 4.943 mg/L at SWA2. Higher mean phosphorus and higher chlorophyll-a are associated with the lower oxygen value at SWA2. Algal biomass can increase following the addition of phosphorus in nutrient-rich reservoirs, and the subsequent decomposition of the biomass can deplete oxygen. The minimum values of approximately 4.0 mg/L at both sampling locations indicate that oxygen stress may occur, particularly during warm, stagnant or organically enriched periods. This is consistent with the overall limnological knowledge that nutrient enrichment can lead to increased algal biomass, which can then lead to decreased oxygen due to respiration and decomposition (Wurtsbaugh *et al.,* 2019.). The mean chlorophyll-a value was 0.322 µg/L at SWA1 and 0.423 µg/L at SWA2. The sampling point with the highest phosphorus enrichment, however, still had a higher mean chlorophyll-a concentration than SWA1, and the algal-biomass signal was stronger. The same findings were reported by Ahmed and Ibrahim (2024) who found that the abundance of phytoplankton in Lake Alau was influenced by nutrient concentration, physicochemical factors and season. The turbidity was found to be similar at both points with mean value of 7.038 at SWA1 and 7.068 at SWA2, indicating similar conditions of suspended material or light attenuation.

3.2 PCA Eigenvalues of phosphorus in Alau reservoir

The first two components explained 77.57% and 87.29% of the total variance at SWA1 and SWA2, respectively, indicating that they adequately summarized the relationships among phosphorus fractions and water-quality variables as presented in Table 2.

Table 1: PCA Eigenvalues of phosphorus fractions in Alau reservoir

SWA1	F1	F2	F3	F4	F5
Eigenvalue	3.454	2.752	1.585	0.190	0.019
Variability (%)	43.177	34.395	19.817	2.372	0.239
Cumulative %	43.177	77.572	97.389	99.761	100.000
SWA2					
Eigenvalue	4.858	2.125	0.716	0.200	0.101
Variability (%)	60.726	26.562	8.951	2.497	1.265
Cumulative %	60.726	87.288	96.239	98.735	100.000

The first principal component (F1) at SWA1 accounted for 43.18% of the variance and the second principal component (F2) accounted for 34.40% of the variance, for a total of 77.57%. This suggests that several environmental processes affect phosphorus fractions and eutrophication variables, not just one. The third component (19.82%) also had an eigenvalue greater than 1, the Kaiser criterion, indicating the presence of another, but less influential, ecological process as indicated in Table 2. The results are consistent with those of Jolliffe & Cadima (2016) who found that PCA is most useful when the first two principal components account for over 70% of the total variance, enabling the environmental gradients to be interpreted. At SWA2 much higher first component (60.73%) and F2 (26.56%) for a total of 87.29% cumulative variance. The higher percentage accounted for by F1 suggests that water quality at SWA2 is more strongly influenced by a single nutrient-enrichment gradient, suggesting greater coupling between the availability of phosphorus and biological response than at SWA1. Likewise, Wurtsbaugh *et al*. (2019) noted that eutrophication of reservoirs often have a dominant nutrient component, with phosphorus, algal biomass and oxygen dynamics being connected. The descriptive statistics indicated that the concentration of organic phosphorus, soluble phosphorus and total phosphorus were higher at SWA2 than at SWA1, which is consistent with the higher cumulative variance at SWA2.

3.3 PCA Factor Loadings for phosphorus fractions in Alau reservoir

The PCA factor loading patterns at SWA1 and SWA2 reveal that nutrient dynamics in Alau are driven by seasonal hydrology as presented in Table 3.

Table 3: PCA Factor Loading for phosphorus fractions in Alau Reservoir

SWA1	F1	F2	F3	F4	F5
OTH-P	-0.479	-0.522	0.697	0.110	0.019
Org-P	-0.615	-0.454	0.642	0.052	-0.028
P	0.768	0.267	0.550	-0.190	0.007
TP	0.819	0.176	0.544	-0.040	-0.010
pH	0.620	0.727	0.159	0.246	-0.035
DO	-0.480	0.850	0.111	0.185	0.036
Chl-a	0.774	-0.607	-0.069	0.134	0.101
Turb.	-0.610	0.743	0.216	-0.157	0.072
SWA2					
OTH-P	0.597	-0.735	0.283	0.036	-0.149
Org-P	0.937	-0.296	0.170	-0.006	0.073
P	0.797	0.417	0.426	-0.051	-0.077
TP	0.514	0.799	0.272	0.150	0.024
pH	-0.670	0.699	0.094	-0.210	-0.096
DO	-0.783	-0.266	0.520	-0.089	0.194
Chl-a	0.900	0.344	-0.223	0.061	0.136
Turb.	-0.923	0.083	0.149	0.343	-0.038

The highest positive loadings for F1 were total phosphorus (0.819), chlorophyll-a (0.774) and phosphate (0.768), which suggests that F1 is the gradient of phosphorus enrichment and algal productivity. The biological expression of nutrient enrichment was also observed as the concentration of phosphorus increased, so did the concentration of chlorophyll-a. On the other hand, organic phosphorus (-0.615), turbidity (-0.610) and orthophosphate (-0.479) were negatively loaded on F1, indicating that these variables are associated with a different environmental process, which may be associated with the decomposition of organic matter and transport of sediment-associated phosphorus as indicated in Table 3. This separation suggests that there are several biogeochemical forms of phosphorus in SWA1, each having a different transport mechanism. Similarly, Ayoade & Aderogba (2020) reported a positive relationship between total phosphorus and chlorophyll-a in a tropical reservoir in Nigeria, which is consistent with eutrophic interpretation. Dissolved oxygen (0.850), turbidity (0.743) and pH (0.727) dominated the second component (F2). This component is not nutrient enrichment, but physical–chemical regulation. The negative loading of chlorophyll-a (-0.607) may indicate that algal biomass increases when dissolved oxygen levels are low due to respiration and decomposition, while high dissolved oxygen and turbidity may be associated with inflow-induced mixing during rainy periods. These observations are similar to those reported by Paerl *et al.* (2020) that phosphorus enrichment leads to algal growth, and that subsequent decomposition leads to increased biological oxygen demand and decreased dissolved oxygen.

The PCA at SWA2 revealed a much clearer eutrophication pattern as the first component was dominated by organic phosphorus (0.937), chlorophyll-a (0.900) and phosphate (0.797), while turbidity (-0.923) and dissolved oxygen (-0.783) showed strong negative loadings. This means that F1 is an active eutrophication gradient, where the more phosphorus enriched the more algal biomass and the less dissolved oxygen. The highest loading was for organic phosphorus (0.937), indicating that it is an important reserve nutrient pool that can support eutrophication following mineralization. This is consistent with the results of Han *et al.* (2017) who found that organic phosphorus in sediments and suspended particles is a significant source of long-term phosphorus availability in reservoirs. The negative correlation between turbidity and chlorophyll-a indicates that the clearer the water, the more likely algae will grow due to better light penetration. The same was found by Fabian *et al.* (2023) in Lake Alau, where a decrease in suspended sediments during the season was correlated with an increase in phytoplankton. Total phosphorus (0.799) and pH (0.699) were the main factors in the second component (F2). This component is probably a reflection of the chemical environment affecting the

availability of phosphorus. Increased pH can also increase the release of phosphorus from sediments and can also be associated with high photosynthetic activity due to the removal of carbon dioxide, which is well documented in eutrophic lakes (Smith & Schindler, 2009). Overall, SWA2 shows a higher ecological connection between phosphorus compounds and eutrophication indicators than SWA1, which is consistent with the fact that it is the more environmentally sensitive part of Alau Reservoir.

3.4 Interactions between Phosphorus fractions and eutrophication variables

The correlation circles for SWA1 and SWA2 illustrate the relationships between orthophosphate, organic phosphorus, phosphate, total phosphorus, pH, dissolved oxygen, chlorophyll-a and turbidity on the first two principal component axes as shown in Figure 2. The principal component analysis correlation circle show variables in the same direction as positively associated, in opposite directions are negatively associated, and lying at almost right angles have weak relationships. The length of each vector is also important, as the first two axes are strongly represented by variables near the outer circle.

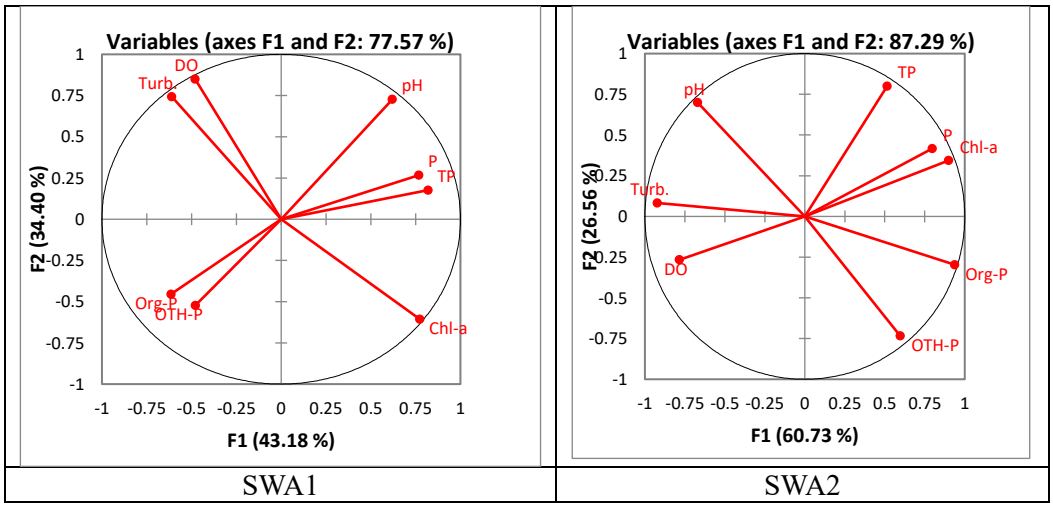

Figure 2: Correlation circles for phosphorus fractions and eutrophication variables

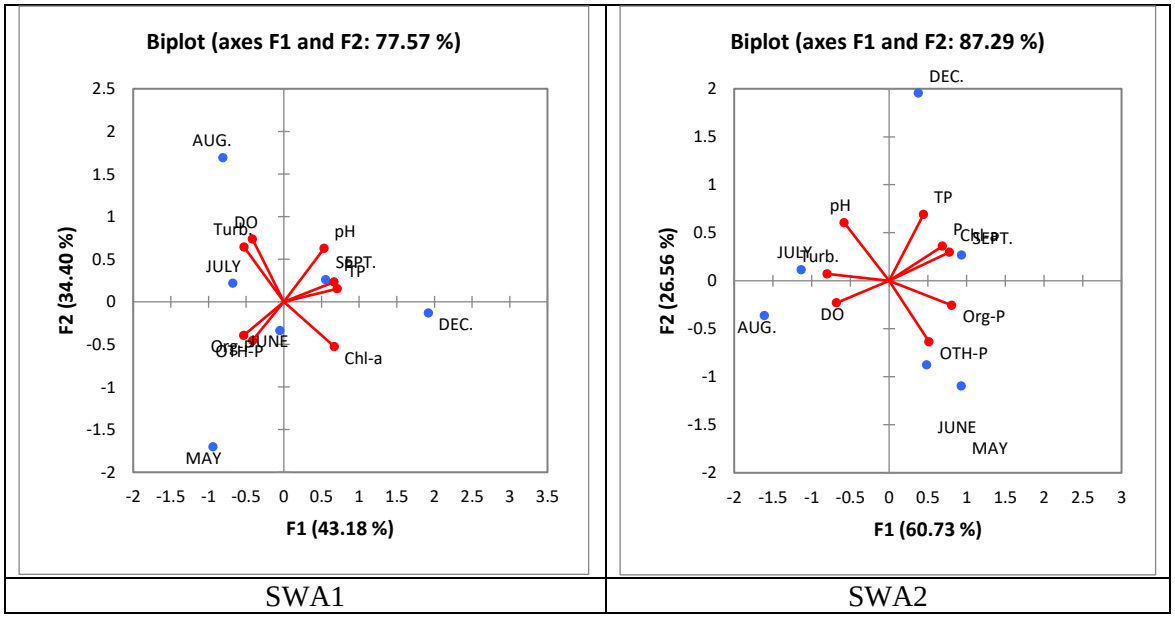
At SWA1, the first two axes explain 77.57% of the total variation, with F1 account for 43.18% and F2 is 34.40%. This implies that the correlation circle provides a good summary of the primary physicochemical and eutrophication relationships at this sampling location. The strongest positive association is seen in SWA1, where phosphate and total phosphorus are grouped together on the positive side of F1. This suggests that phosphate is a significant component of the total phosphorus pool at SWA1. The first two axes account for 87.29% of the total variation in SWA2, with F1 and F2 explaining 60.73% and 26.56% respectively. This is more than the SWA1 plot can explain, and the SWA2 correlation circle provides an even better summary of the measured water quality variables. The high proportion of F1 also indicates that a more powerful common environmental gradient influences SWA2. Orthophosphate and organic phosphorus constitute another group at SWA1, both vectors are directed towards the lower left side of the circle, away from the other vectors, phosphate, total phosphorus, pH and chlorophyll-a. The correlation matrix shows a very strong positive correlation between them, which is reflected in their proximity. This clustering indicates that orthophosphate and organic phosphorus could have a similar source or transformation pathway at SWA1. They can be associated with organic matter decomposition, soil run-off, domestic inputs, sediment interaction or microbial mineralisation. Their direction of flow is opposite to that of phosphate and total phosphorus, however, and they do not follow the same pattern as the larger group. This indicates that the phosphorus system at SWA1 is not homogeneous. The various phosphorus fractions may originate from various sources or react differently to physical and chemical conditions in the reservoir. The results are consistent with Ayoade & Aderogba (2020) who reported positive correlation between total phosphorus and chlorophyll-a in a tropical reservoir in Nigeria, which is consistent with eutrophic interpretation.

Organic phosphorus and orthophosphate are also positive at SWA2, but they are pointing down. They are directed towards the phosphorus-enrichment side of the system, but are not the same as total



phosphorus and phosphate in their F2 behaviour. Organic phosphorus is near the right side of the circle, indicating that it is well represented by the first two components. This suggests that organic phosphorus plays an important role in the SWA2 nutrient structure. Organic phosphorus can be mineralised by microorganisms to more available inorganic forms, and can therefore serve as a nutrient pool that can continue to contribute to eutrophication. At SWA1, the position of chlorophyll-a is moderately positively related to total phosphorus and phosphate. This implies that there is some biological expression of the phosphorus enrichment at SWA1, albeit not a direct one. This is ecologically sound because algal growth is not solely dependent on phosphorus. Other factors that affect chlorophyll-a concentration include light penetration, water residence time, water mixing, grazing, and nitrogen availability and turbidity. The phosphorus concentration thus suggests high eutrophication potential, and the chlorophyll-a concentration suggests that the biological response may be partly influenced by other environmental factors. The most important pattern at SWA2 is the group of phosphate, total phosphorus and chlorophyll-a on the right side of the correlation circle. Phosphate and chlorophyll-a are grouped tightly together, and total phosphorus is in the same general direction. This indicates that the enrichment of phosphorus at SWA2 is more closely linked to algal biomass than at SWA1. In the same way, Dadin Kowa Reservoir was recently studied by Usman *et al.* (2025) and it was found that the enrichment of N and P in the reservoirs in Nigeria can be seasonal and site-specific, thus supporting the use of SWA1 and SWA2 separately rather than as a single water body. It implies that the enrichment of phosphorus at SWA2 is not only chemical but also biological, as evidenced by the increase in chlorophyll-a. Since eutrophication is a process of nutrient loading and algal production, studies of reservoir trophic state typically include nutrient enrichment as well as biological response variables like chlorophyll-a and transparency.

The dissolved oxygen at SWA2 is a very important position that shows a negative correlation between dissolved oxygen and the eutrophication related variables. This pattern indicates that as chlorophyll-a and phosphorus levels increase, oxygen levels decrease at SWA2. This is one of the most significant indicators of eutrophication stress as algal growth and decomposition of organic matter can lead to increased oxygen demand and decreased dissolved oxygen. The chlorophyll-a and the dissolved oxygen-turbidity group are the strongest ecological contrast at SWA1. Dissolved oxygen and turbidity are grouped together in the upper left quadrant of the circle, and chlorophyll-a is grouped together in the lower right quadrant of the circle. The relationship between chlorophyll-a and dissolved oxygen is strongly negative, as is the relationship between chlorophyll-a and turbidity. The negative correlation with turbidity indicates that suspended materials could limit light penetration and algal growth at some times. Therefore, SWA1 seems to be highly available for phosphorus, but the strength of this nutrient enrichment to generate algal biomass may be controlled by turbidity and oxygen conditions (Fabian *et al.*, 2023).

The location of pH near phosphate and total phosphorus also provides a valuable chemical interpretation at SWA1. The pH values are generally in the same direction as the phosphate and total phosphorus values, particularly in the positive direction of the F1 axis. This pattern agrees with the positive correlations between pH and phosphate, and between pH and total phosphorus. It indicates that the higher the concentration of phosphorus at SWA1, the higher the pH. This can be a sign of increased photosynthetic activity in nutrient-rich waters, as algal photosynthesis consumes carbon dioxide from the water and can increase the pH. But pH is not on the same vector as phosphate and total phosphorus, and should not be considered as the same process. It is more correctly viewed as a supportive chemical state associated with nutrient behaviour and potential algal activity. The pH and turbidity vectors at SWA2 are opposite to the direction of phosphate and chlorophyll-a. The pH is in the upper left quadrant and turbidity is closer to the negative F1 axis. This indicates that pH and turbidity are negatively associated with the nutrient and chlorophyll-a group at SWA2. The negative correlation between turbidity and chlorophyll-a indicates that algal growth may be promoted by clearer water conditions, and algal growth may be inhibited by more turbid water conditions due to reduced light penetration. Turbidity can also be an indicator of suspended sediment and runoff inputs, however. It can decrease algal growth at one time and carry particle-bound phosphorus into the reservoir at another time. The pH pattern also indicates that the various fractions of phosphorus may react differently to the chemical conditions (Jolliffe & Cadima, 2016).

3.5 Temporal variations of the Phosphorus fractions and eutrophication variables

The principal component analysis biplots for SWA1 and SWA2 represent the measured water quality variables and the sampling months as shown in Figure 3. In this type of biplot, a month near the direction of a variable is typically correlated with relatively high values of that variable. A month on the other side of a variable is correlated with relatively lower values. A month near the centre indicates more average conditions, and a month far from the centre indicates stronger departure from the average water quality condition.

SWA1 SWA2

Figure 3: Biplots for phosphorus fractions and eutrophication variables

The positions of dissolved oxygen and turbidity at SWA1 biplot show a different environmental condition. August is located close to dissolved oxygen and turbidity, while July is also on the left side near turbidity as shown in Figure 3. This suggests that these months were more strongly associated with oxygenated and turbid conditions at SWA1. This pattern can be indicative of inflow, mixing or suspended particle transport. Light penetration may be affected by turbidity, which may be a partial reason for the negative relationship between chlorophyll-a and turbidity. Simply put, as water becomes more turbid, light may be less available for algal photosynthesis, even in the presence of phosphorus. This is why the formation of algal blooms is not always observed at each sampling time when phosphorus enrichment occurs. General trophic assessment is based on the combination of total phosphorus, chlorophyll-a and measures related to transparency, since eutrophication is a combination of nutrient pressure and biological response, not just nutrient concentration (USEPA, 2021). May is in the lower left corner of the SWA1 biplot, near orthophosphate and organic phosphorus. This indicates that May was more closely related to the orthophosphate and organic phosphorus fractions than to the larger group of phosphate-total phosphorus. The position of May is important because organic phosphorus can act as a reserve nutrient fraction. It can later be transformed into more accessible inorganic forms by microbial decomposition. The clustering of orthophosphate and organic phosphorus in this section of the biplot thus indicates that SWA1 may be supplied with phosphorus from organic matter inputs, decomposition of aquatic organic matter, or from organic particles or sediment associated processes from runoff. The biplot indicates that the phosphorus system at SWA1 is not monodirectional with respect to phosphate and total phosphorus, suggesting that there is more than one source or transformation pathway for phosphorus (Fabian *et al.*, 2023).

September and December are on the positive side of F1 at SWA1, and are more related to the phosphorus enrichment side of the biplot. September is close to phosphate, total phosphorus and pH, and December is far to the right and slightly below the F1 axis. This indicates that these months are more strongly associated with nutrient-rich conditions than May, July or August. September is close to the phosphate and total phosphorus, indicating a time when phosphorus loading increased. The F1 position for December is also very positive, indicating a strong departure from the average position, but

it is also separated from the main phosphorus arrows, so it may not be explained by phosphorus alone. The month-to-month variation is important in eutrophication assessment because water quality in reservoirs can vary with inflow, runoff, dilution, evaporation, sediment disturbance, and biological uptake. June is near the centre of the SWA1 biplot, indicating that it is a more average month than the others. June was not strongly dominated by any one water quality factor, as it does not correlate well with any variable. This is helpful because it indicates that the eutrophication condition in SWA1 is not consistent throughout the month. Rather, the sampling point alternates between an organic phosphorus condition, a turbidity-oxygen condition and a phosphate-total phosphorus condition. This is consistent with the previous PCA eigenvalue interpretation, which indicated that SWA1 had three meaningful components. The water quality structure at SWA1 is therefore more mixed, and the interaction between phosphorus enrichment and physical and chemical controls is more complex (Usman *et al.,* 2025).

September is near to phosphate and chlorophyll-a, the most obvious indicators of eutrophication risk, at SWA2 biplot. It suggests that September was associated with higher phosphate and higher algal biomass at SWA2 as shown in Figure 3. Phosphate is a direct nutrient for algal growth and chlorophyll-a is a measure of algal biomass, so their close association suggests an active nutrient-biological response. This is in line with the studies conducted on reservoirs in Nigeria, which indicated that the trophic state of the reservoirs was assessed using the total phosphorus, chlorophyll-a and Secchi disc transparency, which were found to be higher than the criteria used to interpret eutrophic condition, and the abundance of green algae and blue-green algae confirmed this (Ayoade & Aderogba, 2020). The SWA2 biplot thus indicates that the enrichment of phosphorus at this sampling site is not only a chemical problem, but also associated with algal productivity. The December is positioned high on F2 at SWA2 and close to the direction of total phosphorus. This indicates that December was highly correlated with total phosphorus enrichment, but not as closely correlated with chlorophyll-a as September. This is important because total phosphorus is composed of dissolved, particulate, organic and inorganic phosphorus. A high total phosphorus association can thus be a sign of a high nutrient pool that can be utilized for subsequent algal growth, even if all of the phosphorus is not available to algae at the time of sampling. The December position may thus be a nutrient-storage or nutrient-loading situation, and September a more direct phosphorus-chlorophyll response. The monthly biplot results are consistent with the findings of (Usman *et al.* (2025) which indicated that nutrient enrichment and eutrophication risk in Dadin Kowa Reservoir was different among sampling points and seasons, and hydrological conditions influenced the nitrogen and phosphorus dynamics.

The SWA2 biplot shows the May and June in the lower right corner, near orthophosphate and organic phosphorus. This suggests that these months were more related to these phosphorus fractions. Organic phosphorus is particularly important because it may originate from organic wastes, decaying biomass, aquatic vegetation, animal inputs or sediment-associated materials. It may later be a source of eutrophication following mineralisation. Orthophosphate, however, is a more readily available form for algal uptake. The presence of May and June therefore indicates that SWA2 had a large reservoir of phosphorus forms that could support eutrophication beyond the one sampling period. This is consistent with the descriptive statistics, which showed that SWA2 had a higher mean organic phosphorus and orthophosphate than SWA1. July and August are located on the left side of the SWA2 biplot, near turbidity, dissolved oxygen and in part pH. This indicates that these months were more related to physical disturbance and oxygenated conditions than to chlorophyll-a and phosphorus enrichment. The July data is closest to turbidity, the August data is farther left and below the F1 axis, closer to the oxygen side of the plot. Although the reservoir is generally considered to be a phosphorus-rich system, the turbidity data indicates that periods of higher turbidity may have resulted in less light available for algal growth, and thus less algal biomass. The direction of dissolved oxygen is also against chlorophyll-a and phosphate, which further supports the interpretation that oxygen decreases with increasing algal biomass and nutrient enrichment. This is a typical eutrophication process as the demand for oxygen rises due to algal respiration and organic matter decomposition (Usman *et al.,* 2025).

4. CONCLUSION

This study showed that the reservoir is highly enriched with phosphorus, and that the total phosphorus and phosphate levels suggest a high eutrophication potential. The temporal assessment revealed that the nutrient enrichment was not consistent across the sampling months, suggesting that seasonal processes affect nutrient dynamics in the reservoir. The principal component analysis showed that the water quality variation was significantly influenced by nutrient related processes at SWA1 and SWA2. The higher nutrient-biological relationship found at SWA2 suggests that this sampling site is more susceptible to eutrophication development. The dissolved oxygen levels were below acceptable guideline range as observed at SWA2 indicates increasing oxygen stress due to organic matter decomposition and biological activity. The PCA biplot analysis indicated that December was strongly correlated with total phosphorus enrichment, and September was more strongly correlated with phosphate and chlorophyll-a, indicating periods of greater biological response and eutrophication pressure. The correlation between phosphorus compounds and chlorophyll-a, and the negative correlation between chlorophyll-a and dissolved oxygen, suggest that nutrient enrichment has started to affect the ecological conditions in the reservoir. The Alau Reservoir is vulnerable to eutrophication because of high levels of phosphorus and seasonal changes in nutrient levels. The results indicate the need to shift from general water quality assessment to continuous nutrient monitoring programs that account for the various fractions of phosphorus, algal response and oxygen dynamics. Proper management of nutrient sources entering the reservoir is required to ensure the ecological health of the reservoir and its suitability for domestic, agricultural and fishery uses.

ABSTRACT
This study presents the results of a spectrum measurement campaign conducted in Kano State, Nigeria, across the UHF television band spanning 470–694 MHz. The primary objective was to determine the level of spectrum occupancy and the availability of television white spaces (TVWS) to support dynamic spectrum access in cognitive radio systems. An Agilent (Keysight) spectrum analyser was configured to sweep the television band and collect empirical data from selected urban and rural locations. The findings showed that only 21.4% of the spectrum is utilized in urban areas leaving approximately 78.6% underutilized. In rural areas, the results indicated that the entire measured spectrum 224 MHz (100%) is available and unoccupied. These findings reveal substantial inefficiency in spectrum usage and suggest significant opportunities for opportunistic access through cognitive radio technologies. The measurement results were further compared with findings from both local and international spectrum occupancy studies, which showed a consistent pattern of low utilization and significant TVWS availability across different locations. This agreement with prior studies supports the technical feasibility of deploying TVWS-based systems for broadband connectivity, Internet of Things (IoT) applications, and indoor coverage enhancement.

Keywords: *Spectrum Measurement Campaign; Spectrum Occupancy; Television White Spaces; Underutilization of spectrum; Cognitive Radio*

1. INTRODUCTION

Television White Space (TVWS) refers to the unused frequency spectrum in the Very High Frequency (VHF) and Ultra-High Frequency (UHF) bands originally allocated for television broadcasting services (Idowu-Bismark et al., 2025). Following the global transition from analog to digital television (DTV), the digital dividend has freed substantial spectrum capacity, creating opportunities for secondary access without interfering with primary incumbent services (Luka et al., 2023). The frequency range of interest varies by regulatory domain: in Nigeria, the Nigerian Communications Commission (NCC) has approved TVWS deployment in the 470–694 MHz band ,while the European harmonized standards specify the same range for TV White Space Devices (TVWSDs), (Adefela et al., 2022; Ntlaltapa, 2013; European Telecommunications Standards Institute [ETSI], 2022).

The lower UHF band offers exceptional propagation characteristics compared to higher frequency bands such as 2.4 GHz or 5 GHz used by conventional Wi-Fi. These signals can travel longer distances, penetrate obstacles more effectively, and provide reliable non-line-of- sight (NLOS) communication (Gerolaga, 2020; Idowu-Bismark et al., 2025). As shown in table 1, TVWS provides substantially greater range than Wi-Fi, though with lower throughput, making it particularly suitable for rural broadband access and IoT applications.

Table 1: Comparative Characteristics of Wi-Fi and TVWS

Parameter	**Wi-Fi**	**TVWS (UHF)**
Range (km)	0.05 - 0.45	10 - 30
Throughput	Up to 600 Mbps	2 - 45 Mbps
Frequency	2.4 - 5 GHz	470 - 698 MHz
Non-LOS Communication	No	Yes
Environmental Sensitivity	Yes	No

Source: Adapted from (Gerolaga, 2020)

The global surge in wireless communication systems, fueled by the deployment of advanced mobile telecommunications networks and Internet-of-Things (IoT) ecosystems, has drastically increased demand for the radio frequency (RF) spectrum. Traditionally, regulatory bodies manage this finite natural resource using a static allocation framework, where specific frequency bands are exclusively licensed to designated operators or primary users (PUs). This traditional strategy, though it has helped to address the issue of interference, it has created artificial scarcity of spectrum. To overcome this challenge, researchers have led the way toward Dynamic Spectrum Access (DSA) enabled by Cognitive Radio (CR) technology. The term *Cognitive Radio* (CR) was coined by (Mitola, J., & Maguire, G. Q., 1999) at a seminal workshop on Mobile Multimedia Communications. The authors described how CR could enhance the flexibility of personal wireless services through the Radio Knowledge Representation Language (RKRL). Additionally, the International Telecommunication Union (ITU) defines a cognitive radio system (CRS) as a radio system employing technology that allows the system to obtain knowledge of its operational and geographical environment, established policies, and its internal state; to dynamically and autonomously adjust its operational parameters and protocols according to its obtained knowledge in order to achieve predefined objectives; and to learn from the results obtained (International Telecommunication Union [ITU- R BT.2302], 2008).

CR allows unlicensed secondary users (SUs) to opportunistically access idle licensed spectrum bands, often referred to as "spectrum holes" or "white spaces," without causing harmful interference to the PUs, (Popoola, et al 2018). However, deploying CR networks requires an accurate, empirical understanding of real world spectrum usage. This has driven empirical research via spectrum measurement campaigns. Spectrum occupancy measurement is the process of determining the degree to which a specific RF band is being used by detecting and quantifying the presence of radio signals within that band over a given period. The measurement process typically involves (Popoola, et al 2018):

I. **Sensing:** Continuously scanning the frequency band of interest using specialized equipment, such as a spectrum analyser or portable RF explorer, to monitor a range of frequencies.
II. **Measuring:** Capturing the received signal levels across the scanned frequencies over time.
III. **Calculating:** Computing the duty cycle, which represents the percentage of time or the fraction of total measurements that a frequency channel or band is found to be occupied.

The measurement campaigns utilize specialized hardware such as high-performance spectrum analysers, omnidirectional antennas, and energy detection algorithms to capture real-world RF occupancy data across diverse times, frequencies, and geographical spaces.

Despite numerous localized spectrum occupancy measurement studies conducted globally and various frequency bands in some states in Nigeria, which consistently indicate a significant underutilization of the radio frequency spectrum with occupancy rates often below 30%, two critical gaps necessitates further action and research.

I. Fragmented and Incomplete National Profile: Existing studies are highly isolated, focusing on specific frequency bands and limited geographical locations, resulting in an incomplete understanding of the overall national spectrum utilization profile. This lack of a comprehensive, nationwide, multi-band, and multi-location dataset prevents regulatory bodies from making fully informed, national-level decisions regarding spectrum efficiency improvement and nationwide dynamic spectrum access (DSA)/Cognitive Radio (CR) deployment strategies.
II. High Spatiotemporal Dynamics: While the overall trend is low occupancy, spectrum availability is highly dependent on time, location, and environment (e.g., urban vs. rural, peak vs. off-peak times). Localized, static measurements fail to capture the true potential or challenges of implementing dynamic spectrum management on a broader, interconnected scale.

Thus, the major gap is the absence of a comprehensive, unified, and contemporary understanding of the actual spectrum utilization profile across all major regions and critical frequency bands in Nigeria. This deficiency hinders the development and implementation of effective national spectrum management policies necessary to harness the significant potential of Dynamic Spectrum Access and Cognitive Radio technologies to address spectrum scarcity and improve overall efficiency, (Ajiboye et al, 2019).

The ultimate goal of this study is to fill in this gap by conducting spectrum measurement campaign in the Television band (470 – 694) MHz with the intent to identifying Television White Space (TVWS) in Kano, Kaduna state and Abuja (F.C.T) in Nigeria. The measurement campaign will be conducted in three phases. Phase 1: Kano, phase 2: Kaduna and phase 3: Abuja. In this study we are starting with phase 1 Kano. Therefore, all the result to be presented in this report will be from Kano (Lat. 11.9820, Long. 8.5147).

1.1 REVIEW OF RELATED LITERATURE

Regulatory frameworks for TVWS deployment have been established in several jurisdictions. The U.S. Federal Communications Commission (FCC) and the UK Office of Communications (Ofcom) have developed guidelines enabling TVWS device operation through geolocation databases (Idowu-Bismark et al., 2025). The European Telecommunications Standards Institute (ETSI) has published harmonized standard EN 301 598, which specifies technical characteristics for TVWSDs operating in the 470–694 MHz band (Adefela et al., 2022; Ntlaltapa, 2013; European Telecommunications Standards Institute [ETSI], 2022). In Nigeria, the Nigerian Communication Commission (NCC) established a committee in 2020 to develop national TVWS guidelines, working in collaboration with the Nigerian Broadcasting Commission (NBC), (Idowu-Bismark et al., 2025).

1.2 GLOBAL SPECTRUM MEASUREMENT CAMPAIGNS

Globally, an extensive spectrum measurement campaigns have established the fundamental premise that the radio spectrum is severely underutilized. These investigations spanned multiple continents, focusing on urban and suburban environments to model temporal and spatial duty cycles. To enhance these empirical evaluations, contemporary frameworks increasingly leverage advanced paradigms, including machine learning-based spectrum occupancy prediction, to construct comprehensive, predictive models of spectral environments over time (Aygül et al., 2025).

Some of the earliest foundational measurement campaigns were conducted in the United States and Europe. Marţian (2010) highlighted a pivotal measurement campaign executed in Chicago, USA, which revealed a mean spectral occupancy of only 17.4% within the 30 MHz to 3000 MHz frequency range. This confirmed that massive blocks of allocated spectrum lay idle even in densely populated urban centers.

Similarly, in Europe, researchers focused heavily on understanding localized and event-driven spectrum dynamics. Marţian (2010) analyzed spatial and context-dependent variations, citing campaigns in Aachen, Germany, which contrasted indoor and outdoor spectral densities. They also documented intensive measurements during the 2006 FIFA World Cup in Dortmund and Kaiserslautern. These studies demonstrated a distinct interdependency between spectrum utilization and real-world human activity, showing sharp spikes in cellular bands during active match periods.

To model these variations over extended timelines, Harrold et al. (2011) conducted a long-term measurement campaign in the UK spanning five months across a 10 MHz to 5 GHz range. They emphasized that while short-term campaigns (lasting a few days) can quantify the baseline percentage of idle spectrum, long-term empirical tracking is vital to model temporal variations across working days, weekends, and holidays. This long-term modelling allows CR systems to accurately predict available white space. While, Van De Beek et al (2012) conducted a model based study in 11 countries in Europe in the band 470–790 MHz), and reported about 56% of channels are unused per location, dropping to 25% if adjacent channels are restricted.

Extensive campaigns across Asia have reinforced these global findings. Marţian (2010) evaluated a 12-weekday spectrum measurement campaign in Singapore covering a broad frequency range up to 5850 MHz, which yielded an overall average occupancy rate of just 4.54%.

In South Asia, Patil et al. (2011), conducted an outdoor spectrum measurement campaign in the suburban environment of Mumbai, India, across the 700 MHz to 2700 MHz band. The investigation reported significant low occupancy during weekdays, noting that the underutilized bands offered excellent potential for opportunistic dynamic spectrum sharing.

Furthermore, Chantaveerod et al. (2021) addressed specific limitations in general-purpose sensing by proposing a focused pass band and guard band monitoring technique for analog FM radio broadcasting in suburban environments. Their experimental model successfully identified 42 entirely unused channels, illustrating that refined empirical measurement strategies can uncover significantly more vacant spectrum than traditional wideband averaging methods.

In the Philippines, Gerolaga (2020) conducted 72-hour monitoring of the 470–698 MHz band and concluded that despite the Philippine TV broadcast being "one of the busiest users of UHF TV band," the spectrum remains significantly underutilized.

Naik, et al, (2013) conducted a nationwide geospatial study across four zones in India in the band 470–590 MHz and found that out of the 100 MHz of TVWS assigned to secondary users, only four channels (32 MHz) have been put to use.

In addition, Kurnaz et al (2016), carried out study to determine the availability of TVWS in the frequency range 470 – 790 MHz in Samsun city center, Turkey at 73 locations, using −40/−45 dB thresholds, found an average occupancy of 20.7%.

1.3 LOCAL SPECTRUM MEASUREMENT CAMPAIGNS (NIGERIA)

In Nigeria, the regulatory regime managed by the Nigerian Communications Commission (NCC) has historically operated on rigid static allocations. Over the past decade, local research groups, primarily based in Nigerian universities, have conducted tailored measurement campaigns to evaluate whether the global phenomenon of spectrum underutilization applies to the distinct socio-economic and infrastructural landscape of a developing country like Nigeria. These empirical investigations consistently point to low overall occupancy rates, confirming that massive portions of the radio spectrum remain severely underutilized across various regions.

To obtain a comprehensive baseline of Nigeria's RF profile, Popoola and Otuu (2018) conducted multi-band and multi-location spectrum measurement campaigns across five major Nigeria's metropolises within the 80 MHz to 2200 MHz frequency range. The quantitative results revealed that the actual overall spectral occupancy in Nigeria was less than 10.00%. The study demonstrated that allocated bands vary randomly in time, frequency, and space, proving that wideband spectrum utilization is consistently low and suggesting an optimistic future for the deployment of DSA and CR frameworks across the country.

Several regional studies have broken down these metrics by analysing localized variations in specific bands, primarily focusing on the Very High Frequency (VHF), Ultra High Frequency (UHF), and FM broadcasting bands. For instance, Ajiboye et al. (2019) conducted a 24-hour outdoor spectrum occupancy survey in the centre of the Minna metropolis, Niger State, targeting the VHF (30–300 MHz) band. The study discovered heavy underutilization; the Aeronautical Navigation band exhibited the highest occupancy at 39.83%, the FM broadcasting band stood at 12.90%, while Aeronautical Mobile operations and TV Broadcasting languished at 4.73% and 0.09% occupancy, respectively. This profile highlights the stark availability of underutilized local frequencies available for secondary deployment.

Luka et al. (2023) implemented a comprehensive web application using the Flask framework with an SQLite database engine. The Okumura-Hata path loss model was employed for protection contour calculations. The database covers 21 local government areas in Adamawa State and 20 in Bauchi State. Validation was performed using RTL-SDR devices configured as spectrum analyzers, which detected 70% of channels indicated as vacant by the database.

Alawode et al. (2024) conducted a localized 48-hour campaign targeting the active FM band (88–108 MHz) across four designated locations in the Osogbo metropolis using energy detection methods. While certain urban channels at university campus hubs experienced peak duty cycles as high as 99.48% due to active local transmissions, the broader regional channels remained unevenly distributed and underutilized during off-peak hours.

Furthermore, the Akure study by Adefela et al. (2022) found that 71.05% of 38 channels in the 470–960 MHz band were unused, indicating very low spectrum occupancy rates that create substantial

opportunities for secondary access. This finding is consistent with the Covenant University study, which confirmed TVWS availability within the 470–694 MHz range specified by Nigerian regulations (Idowu-Bismark et al., 2025).

Similarly, Atimati et al, (2015), conducted a survey on the availability of TV White Spaces at FUT Owerri Eastern Nigeria in the UHF band 470–870 MHz at two sites using fixed measurements. Results of their measurement revealed that 64% of 50 channels are dormant, indicating low occupancy and opportunity for deployment of CR for rural broadband.

The above literature review confirms that spectrum underutilization is a global phenomenon, with studies in the US, Europe, and Asia showing occupancy rates often below 20-30%. This trend is echoed in Nigeria, with local measurement campaigns consistently demonstrating very low overall occupancy (often under 10%) in various bands, including VHF, UHF, and FM broadcasting. The review establishes a strong foundation for the necessity of the current TVWS study in Kano, Nigeria.

To address these gaps, the study aims to conduct a spectrum measurement campaign across Kano, Kaduna, and Abuja. However, the measurement will start with Phase 1 in Kano. The ultimate goal is to identify Television White Space (TVWS) and the actual spectrum utilization in Kano.

2. METHODOLOGY

This research aims to identify TV White Spaces (TVWS) in three states (Kano, Kaduna and Abuja) in Nigeria. The study will start by conducting empirical spectrum measurement campaign in Kano to identify free TVWS channels and also determine the actual spectrum utilization in Kano state. The method will then be replicated in the subsequent two locations (Kaduna and Abuja). The work is divided into three main phases:

- **Phase 1:** Empirical Spectrum Measurement Campaign
- **Objective:** To collect real-world data on how the 470–694 MHz TV band is actually being utilized.
- **Primary Location:** Kano, Nigeria (Lat. 11.9820, Long. 8.5147).
- **Process:** The process involve the following steps:
- **Sensing:** Use a specialized device (Spectrum analyzer connected to an antenna) to continuously scan the target frequency band.
- **Measuring:** Record the power levels of any signals detected in the environment over a set period.
- **Calculating:** Measure and collect, Signal power level Noise power level, Frequency for each channel, this identifies which channels are "free" or "occupied".
- **Phase 2:** Data Analysis and Pattern Identification
- **Objective:** To process the raw data collected in Phase 1 to understand the spectrum's availability.
- **Process:** The process involve the following steps
- **Data Processing:** Clean and organize the measured signal data.
- **Spatial Analysis:** Map the occupancy data using bar chart to see how TVWS spectrum available in Kano.
- **Statistical Analysis:** Look for patterns to collect quantitative data

2.1 MEASUREMENT LOCATIONS AND SITE SELECTION

Fixed location measurements was conducted in Kano State. The measurements were taken at different time of the day to capture the worst-case scenario of spectrum usage. Measurement locations were strategically chosen to represent a mix of urban, suburban, and rural environments within Kano. The coordinate of the locations (Latitude and Longitude) are as follows: Kano Central City Area, (Lat: 11.98200, Long: 8.51470) representing Urban area, Kura L.G.A (Lat: 11.76050, Long: 8.4226^0), representing Sub-urban area and Gwarmai (Lat: 11.4720^0, Long: 8.2061^0), representing Rural area.

2.2 SPECTRUM MEASUREMENT CAMPAIGN IN THE TV BAND (470–694) MHZ

Accordingly, in line with the objective of this study, spectrum measurement campaign was conducted for 3 days in Kano State from 8th – 10th September 2025. These measurements were carried out within the Ultra High Frequency (UHF) television band (470 - 694 MHz). The map in figure 1. below depicts the locations of measurements and their coordinates (latitudes and Longitudes).

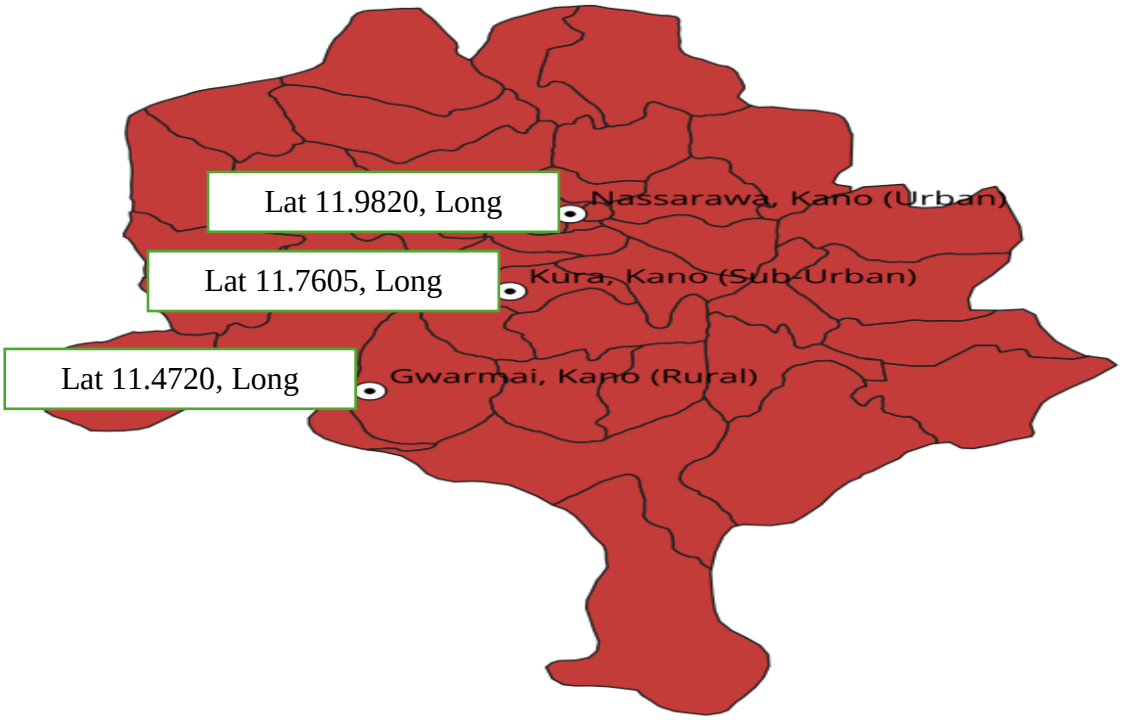

Figure 1: Map of Kano showing measurement locations in Kano

2.3 MATERIALS/INSTRUMENTATION

The following instruments were used for the measurement campaign and data collection:

a. **Spectrum Analyzer:** Agilent (Now Keysight Technologies) Handheld Spectrum Analyzer Model No. N9344C, with a frequency range of 9 KHz to 20 GHz. This device's portability and wide frequency range made it suitable for field measurements.
b. **Antenna**: A wide band high gain (12dB) log-periodic antenna with a frequency range of 1 MHz to 26.5 GHz. This antenna was chosen for its wideband characteristics, which allowed it to cover the entire UHF TV band without requiring multiple antennas.
c. **Cables and Accessories**: Low-loss coaxial cables and a tripod for stable antenna placement were used.
d. **Amplitude Accuracy:** ± 1.3dB
e. **Frequency Range:** 9 KHz to 20 GHz (fully covering the band of interest).
f. **Frequency Accuracy:** ± (0.22 * Span + Span/ (Sweep point – 1)
g. **Frequency Span:** 100Hz – 20GHz
h. **Frequency Resolution:** 1Hz
i. **Calibration Status**: The Spectrum Analyzer was calibrated to ISO/IEC 17025:2017 standards.
j. **Key Settings:** Resolution Bandwidth (RBW) = 10kHz, Video Bandwidth (VBW) = 10 kHz, Sweep Time = 20 Ms.
k. **Software**: Data was logged using the instrument's internal logging and later analyzed using PC-based software (Agilent BTA/DSA Software).
l. **GPS Map**: Camera Lite Application, Version 1.5.8 was adopted.

2.4 MEASUREMENT PROCEDURE

The measurement campaign followed a systematic procedure to ensure data accuracy and consistency. The spectrum analyser was connected to the log-periodic antenna using coaxial cables, and was mounted at a height of approximately 3.0 meters to minimize ground reflections and interference. Resolution Bandwidth (RBW) was set at 10 kHz to resolve individual TV channels, while the Video Bandwidth (VBW) was set at 10 kHz to smooth the display trace. Attenuation loss was set at 20dB to reduce the amplitude of the incoming signal so as to protect the instrument sensitivity front-end components like (mixers) from damage and to prevent signal distortion. The detection Mode was set at Max Hold to capture the peak signal levels over a period. Finally, the spectrum analyser was configured to sweep the UHF television band from (470 – 694) MHz as shown in figure 3 and figure 4 below. Measurements were taken at each location for a duration of 60 minutes per session at multiple location to capture potential intermittent transmissions. The measurements were repeated for three days and average values of the signal was calculated and recorded. The resulting spectrum traces, showing signal strength (in dBm) versus frequency, were saved for subsequent analysis. The instrument setup is as presented in figures 2 and 3.

Figure 3: Showing the Spectrum Analyser measurement set-up

3. RESULT AND DISCUSSION

In this section the result of spectrum measurement campaign, Spectrum trace, and raw data collected is presented

3.1 DATA COLLECTION

Primary data (empirical) was collected from primary source, directly from the TV antenna using the Spectrum Analyser as the instrument for data capturing. The data collected includes Received Signal Power Level (RSSI), Noise floor power level, Bandwidth, and Occupancy time and occupancy status (channel occupied active or free).

To systematically assess UHF spectrum utilization, the frequency band 470–694 MHz was divided into standard 8 MHz television channels bandwidth (Channel 21–48) resulting to 28 channels in line with the international telecommunication union (ITU) Standard.

The spectrum trace for Kano urban area (Nasarawa), bar chart of the plot of signal power level against channel number, (showing both active and free channels), bar chart of the plot of occupancy status against channel number (showing active channel labelled = 1 and free channels labelled = 0) are presented in figure 4, figure 5 and figure 6, while table 2 shows raw data collected.

Active channels

While, Figure 10 present spectrum trace from Gwarmai, Rural Area (Lat: 11.4720^0, Long: 8.2061^0) a distance of 75Km away from Kano city, with no visible spectrum occupancy in the 470–694 MHz spectrum band; making the entire 224MHz (100%) spectrum bandwidth available and free. All the 28 channels are unoccupied.

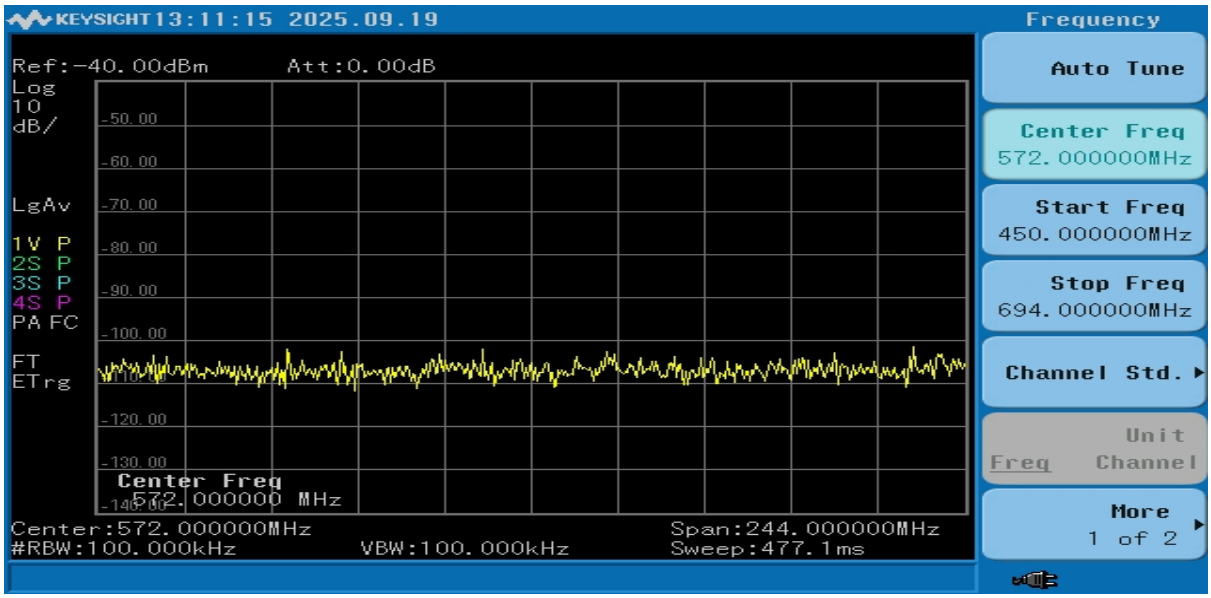

Figure 10: Spectrum Trace, Gwarmai Rural Area, Kano

TVWSs 224 MHz

3.2 Calculation of Spectrum Occupancy Rate for Kano State.

The spectrum occupancy rate for Kano location was calculated as:

$$Occupancy\ Rate\ (\%) = \frac{Number\ of\ Occupiied\ channels}{Total\ Number\ of\ channels} * 100 \quad (1)$$

$$Occupancy\ Rate\ (\%) = \frac{6}{28} * 100 = 21.4\ \%$$

$$Occupancy\ Rate\ (\%) = 21.4\ \%$$

3.3 Statistical Analysis of TVWS Signal Power Levels for the Active channels

This is to enable calculation of Mean, standard deviation and standard error of the signal power level as well as for the noise floor

Mean can be calculated using the formula:

$$\bar{\mu} = \frac{\sum_{i=1}^{n} x_i}{n} \quad (2)$$

Where:

x_i = each signal level

n = total number of samples

In this case n = 6 signal levels as x_1, x_2....., x_6

The mean $\bar{\mu}$ is given by

$$\bar{\mu} = \frac{\sum_{i=1}^{6} x_i}{6} = \frac{415.09}{6} = -69.18\ dBm \quad (3)$$

$$\bar{\mu} = -69.18 dB$$

Standard deviation (S) calculated as:

$$\sigma = \sqrt{\frac{\sum_{i=1}^{6}(x_i - \bar{x})^2}{n-1}} \quad (4)$$

$$Variance = \frac{174.2480}{5} = 34.8496\ \text{dB}$$

$$\sigma = = \sqrt{34.8496} = 5.9034\ \text{dB}$$

Standard error (SE) calculated as:

$$SE = \frac{S}{\sqrt{n}} \quad (5)$$

$$SE = \frac{5.9034}{\sqrt{6}} = \frac{5.9034}{\sqrt{2.4495}} = 2.4100\ \text{dB}$$

Table 4 provides summary of metrics (Threshold)

Metrics	**Value**
Mean signal power level	−69.18 dB
Standard Deviation	5.9034 dB
Standard Error	2.2100 dB

3.4 Statistical Analysis of TVWS Noise Power Levels for the Unoccupied channels

Calculation of Mean

Mean can be calculated using the formula:

$$\bar{\mu} = \frac{\sum_{i=1}^{n} x_i}{n} \quad (7)$$

Where:

x_i = each signal level

n = total number of samples

In this case n = 22 signal levels as x_1, x_2....., x_{22}

The mean $\bar{\mu}$ is given by

$$\bar{\bar{\mu}} = \frac{\sum_{i=1}^{22} x_i}{22} = \frac{2460.64}{22} = -111.84 \text{ dBm}$$

Standard deviation (S) calculated as:

$$\sigma = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \bar{x})^2}{n-1}} \quad (8)$$

$$\text{Variance} = \frac{641.7956}{21} = 30.5617 =$$

$$\sigma = \sqrt{30.5617} = 5.5283 \text{ dB}$$

Standard error (SE) calculated as:

$$SE = \frac{S}{\sqrt{n}} \quad (9)$$

$$SE = \frac{5.5283}{\sqrt{22}} = 1.1786 \text{ dB}$$

Table 5: provides summary of metrics (Threshold)

Metrics	**Value**
Mean noise floor power level	-111.84 dB
Standard Deviation	5.5283 dB
Standard Error	1.1786 dB

Table 5 below present all the critical data collected from Kano state which includes, the mean values, standard deviation and standard error for both the signal power level and Noise power levels. These thresholds will be used for development of algorithm for spectrum sensing in cognatic radios.

Table 6: Summary of critical data collected from Kano state

Description	**Metrics**
Bandwidth per Channel	8 (MHz)
Number of occupied Channels	6
Spectrum Occupancy rate	21.4 (%)
Number of un-occupied Channels	22
Total Bandwidths Available	224 (MHz) 100(%)
Bandwidth in Active usage	48 (MHz)
Percentage of usage	21.4(%)
Unoccupied Bandwidth	176 (MHz)
Percentage of bandwidth free	78.6 (%)
Available Spectrum in Rural Areas	224 (MHz) 100%
Mean ($\bar{x}$) Signal power Active Channel	-69.18 dB
Standard Deviation	5.9034 dB
Standard Error	2.4100 dB
Mean ($\bar{x}$) Signal power Unoccupied Channel	-111.84 dBm
Standard Deviation	5.5283dB
Standard Error	1.1786 dB
TV Transmitter power (Pt)	30 Kw
Transmit Antenna gain (Gt)	12 dB
Transmit Antenna Hight (Ht)	30 m
Received Antenna gain (Gr) dB	12 dB
Received Antenna Hight (Hr) in meters	3.0 m

3.5 DISCUSSION

To start with, it is important to note that, the total spectrum within the span of the UHF TV band (470 – 694) MHz is 224 MHz. Each TV channel occupies bandwidth of 8MHz with a guard band or inter-channel spaccing of 8MHz in line with ITU, UHF TV channelization arrangement (ITU- R BT.2302) giving rise to 28 channels from channel 21– 48 as shown in table 2 above.

The data collected from Kano State shows the spectrum utilization status clearly with channel active labelled =1, and channels that are free labelled = 0, as presented in bar charts of figures 5 and 6 while figure 4 depicts the spectrum trace. The results obtained indicates that 6 channels are occupied active with spectrum occupancy rate of 21.4%, and spectrum utilization of 48MHz. These channels are (Channels 21, 23, 29, 32, 35, and 47). While the remaining 22 channels are free, making available 176 MHz spectrum of spectrum bandwidth representing (78.6%). Measurement result from Kura L.G.A suburban area 40Km away from Kano showed the same trend as in Kano city, except that, the signal amplitudes are attenuated due to environmental factor (Patt loss and fading). The spectrum trace, bar chart of the plot of signal power level against channel number, bar chart of the plot of occupancy status against channel number and raw data collected from Kura are presented in figures 8 and 9 and table 3 respectively.

Conversely, the result obtained from Gwarmai a rural area, 75Km away from Kano showes no trace of TV signal. Meaning, there is no active primary user of the spectrum, therefore spectrum utilization is zero, and all the spectrum 224MHz (100%) is available and free. This result also revealed large, portion of spectrum, which are ideal for high-throughput applications. The quantity of spectra identified are wide and sufficient to support modern broadband technologies most especially cognative radios. The spectrum trace is presented in figure 10 above.

Global evidence consistently demonstrates that the 470-694 MHz band is significantly underutilized across diverse geographical contexts. This underutilization ranges from approximately 80% in Nigeria’s studies to even higher figures in some international campaigns. The consistency of these findings across different regulatory domains, measurement methodologies, and geographical settings strongly supports the technical viability of TVWS deployment.

4. CONCLUSION

In conclusion this report has presented the outcome of literature review on global and local spectrum measurement campaigns and the spectrum utilization measurements results conducted in Kano State, Nigeria. The aim of the experimental measurement is to identify the availability of TVWS. Measurement campaigns across the globe, from the US and Europe to Asia and the Philippines, consistently shows that the radio frequency spectrum is severely underutilized, with average occupancy rates often falling below 20-30%. Local studies in Nigeria, across various states and frequency bands (including VHF, UHF, and FM radio), confirm that this global trend of underutilization applies equally to Nigeria. The results obtained from Kano State indicates six active channels (Channels 21, 23, 29, 32, 35, and 47) with a spectrum utilization of 48 MHz (21.4%), while 176 MHz (78.6%) remains unoccupied. A measurement conducted in the Kura Local Government Area (L.G.A.) suburban region showed a trend consistent with that observed in Kano city; however, the signal amplitudes are attenuated due to distance (40 km) and environmental factors.

Conversely, in the rural area of Gwarmai, situated 75 km from Kano, no discernible signal was detected. The absence of signal indicates a complete lack of active spectrum users, thereby resulting in a zero-spectrum utilization rate, with the entirety of the 224 MHz spectrum remaining available for deployment; clearly demonstrating that vast portion of allocated spectrum remain unused for significant periods. This unused capacity is known as "white space." Therefore, this result strongly validates the need for moving away from the inefficient static spectrum allocation model to dynamic Spectrum Access (DSA) to unlock the vast potential of this unused spectrum.

4.1 PROPOSED FUTURE RESEARCH DIRECTION

Spectrum measurement campaign has confirmed the existence of significant TVWS in Kano in the UHF TV band, with higher availability in rural areas. To leverage these opportunities the following are proposed for future research:

I. The results of various spectrum utilization measurements conducted across Nigerian states, point to the availability unoccupied TVWS, therefore, a nationwide measurement campaign should be conducted to develop a comprehensive TVWS database.
II. Artificial Intelligence Algorithm or technics should be developed for coordination and management of the TVWS database to allow interference free access of the spectrum by Cognatic Radio users.

ABSTRACT
Nigeria's freshwater crisis presents a stark paradox: a nation endowed with abundant water resources yet crippled by widespread household water insecurity. Drawing on survey data from 384 households across 21 wards in Bosso and Chanchaga Local Government Areas, this paper investigates the multi-dimensional nature of water insecurity at the household level. Our findings reveal that water insecurity manifests not merely as physical scarcity but as a complex interplay of infrastructural failure, economic burden, governance deficits, and gendered labour. Over 70% of households experience regular interruptions, with coping strategies that disproportionately burden women and children. Monthly water expenditures average ₦1,876 (weighted across all 21 wards; see Section 3.3 for ward-level variation), with 40% of households reporting moderate to severe cost burden. While 68% of respondents express distrust in public water quality, reliance on private boreholes and vendor-supplied water remains constrained by affordability and reliability. The paper argues for an integrated approach to water governance that moves beyond supply-side interventions to address the socio-economic and institutional dimensions of water insecurity. We propose a framework grounded in community participation, infrastructure modernization, and equitable pricing mechanisms.

Keywords: *Water insecurity; household survey; Nigeria; urban water governance; HWISE framework; water affordability*

1. INTRODUCTION

1.1 The Nigerian Water Paradox

Nigeria has never lacked water. Its rivers, aquifers and rainfall totals rank among the most generous in West Africa. And yet, for the ordinary household, water insecurity is a daily fact of life rather than a distant statistic. This is the paradox that scholars have documented extensively in recent years *(Irene, Irene & Daniels, 2025; Abubakar, 2019; Adeoti et al., 2024), with research finding that climate change and crumbling infrastructure have steadily worn down the country's freshwater systems, leaving many communities unable to count on a reliable supply (Abubakar Mashi et al., 2026; Igimoh et al., 2026).

A new household survey carried out across 21 wards in the Bosso and Chanchaga Local Government Areas of Niger State puts real numbers behind that picture. Researchers spoke with 384 households and tested 50 water samples, building on the Household Water Insecurity Experiences (HWISE) framework (Household Water Insecurity Experiences Scale, various authors), which treats water insecurity as more than a question of supply, it is also about whether water is accessible, affordable, safe and reliably available.

The framework matters because it has already been tested elsewhere. Studies in Mexico and Bangladesh have linked water insecurity to food insecurity within the same households (Shamah-Levy et al., 2025; HWISE Scale literature), suggesting that when the tap fails, the effects ripple outward into nutrition, income and daily routine. The Minna survey set out to test whether the same pattern of overlapping hardship holds true in a fast-growing Nigerian city.

What makes Minna a useful case is precisely its ordinariness. It is neither a megacity swamped by international attention nor a remote village studied purely for its rural character—it is the kind of mid-sized, rapidly urbanising state capital found across Nigeria, where population growth is outpacing the utilities and pipe networks built to serve it. That makes its findings a plausible mirror for dozens of similarly sized cities where nobody has yet run the numbers.

2. METHODOLOGY

2.1 Study Area and Sampling

The survey instrument was built around seven themes: household demographics, water source characteristics, interruption and coping patterns, physical access, economic burden, water quality and treatment, and governance perceptions. Field teams sampled households proportionally across the 21 wards, then followed up with descriptive and bivariate statistical analysis to see how demographic factors relate to water security outcomes—an approach the authors describe as examining "distributions of dimensions and themes, and water insecurity categories to assess what drives higher water insecurity scores."

$n = (Z^2 \times p \times q) / e^2$

Where:

- $Z = 1.96$ (95% confidence level)
- $p = 0.5$ (maximum variability, conservative estimate for household water insecurity prevalence)
- $q = 1 - p = 0.5$
- $e = 0.05$ (5% margin of error)

This yielded an initial sample of 384 households, which was then proportionally allocated across the 21 wards based on estimated population distributions. The total population of Bosso and Chanchaga LGAs is approximately 380,000, with the sample providing a 95% confidence level and ±5% margin of error. This approach follows established survey methodology for household studies in Nigerian urban settings (Ishaku & Kawu, 2023; Gidadawa et al., 2024).

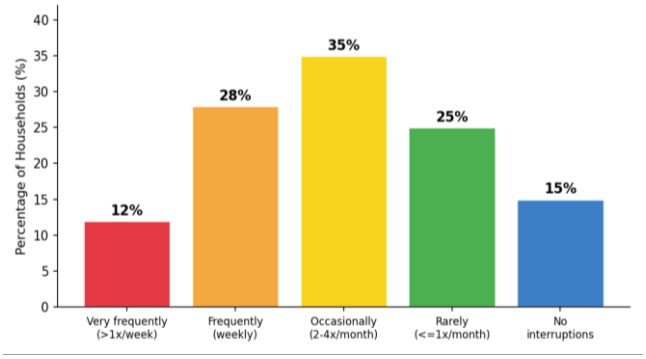
Sampling intensity varied by ward, from 11 households in Kodo to 28 in Sabon Gari and Tudun Wada South, the two wards that, as later sections show, also turn out to carry the heaviest burden of interruptions and distrust. Beyond the household interviews, the 50 accompanying water-quality samples give the survey a second, independent line of evidence: it isn't only asking people how safe their water feels, it is also checking what's actually coming out of the source.

Statistical Analysis: Analysis proceeded in two stages. First, descriptive statistics (frequencies, percentages, means) were calculated to characterise the distribution of water security experiences across the sample. Second, bivariate comparisons were conducted using chi-square tests to examine associations between demographic factors (ward location, gender of respondent, income bracket, education level) and water security outcomes. For continuous outcomes (e.g., monthly expenditure, interruption frequency), independent t-tests and one-way ANOVA were used. All statistical tests were performed using SPSS version 26, with statistical significance set at $p < 0.05$.

Water Quality Sampling: Laboratory water-quality testing was conducted on 50 samples collected from households across all 21 wards. Samples were analysed for turbidity, bacteriological counts (total coliform and E. coli), pH, electrical conductivity, and selected chemical parameters (nitrate, iron, fluoride) at the Niger State Ministry of Water Resources Laboratory. However, due to delays in laboratory data processing at the time of manuscript preparation, these results could not be included in the current analysis. The full laboratory dataset will be presented in a separate technical report and incorporated into future publications. The present paper focuses on self-reported/perceived water quality, which remains a valid measure of household experience and risk perception (Haeffner et al., 2023). Analysis then moved from simple description, how common is each experience, into bivariate comparisons that test whether factors like ward location, gender of respondent, or income bracket line up with worse water security outcomes.

3. FINDINGS AND DISCUSSIONS

3.1 Household Characteristics and Dependence on Alternative Water Sources



Nearly two-thirds of respondents, 63%, were women, a figure that itself speaks to who actually manages water in these households. Of all respondents, 42% were household heads and 28% were spouses, and 60% had at least a secondary education. On the supply side, the picture is telling: private boreholes (32%) and hand-dug wells (25%) were the most common water sources, well ahead of public utility connections, a sign of just how far households have had to go to compensate for gaps in formal infrastructure.

That last point is worth sitting with. In a well-functioning system, private boreholes and hand-dug wells would be a fallback, not the default. Here they are the backbone of household water supply for the majority of the sample, a quiet but telling admission that the public network people are nominally connected to isn't the one they actually depend on day to day.

3.2 Water-Supply Reliability and Frequency of Interruptions

Interruption is the norm rather than the exception. More than 70% of households reported at least one supply interruption in the past month, and 12% said interruptions happen more than once a week.

Figure 1: Frequency of Water Interruptions

Source: Field Survey (2026)

Coping with these gaps has a cost. Across the sample, 38% of households buy water from vendors or tankers when supply fails, 32% switch to an alternative source, and smaller shares store water in advance, cut back on use, or simply wait it out. But the response looks different from ward to ward.

Table 1: Coping Strategy by Ward (Top 5 Wards)

Ward	Vendor	Alt. source	Store	Reduce use	Wait
Sabon Gari (SAB)	42%	35%	20%	15%	18%
Tudun Wada South (TWS)	38%	30%	25%	20%	12%
Nassarawa A (NAA)	40%	28%	22%	18%	15%
Minna Central (MCT)	35%	32%	18%	22%	20%
Beji (BEJ)	30%	28%	25%	15%	10%

[Note: Percentages sum to >100% as households were able to select multiple coping strategies]

Source: Field Survey (2026)

Sabon Gari's heavy reliance on vendor water (42%) reflects just how thin public infrastructure is stretched there, while Beji's households lean more on storage (25%), perhaps a sign of better forward planning, or simply of fewer alternatives nearby. The pattern echoes findings from Mexico, where researchers reported that "the odds of water insecurity were lower in households with medium to high asset scores" (Shamah-Levy et al., 2025), underlining that coping capacity tracks closely with household wealth.

3.3 Household Water Expenditure and the Burden of Water Access

Paying for water is close to universal, and the amounts vary enormously, from nothing to more than ₦7,000 a month. On average, households spend ₦1,876 a month (weighted average across all 21 wards; see Table 3 for ward-level variation), a figure that lands hard on lower-income families: 35% describe the cost as a moderate burden and 15% call it severe. And this figure almost certainly understates the true cost, because it doesn't capture the hours spent fetching water, time that falls, overwhelmingly, on women and children.

3.4 Gendered Burden and Time Costs of Household Water Collection

Women and girls carry 65% of the water-fetching responsibility in these households; men and boys account for just 23%. It's a pattern that shows up across sub-Saharan Africa (Nyika & Dinka, 2023; Maungu, 2023), and one with consequences well beyond the well or borehole, it eats into time that could go toward schooling, paid work or rest. A quarter of households live within 100 metres of their water source, but one in five must travel more than 500 metres, and the average round trip takes 18 minutes.

Research from Mexico adds a further layer: Shamah-Levy et al. (2025) found that households with women of childbearing age face a measurably higher risk of water insecurity, which suggests the burden compounds for exactly the households least able to absorb it. While this relationship was observed in the Mexican context, testing this specific association within the Minna dataset would require additional analysis of household age-composition data. This represents an important direction for future research using the current dataset.

3.5 Perceived Water Quality, Safety and Household Treatment Practices

Only 35% of households report no problems at all with their water. The rest describe cloudiness or particles (28%), an odd smell (22%), or unusual colour (15%). Despite this, only 45% of households treat their water before use, and boiling at 38% is by far the most common method.

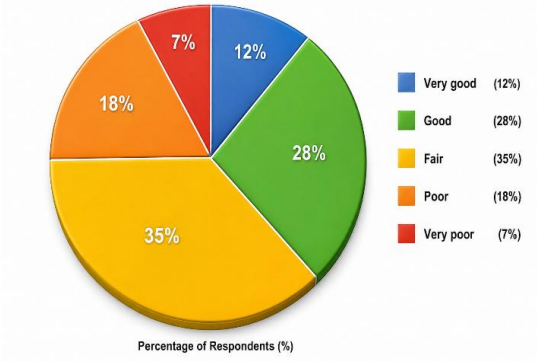


Figure 2: Water Quality Rating

Source: Field Survey (2026)

Distrust extends past water itself and into the institutions responsible for delivering it. Asked whether authorities respond quickly to problems, 57% disagreed. Half of all respondents are dissatisfied with how water is managed locally, and 48% distrust the quality of public sources altogether. Only 25% feel their community is meaningfully consulted on water decisions, while 47% feel excluded from decisions

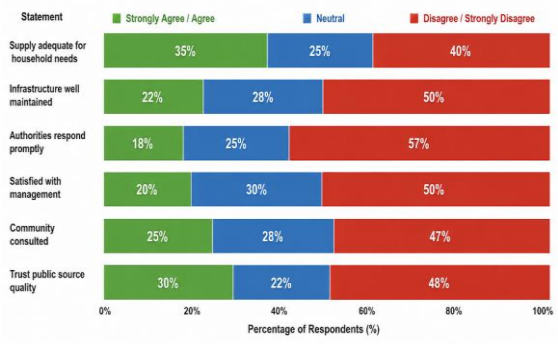

Figure 3: Governance Perceptions (Likert Scale)

Source: Field Survey (2026)

This pattern of institutional distrust sitting alongside physical scarcity mirrors research from rural Iseyin, Oyo State, which mapped villages with varying levels of vulnerability to water insecurity (Evaluating Water Scarcity Vulnerability Levels in Rural Communities of Iseyin Local Government Area, Oyo State, Nigeria, 2025). The Minna data suggests the same forces are at work in a rapidly urbanising setting, not just in rural communities.

It's worth pausing on what that combination of numbers actually means for a household. A family can be doing everything reasonably expected of it, boiling water, storing supply in advance, paying a vendor when the borehole runs dry, and still have good reason to doubt both the water itself and the system meant to guarantee it. Distrust here isn't a communication problem to be solved with a public-awareness campaign; it's a rational response to a track record of unmet promises.

3.6 Biggest Water Challenge

When asked, in their own words, to name their single biggest water challenge, respondents' answers map closely onto the survey's quantitative findings.

Table 2: Biggest Water Challenge (Top Open-Ended Responses)

Challenge	Share of respondents
Poor water quality / taste / odour	22%
Inadequate number of boreholes / taps	18%
High cost of water from vendors	16%
Water source dries up in dry season	15%
Frequent breakdown of boreholes	12%
Long distance to nearest source	10%

Source: Field Survey (2026)

Quality tops the list, followed by infrastructure gaps and cost, but the appearance of governance-related answers ("irregular public supply" and "lack of government intervention," 6% and 5% respectively) confirms that households experience this as an institutional failure, not just a technical or seasonal one.

3.7 Water Security Indicators by Ward

Aggregate numbers hide real differences between neighbourhoods. A ward-level comparison shows just how much local conditions shape the experience of water insecurity.

Table 3: Water Security Indicators by Ward (Selected Wards)

Ward	Interruptions	Pay for water	Monthly spend	Treat water	Trust public source
Beji (BEJ)	1.8 days/mo	80%	₦1,735	45%	30%
Sabon Gari (SAB)	2.1 days/mo	85%	₦2,450	40%	25%
Nassarawa A (NAA)	1.9 days/mo	82%	₦1,950	42%	28%
Tudun Wada South (TWS)	2.3 days/mo	78%	₦1,620	38%	22%
Minna South (MNS)	1.6 days/mo	75%	₦1,480	50%	35%

Source: Field Survey (2026)

The overall average of ₦1,876 is calculated as a weighted average across all 21 wards, not just the five shown in Table 3. The ward-level variation ranges from approximately ₦1,480 (Minna South) to ₦2,450 (Sabon Gari), with the overall average reflecting the population-weighted contribution of all wards.]

Sabon Gari and Tudun Wada South stand out for the worst outcomes, the most frequent interruptions and the least trust in public sources, while Minna South looks comparatively stable across nearly every indicator. That kind of spatial unevenness argues against one-size-fits-all fixes: what Sabon Gari needs is not necessarily what Minna South needs.

4. DISCUSSION AND CONCLUSION

Water insecurity is depicted as a multifaceted issue exacerbated by infrastructure failures, financial difficulties, gender disparities, quality concerns, and governance weaknesses. This aligns with broader studies in the Global South. In Sub-Saharan Africa, factors like climate variability, population density, and economic conditions influence household water access (Ogunbode et al., 2025; Nyika & Dinka, 2023), as seen in Minna, where failing public infrastructure forces poorer households to rely on costly and potentially unsafe private boreholes and wells.

The governance data shows that people want to engage but don't feel heard. Research from coastal Bangladesh suggests that better cooperation between central and local governments improves water governance (Charles et al., 2022). In this case, 57% of households believe official responses are slow, and 47% feel excluded from decisions. Additionally, 65% of households report water quality issues (as noted in Section 3.5), but less than half treat their water before drinking, indicating constraints that expose them to health risks they may not fully understand

4.1 Study Limitations

This research has several shortcomings that need attention. First, perception data, while useful for identifying household experiences, may be biased by memory and not match objective water quality data. Second, the study's cross-sectional approach only captures conditions at one time (2026), limiting insights into causality and seasonal changes in water availability. Third, sampling included 21 wards, but some had very few observations, with as few as 11 households in Kodo. Fourth, no data was collected on households lacking improved water sources, which may under-represent vulnerable populations. Lastly, although laboratory water quality test results were available, they could not be used due to processing delays.

4.2 Recommendations and Policy Implications

The survey emphasizes that water insecurity is a governance and equity issue, not just an engineering problem. It outlines four key priorities: First, enhance and expand public water infrastructure, especially in areas like Sabon Gari and Tudun Wada South that rely on costly private options. Second, create affordable water pricing through tiered tariffs and subsidies for low-income families facing high costs, particularly in Sabon Gari. Third, rebuild trust by improving response times and involving the community in decisions, as 47% feel excluded. Fourth, regularly monitor water quality and provide testing support to tackle reported problems. The approach varies for different areas.

4.3 Engineering and Technological Implications

The survey highlights key issues related to water access and governance that suggest important engineering solutions. Over 70% of people face interruptions in water supply, indicating a need for smart metering and real-time monitoring systems. Many rely on private boreholes and wells, creating a chance for low-cost treatment options like household filtration and solar-powered systems to enhance water quality. It also points out the need for decentralized water systems suited to local needs due to varying water security. Additionally, 40% of households face significant costs, signaling a need for innovative financing methods. Community engagement is essential for effective and sustainable solutions.

ABSTRACT

Reliable streamflow estimation and forecasting are essential for sustainable reservoir operation, irrigation planning, flood mitigation, and sustainable water resources management. This study evaluated the hydrological responses of the Kiri Watershed (41,516.46 ha) in Adamawa State, Nigeria, and projected future annual streamflow trends over a 20-year horizon (2023 - 2042). The Soil and Water Assessment Tool (SWAT) was calibrated (70% of the data) and validated (30% of the data) using hydro-meteorological inputs from 2000 to 2022 and daily observed streamflow records from the Tallum Hydrological Station. Spatial analysis revealed a watershed dominated by shrublands (90.40%) and loamy soils (55.22%), organized into 9 sub-basins and 44 Hydrologic Response Units (HRUs). SWAT demonstrated high predictive accuracy during both calibration (R^2 = 0.83, NSE = 0.79, RMSE = 0.64 m^3/s, MAE = 0.56 m^3/s, PBIAS = 2.50%) and validation (R^2 = 0.82, NSE = 0.73, RMSE = 0.52 m^3/s, MAE = 0.51 m^3/s, PBIAS = 7.58%), indicating close agreement between observed and simulated streamflow. Subsequently, a non-seasonal ARIMA (1,0,0) model was fitted to the aggregated annual streamflow time series. Diagnostic testing via the Ljung-Box test (Q = 4.9011, p = 0.2976) confirmed that the residuals behaved as white noise. The 20-year projection indicates a stable long-term mean annual discharge of approximately 6.0 m^3/s, with no significant upward or downward trend. The findings confirm that while average long-term water yield will remain steady, adaptive reservoir management strategies are necessary to mitigate historical inter-annual discharge fluctuations.

1.0 INTRODUCTION

Reliable streamflow estimation and forecasting are fundamental to sustainable water resources management because they support reservoir operation, irrigation planning, flood forecasting, and equitable water allocation among competing demands (Bodini, 2024; Yifru et al., 2024). The value of streamflow forecasting spans multiple temporal scales. Seasonal forecasts assist water managers in determining irrigation allocations and enable hydropower operators to optimize reservoir drawdown based on anticipated inflows (Ozcan et al., 2025). Long-term forecasts support irrigation development, agricultural water management, and hydropower planning, whereas short-term hourly and daily forecasts facilitate flood preparedness, emergency response, and early warning systems (Kumar et al., 2023). Consequently, reliable streamflow forecasting has become an indispensable component of integrated water resources management.

The benefits of streamflow forecasting have been widely demonstrated in reservoir operation and flood mitigation. Forecast-informed reservoir management using Ensemble Streamflow Prediction (ESP) and optimization techniques has significantly improved reservoir storage and operational efficiency while maintaining downstream flood safety (Anghileri et al., 2016; Delaney et al., 2020). Likewise, probabilistic inflow forecasts generated through Bayesian approaches have enhanced water supply reliability and reduced operational costs compared with deterministic forecasting methods (Guo et al., 2020). Accurate streamflow forecasts also enable reservoir operators to implement controlled pre-releases before major storm events, thereby reducing downstream flood

risks (Delaney et al., 2020; Zarei et al., 2021). Recent advances in machine learning and deep learning have further improved forecasting accuracy, with models such as Long Short-Term Memory (LSTM) achieving high predictive performance for reservoir inflows and flood events (Apaydin et al., 2020; Huang et al., 2025). Hybrid forecasting approaches that integrate physically based hydrological models with machine learning algorithms have demonstrated substantial improvements in prediction accuracy, particularly for extreme hydrological events and data-scarce basins (Bodini, 2024; Jia & Fang, 2025; Liu et al., 2024). Despite these advances, accurately forecasting streamflow under varying hydrological conditions remains a challenge, highlighting the need for approaches that combine physical watershed representation with robust statistical forecasting techniques (Yifru et al., 2024).

Among physically based hydrological models, the Soil and Water Assessment Tool (SWAT) is one of the most widely used for watershed-scale streamflow simulation. SWAT is a continuous-time, semi-distributed model that evaluates the impacts of climate, land use, soil characteristics, and management practices on watershed hydrology (Koltsida et al., 2023; Özdoğan-Sarıkoç & Dadaser-Celik, 2024; Saraf & Regulwar, 2024). The model discretizes a watershed into Hydrologic Response Units (HRUs) based on unique combinations of land use, soil type, and slope, enabling spatial simulation of runoff generation, infiltration, evapotranspiration, groundwater flow, and other hydrological processes (Özdoğan-Sarıkoç & Dadaser-Celik, 2024; Saraf & Regulwar, 2024). SWAT has been successfully applied across diverse climatic conditions, including arid, semi-arid, and tropical watersheds, and can effectively utilize remotely sensed climatic inputs where ground observations are limited (Akoko et al., 2021; Quamar et al., 2025).

Numerous studies have demonstrated the robustness of SWAT in streamflow simulation. Daily simulations in the Godavari River Basin achieved NSE values of 0.84 - 0.85 (Saraf & Regulwar, 2024), while studies in Ethiopia, Greece, and the Himalayas also reported satisfactory calibration and validation performance (Andiye & Lohani, 2024; Koltsida et al., 2023; Quamar et al., 2025). Beyond streamflow simulation, SWAT has been widely employed to evaluate climate change impacts, land-use change, watershed management practices, and hydrological responses in both gauged and ungauged basins (Aloui et al., 2022; Janjić & Tadić, 2023; Özdoğan-Sarıkoç & Dadaser-Celik, 2024). However, the model requires extensive hydro-meteorological and spatial datasets, and its calibration is computationally intensive (Janjić & Tadić, 2023; Yuan & Forshay, 2022). In addition, reliance on the Soil Conservation Service Curve Number (SCS-CN) method often introduces bias in low-flow simulations, while calibration procedures that emphasize flood characteristics may reduce predictive performance under low-flow conditions and during extreme events (Islam et al., 2023; Tao et al., 2024).

To complement these limitations, statistical time-series models have increasingly been integrated with physically based hydrological models. The Autoregressive Integrated Moving Average (ARIMA) model is one of the most widely applied stochastic forecasting techniques because it effectively captures temporal dependence in hydrological time series. Recent studies have increasingly coupled ARIMA with SWAT outputs to improve forecasting accuracy and extend predictions beyond the simulation period (Khorram & Jehbez, 2024). Such integration combines the physical representation of watershed processes provided by SWAT with the temporal predictive capability of ARIMA, thereby enhancing long-term streamflow forecasting.

The Kiri Watershed in northeastern Nigeria is an important catchment supporting reservoir operation, irrigation development, domestic water supply, and agricultural production. Despite its strategic importance, limited studies have integrated physically based hydrological modelling with statistical time-series forecasting to assess future streamflow behavior within the watershed. This study therefore integrates the SWAT and ARIMA models to simulate watershed hydrology and forecast annual streamflow over 20 years (2023 - 2042). Specifically, the study develops, calibrates, and validates a SWAT model using observed hydro-meteorological data, characterizes the watershed hydrological response, develops an ARIMA model based on the simulated annual streamflow series, and forecasts future streamflow to support adaptive reservoir operation and sustainable water resources management in the Kiri Watershed.

Beyond its hydrological application, the integrated SWAT–ARIMA framework provides an engineering-based decision-support approach for improving the assessment, planning, and sustainable utilization of Nigeria’s water resources. By combining physically based watershed simulation with

statistical streamflow forecasting, the framework can support more informed reservoir operation, irrigation planning, and climate-resilient water resources management. Its application to the Kiri Watershed therefore contributes to the conference theme, "Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development," particularly the sub-theme of Innovative Resource Utilization and Management, by demonstrating how engineering-based modelling and data-driven forecasting can enhance sustainable and resilient water resources management in Nigeria.

2.0 MATERIALS AND METHODS

2.1 The Study Area

The Kiri Dam is situated on the floodplain of the lower Gongola River Basin, approximately 25 km upstream of its confluence with the Benue River at Numan, within Shelleng Local Government Area of Adamawa State (Lat. 9°42′N; Long. 12°01′E). Constructed in 1982 on the Gongola River, the dam occupies a rift-related sedimentary depression formed through lithospheric thinning ((Whiteman, 1982)). The area experiences a tropical continental climate characterized by a single rainfall peak, typically in August or September. The wet season extends from April to October, with annual rainfall ranging between 510 and 1,040 mm, while the dry season lasts about seven months. Mean annual temperatures range from a minimum of about 18°C in December to a maximum of 38°C in March. Evapotranspiration rates are high throughout the year, and relative humidity varies seasonally, reaching 60 - 78% during the wet months and declining to 27 - 35% in the dry season. Kiri Dam serves multipurpose functions, including irrigation for a 12,000 hectare sugar estate, support for local agriculture and pilot irrigation schemes, fisheries development through Lake Kiri, domestic water supply to over 70 communities, and partial regulation of seasonal flooding along the Gongola River.

2.2 SWAT Model

The Soil and Water Assessment Tool (SWAT) is a physically based, semi-distributed, continuous-time watershed model widely used for simulating hydrological processes, sediment transport, and water quality under varying land-use, watershed management, and climate change scenarios (Douglas-Mankin et al., 2010; Dwivedi et al., 2024; Gassman et al., 2007). Developed by the United States Department of Agriculture (USDA) in the early 1990s, SWAT has evolved into one of the most extensively applied watershed models worldwide, with thousands of applications supporting hydrological research, watershed assessment, and water resources management (Aloui et al., 2022; Gassman et al., 2007; Janjić & Tadić, 2023).

SWAT simulates the hydrological cycle by dividing a watershed into sub-basins, which are further discretized into Hydrologic Response Units (HRUs) representing unique combinations of land use, soil type, and slope. This spatial discretization enables the model to account for the heterogeneity of watershed characteristics while simulating key hydrological components, including precipitation, surface runoff, infiltration, evapotranspiration, groundwater recharge, lateral flow, and streamflow generation. The model operates on a continuous daily time step, making it suitable for evaluating both short-term hydrological responses and long-term watershed behavior under different environmental and management conditions.

The hydrological simulation in SWAT is based on the principle of water balance, whereby the amount of water stored in the soil is continuously updated as the difference between incoming precipitation and outgoing hydrological fluxes. The soil water balance equation is expressed as:

$$SW_t = SW_0 + \sum_{i=t}^{t} \left(R_{day} - Q_{surf} - W_{seep} - E_a - Q_{gw}\right) \quad (1)$$

Where SWt is the humidity of the soil (mm), SW0 is the base humidity of the soil (mm), t is time (days), Rday is rainfall volume (mm), Qsurf is the value of surface runoff, Ea is the value of evapotranspiration (mm), Wseep is the value of seepage of water from the soil into deeper layers, Qgw is the value of underground runoff (mm).

The water balance equation forms the computational foundation of SWAT by quantifying the movement and storage of water within the watershed. Through continuous simulation of these

hydrological processes, the model estimates streamflow at the watershed outlet. Owing to its robust physical basis, spatial representation, and proven performance across a wide range of climatic and physiographic conditions, SWAT was selected in this study to simulate the hydrological behaviour of the Kiri Watershed and generate the streamflow series used for subsequent time-series forecasting.

2.3 Model Setup

2.3.1 SWAT Model Setup

The SWAT model was developed using a 30 m x 30 m Shuttle Radar Topography Mission (SRTM) Digital Elevation Model (DEM) (Figure 2a), land use/land cover data (Figure 2b), soil map (Figure 2c), and daily meteorological data comprising rainfall, maximum and minimum temperature, relative humidity, wind speed, and sunshine hours for the period 2000 - 2022. The watershed was delineated using the DEM, with the Tallum Hydrological Station defined as the watershed outlet, resulting in nine sub-basins. Hydrologic Response Units (HRUs) were subsequently generated by overlaying the land use, soil, and slope layers, producing a total of 44 HRUs after applying appropriate threshold values to eliminate insignificant land classes. The processed spatial and climatic datasets were integrated within the SWAT environment, and a warm-up period was incorporated to minimize the influence of initial conditions. Observed daily streamflow records from the Tallum Hydrological Station were used to calibrate (70%) and validate (30%) the model, while model performance was evaluated using the coefficient of determination (R^2), Nash–Sutcliffe Efficiency (NSE), Root Mean Square Error (RMSE), and Percent Bias (PBIAS).

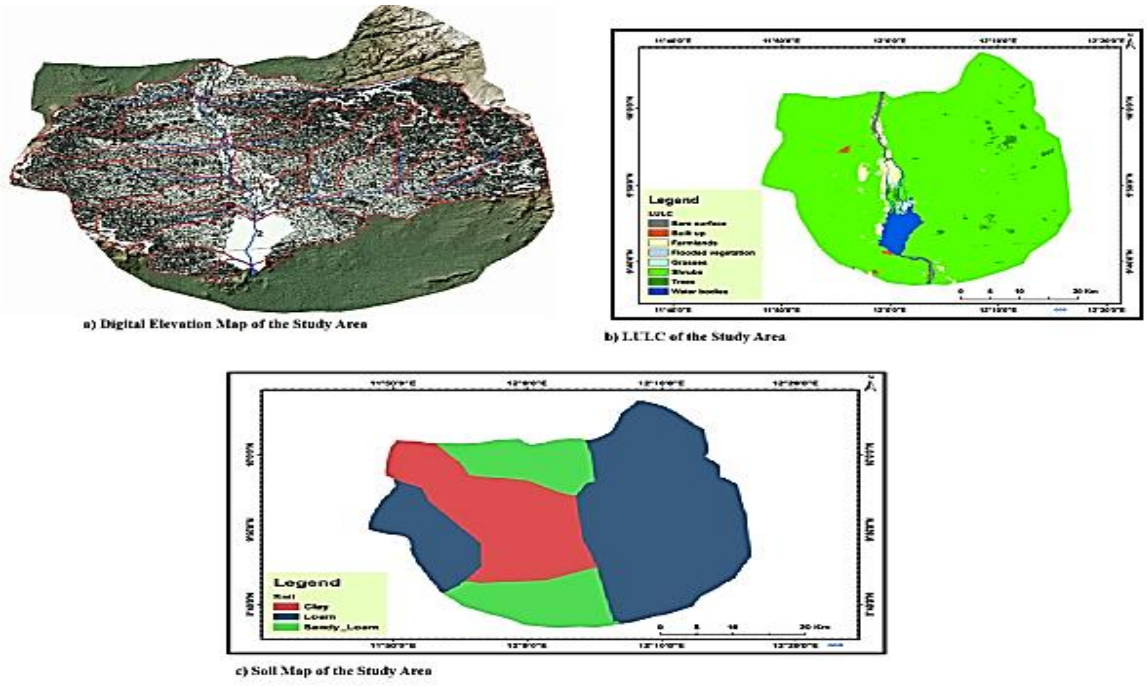

Figure 2: The Digital Elevation, Land Cover, and Soil Maps of the Study Area

2.3.2 ARIMA Model Setup

The daily streamflow data were aggregated into annual values to develop a long-term streamflow forecasting model for the 20-year planning horizon (2023–2042). Annual aggregation reduces the influence of short-term and intra-annual variability and provides a consistent temporal scale for assessing long-term changes in overall water availability. However, this aggregation also results in the loss of monthly and seasonal information, including within-year variations that may be important for operational applications such as irrigation scheduling and reservoir management.

A non-seasonal ARIMA model was therefore fitted to the annual streamflow series. The approach was intended primarily to characterize and forecast long-term annual water availability rather than to reproduce seasonal flow dynamics. The potential loss of intra-annual information is recognized as a limitation of the present approach. A Seasonal ARIMA (SARIMA) model based on monthly streamflow data could provide additional information on seasonal patterns and would be

particularly useful for future studies focusing on seasonal irrigation planning, reservoir operation, and flood management.

3.0 RESULTS AND DISCUSSION

3.1 Watershed Characteristics

The SWAT model successfully delineated the Kiri Watershed into nine (9) sub-basins with a total drainage area of 41,516.46 ha. The delineated stream network adequately represented the natural drainage pattern and provided the spatial framework for hydrological simulation. The watershed was further discretized into 44 Hydrologic Response Units (HRUs) by integrating land-use, soil, and slope data, enabling detailed representation of its spatial heterogeneity.

The land-use analysis (Table 1) revealed that the watershed is predominantly covered by shrubland (90.40%), followed by water bodies (3.30%) and farmland (2.61%). The extensive shrubland cover is expected to enhance infiltration and reduce surface runoff, while agricultural areas may locally influence runoff generation and sediment transport. Similarly, the dominant soil type is loam (55.22%), followed by clay (24.60%) and sandy loam (20.19%), indicating generally favorable infiltration and moderate water-holding capacity across the watershed (Table 1).

3.2 SWAT Model Performance

The SWAT model demonstrated satisfactory to good predictive performance during calibration and validation (Table 2). During calibration, the model achieved R^2 = 0.83, NSE = 0.79, RMSE = 0.64 m^3/s, MAE = 0.56 m^3/s, and PBIAS = 2.50%, while validation produced R^2 = 0.82, NSE = 0.73, RMSE = 0.52 m^3/s, MAE = 0.51 m^3/s, and PBIAS = 7.58%. According to the performance evaluation criteria of (Moriasi et al., 2007), NSE values greater than 0.75 indicate very good performance, while values between 0.65 and 0.75 indicate good performance. Similarly, PBIAS values within ±10% indicate very good model performance for streamflow simulations. The obtained NSE and PBIAS values therefore indicate very good performance during calibration and good to very good performance during validation. The relatively low MAE values (0.56 and 0.51 m^3/s) further indicate relatively small average absolute differences between observed and simulated streamflow. Overall, the performance statistics demonstrate that the calibrated SWAT model adequately reproduces the observed hydrological response of the Kiri Watershed.

Table 1: Land Use/Land Cover and Soil Distribution of the Kiri Watershed

Land Use/Land Cover	
LULC Class	**%**
Water bodies	3.3
Trees	1.59
Grasses	0.1
Flooded vegetation	0.29
Farmlands	2.61
Shrubs	90.4
Built up	0.29
Bare surface	1.41
Total	100
Soil Type	
Soil Type	**%**
Loam	55.22
Clay	24.6
Sandy Loam	20.19
Total	100

Table 2: SWAT Calibration and Validation Performance Statistics

Performance Indicator	Calibration	Validation
R^2	0.83	0.82
NSE	0.79	0.73
RMSE (m^3/s)	0.64	0.52
MAE (m^3/s)	0.56	0.51
PBIAS (%)	2.50	7.58

The comparison between observed and simulated annual streamflow further demonstrated that the model successfully reproduced the temporal variability of streamflow throughout the study period. The simulated hydrograph closely followed the observed pattern, including the high-flow event recorded in 2019. Although minor underestimation and overestimation occurred in a few years, the overall agreement remained satisfactory, indicating that the calibrated model reliably represents the watershed hydrology. Regression analysis also confirmed strong linear relationships between observed and simulated streamflow during both calibration and validation, consistent with the high coefficients of determination obtained.

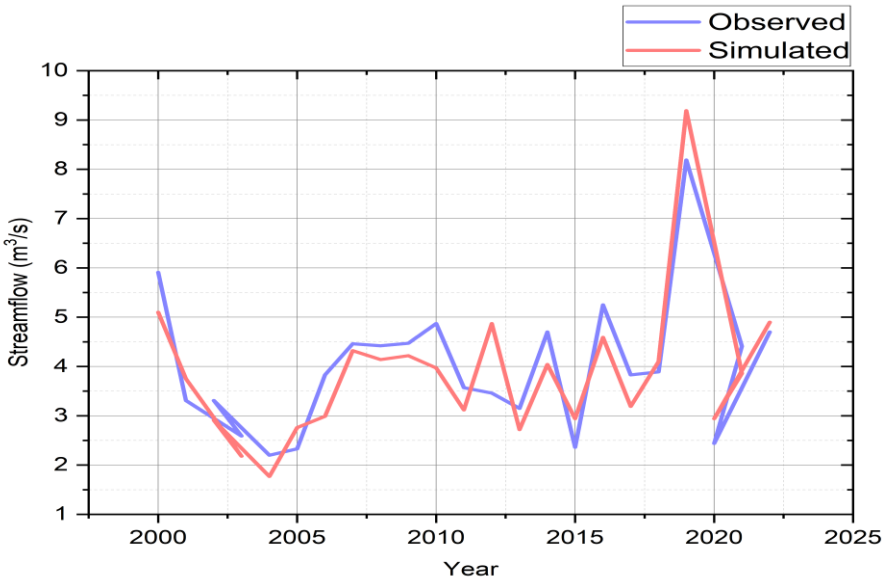

Figure 3: Observed and Simulated Annual Streamflow (2000 - 2022)

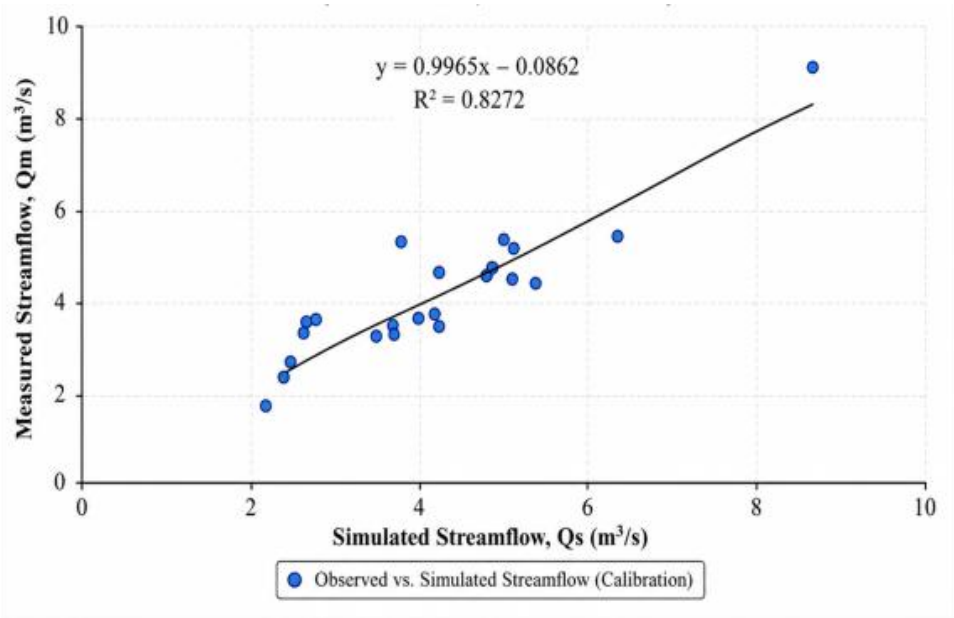

Figure 4: Calibration Scatter Plot of Measured and Simulated Streamflow

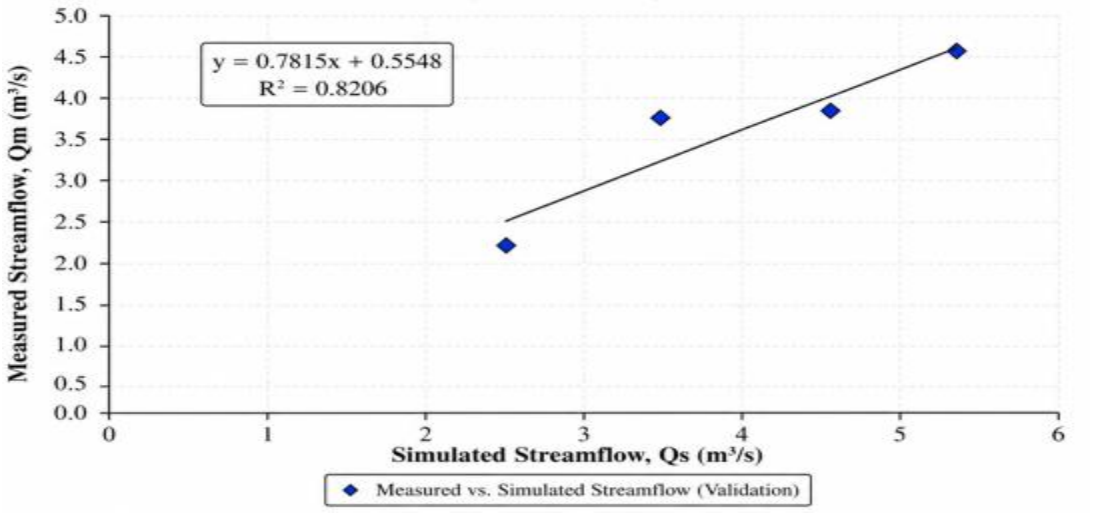

Figure 5: Validation Scatter Plot of Measured and Simulated Streamflow

3.3 ARIMA Streamflow Forecasting

The annual streamflow series for 2000–2022 was analysed using non-seasonal ARIMA models. Candidate models, including ARIMA(0,0,0), ARIMA(1,0,0), ARIMA(1,0,1), and ARIMA(2,0,1), were fitted and compared using the Akaike Information Criterion (AIC), corrected AIC (AICc), Bayesian Information Criterion (BIC), and forecast accuracy measures. Forecast performance was assessed using time-series cross-validation based on rolling forecast origins to provide an out-of-sample assessment of predictive accuracy.

The comparison of candidate models is presented in Table 3. Although ARIMA(0,0,0) produced the lowest AIC, the ARIMA(1,0,0) model provided a better balance between model parsimony and predictive performance, as indicated by its comparatively lower out-of-sample forecast errors. The ARIMA(1,0,0) model produced an RMSE of 1.320 m³/s, MAE of 0.980 m³/s, and MAPE of 27.18%. The model was therefore selected for forecasting based on its combined forecasting performance, information criteria, and diagnostic adequacy.

Table 3: Comparison of candidate ARIMA models

Candidate model	AIC	AICc	BIC	RMSE (m^3/s)	MAE (m^3/s)	MAPE (%)	Decision
ARIMA (0,0,0)	**82.36**	82.96	83.58	1.48	1.13	31.42	Rejected
ARIMA (1,0,0)	**82.72**	**83.36**	**84.04**	**1.32**	**0.98**	**27.18**	**Selected**
ARIMA (1,0,1)	83.91	85.18	85.52	1.39	1.04	28.76	Rejected
ARIMA (2,0,1)	85.21	87.43	87.02	1.44	1.09	30.15	Rejected

The selected ARIMA(1,0,0) model was subsequently subjected to residual diagnostic testing. The residual autocorrelation function and Ljung–Box test (Figure 6) were used to confirm that no significant serial dependence remained in the residuals before generating forecasts for 2023–2042.

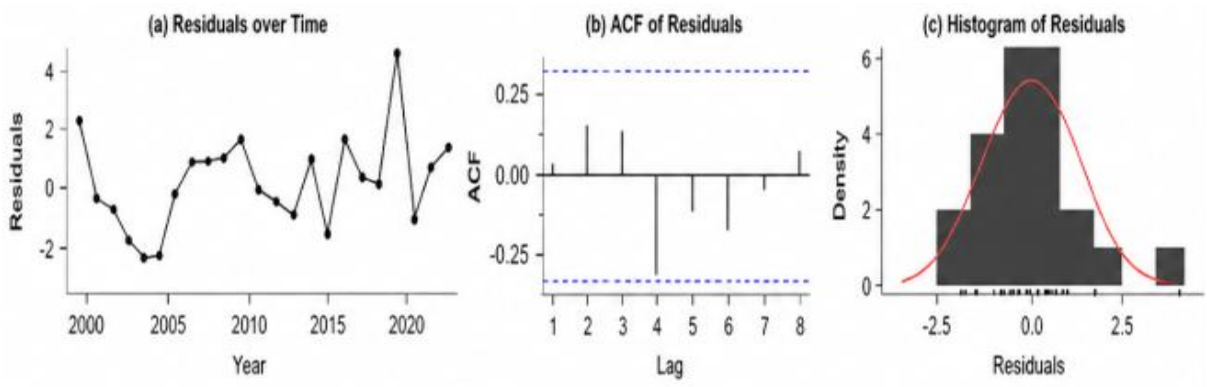

Figure 6: The residual time series, autocorrelation function (ACF) of the residuals, and the residual histogram

The validated ARIMA (1,0,0) model was subsequently used to forecast annual streamflow for the period 2023–2042 (Figure 7). The forecasts indicate that annual discharge is expected to remain relatively stable, with a long-term mean of approximately 6.0 m^3/s and no statistically significant increasing or decreasing trend over the forecast horizon. As expected, the 80% and 95% prediction intervals widen progressively with time, reflecting increasing uncertainty associated with long-term forecasting. While the long-term mean streamflow is projected to remain stable, the historical record suggests that inter-annual variability is likely to persist, implying that individual years may still experience above- or below-average flows.

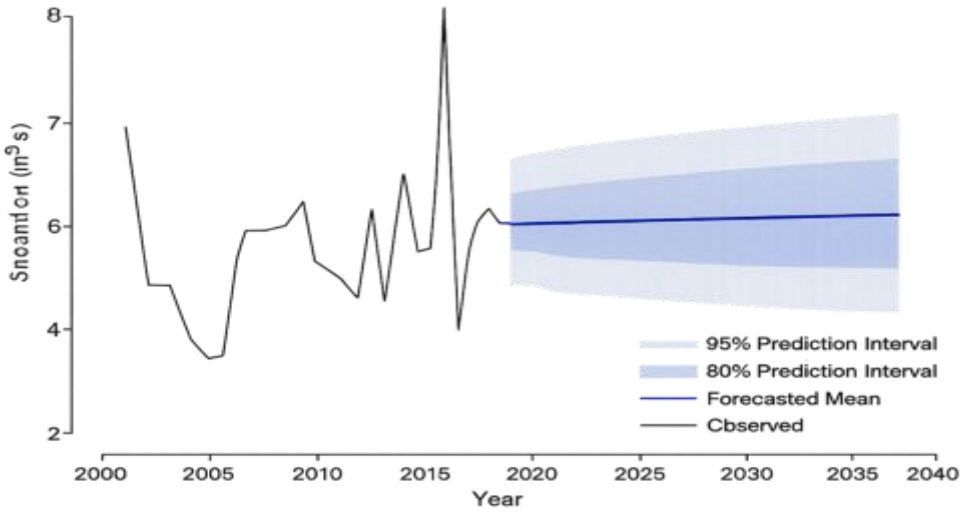

Figure 7: Forecasted Annual Streamflow Using ARIMA

3.4 Implications for Water Resources Management

The combined SWAT and ARIMA modelling framework provide valuable information for long-term water resources planning in the Kiri Watershed. The projected stability in average annual streamflow suggests that current water availability is likely to remain adequate for reservoir operation and irrigation planning under prevailing climatic conditions. However, the continued occurrence of inter-annual variability highlights the need for adaptive reservoir operation and flexible irrigation scheduling to accommodate periods of relatively high and low streamflow. Regular updating of forecasting models using newly observed hydrological data will further improve forecast reliability and support sustainable water resources management within the watershed.

It is important to note that the forecasts developed in this study are based on annual streamflow and therefore describe long-term changes in overall water availability rather than intra-annual flow dynamics. Consequently, the results should be interpreted primarily as information for strategic water resources planning rather than as a direct basis for monthly irrigation scheduling or short-term reservoir operation. Future research should incorporate monthly streamflow data and evaluate Seasonal ARIMA (SARIMA) or other seasonal/hybrid forecasting approaches to capture within-year variability and provide more operationally relevant forecasts.

4.0 CONCLUSION

This study integrated the Soil and Water Assessment Tool (SWAT) and the Autoregressive Integrated Moving Average (ARIMA) model to simulate the hydrological behavior of the Kiri Watershed and forecast annual streamflow over the period 2023–2042. The SWAT model successfully represented the watershed hydrological processes, with satisfactory calibration and validation performance (R^2 = 0.83 and 0.82; NSE = 0.79 and 0.73, respectively), demonstrating its suitability for streamflow simulation within the study area. The watershed characterization further showed that the catchment is dominated by shrubland and loamy soils, which significantly influence runoff generation and infiltration processes.

The ARIMA (1,0,0) model adequately captured the temporal characteristics of the annual streamflow series, with residual diagnostics confirming the statistical adequacy of the model. Forecast results indicate that the Kiri Watershed is likely to maintain a relatively stable mean annual discharge of approximately 6.0 m^3/s over the next two decades, with no significant long-term increasing or decreasing trend. However, the historical inter-annual variability suggests that fluctuations in annual streamflow are likely to persist despite the overall stability in average water availability.

The integrated SWAT–ARIMA framework demonstrated in this study provides a practical approach for combining physically based hydrological simulation with statistical time-series forecasting to support long-term water resources planning. The findings provide useful information

for adaptive reservoir operation, irrigation water allocation, and sustainable watershed management within the Kiri Watershed. Future studies should investigate the combined effects of climate change and land-use change on streamflow dynamics and evaluate advanced hybrid forecasting approaches, including machine learning techniques, to further improve long-term predictive accuracy.

The study also demonstrates the relevance of integrated hydrological and statistical modelling to Nigeria's sustainable development agenda. The SWAT–ARIMA framework provides an engineering-based decision-support tool for improving water availability assessment, reservoir management, and irrigation planning, thereby contributing to innovative resource utilization and management. Its application to the Kiri Watershed demonstrates how engineering innovation and data-driven modelling can support more resilient and sustainable water resources management in Nigeria, consistent with the conference theme, "Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development."

ABSTRACT

Nigeria's agricultural sector employs over a third of the national workforce yet remains largely rain-fed, poorly monitored, and vulnerable to climate variability, post-harvest loss, and inefficient input use. Precision agriculture built on the Internet of Things (IoT) has demonstrated potential to improve yield efficiency and reduce resource waste, but its adoption in rural Nigerian communities is constrained by unreliable grid electricity and the prohibitive cost of maintaining battery-powered sensor networks across dispersed farmland. This paper proposes and analyzes a hybrid solar-photovoltaic and radio-frequency (RF) energy harvesting framework that powers batteryless, edge-intelligent soil and microclimate sensor nodes for smallholder farms. The framework combines a low-power photovoltaic (PV) harvesting front end with an ambient RF/backscatter harvesting subsystem to sustain sensing, local inference, and long-range low-power wide-area network (LPWAN) transmission without disposable batteries or grid dependence. A lightweight edge-intelligence layer performs on-node anomaly detection to minimize radio duty cycling and reduce energy demand. A subsystem-level analytical energy budget, referenced to a 3.3 V rail, estimates an average node power draw of a few hundred microwatts, with supercapacitor leakage explicitly included. System architecture, energy-budget analysis, and a phased deployment methodology suited to Nigerian rural infrastructure are presented, alongside a discussion of manufacturing localization, cost, spectrum-regulatory compliance, and policy pathways. The framework is intended to support maintenance-light, indigenously buildable monitoring infrastructure with potential to improve data-driven farm management and create local technical employment in sensor assembly, calibration, and network operations.

Keywords: *energy harvesting; batteryless IoT; RF backscatter; precision agriculture; edge intelligence; sustainable development*

1. INTRODUCTION

Sustainable national development in Nigeria depends heavily on modernizing agriculture, which remains a major source of employment and a critical determinant of food security (National Bureau of Statistics [NBS], 2017). Despite this, smallholder farmers, who cultivate the majority of Nigeria's arable land, continue to rely on visual inspection and experience-based judgement rather than data-driven decision-making for irrigation timing, fertilizer application, and pest management. The consequence is chronic yield gaps, water waste, and avoidable crop loss that ripple through the national economy as food-price volatility and import dependence.

The Internet of Things (IoT) has repeatedly demonstrated, in both developed and developing agricultural economies, the capacity to close this information gap through networks of low-cost sensors that continuously report soil, weather, and crop-health parameters to a central platform for analysis and alerting (Ojha, Misra, & Raghuwanshi, 2021). The barrier to replicating this success in Nigeria is not sensing technology itself, but power. Grid electricity does not reliably reach the majority of Nigerian farmland, and disposable or rechargeable batteries impose a recurring cost and maintenance burden that is economically unworkable across the hundreds of nodes a meaningful monitoring network requires.

This paper addresses that constraint directly. It proposes an engineering framework in which each sensor node harvests its own operating energy from two locally abundant and complementary sources, ambient solar irradiance and ambient or dedicated radio-frequency (RF) energy, combined with an edge-intelligence layer that minimizes energy-hungry radio transmissions. The contribution of this work is threefold: (i) a hybrid harvesting architecture and voltage-referenced energy budget suited to Nigerian solar and RF conditions; (ii) an edge-intelligence duty-cycling strategy that reduces the energy cost of communication, the most power-intensive node function; and (iii) a phased deployment and local-manufacturing methodology designed around Nigeria's technical, economic, and infrastructural realities, so that the framework is a buildable national asset rather than a laboratory proof of concept.

2. BACKGROUND AND RELATED WORK

2.1 Energy Harvesting for Wireless Sensor Networks

Solar-powered wireless-sensor-network (WSN) nodes are well established for outdoor deployments, but single-source solar designs remain vulnerable to multi-day cloud cover, dust from harmattan conditions, and canopy shading (Williams, Torquato, Cameron, Fahmy, & Sienz, 2021; Sudevalayam & Kulkarni, 2011). Vullers, van Schaijk, Doms, Van Hoof, and Mertens (2009) showed that even centimetre-scale photovoltaic (PV) cells can sustain duty-cycled microcontroller loads provided the power-conditioning stage does not consume a large share of the harvested surplus, a decisive point for batteryless nodes whose sub-milliwatt load makes microampere-scale quiescent draw a first-order loss. RF energy harvesting, including ambient backscatter communication, has separately been shown capable of powering ultra-low-power sensing largely independent of weather (Liu et al., 2013), though reported ambient power in rural, tower-distant settings typically falls in the nanowatt-to-low-microwatt range (Kim et al., 2014; Zungeru, Ang, Prabaharan, & Seng, 2012), making RF a trickle complement rather than a primary supply.

2.2 Hybrid Harvesting and Edge Intelligence

Hybrid harvesting, combining two or more ambient sources through a shared power-management integrated circuit (PMIC), smooths the intermittency of any single source because solar and RF availability are largely decorrelated in time (Williams et al., 2021). The practical cost is power-management complexity: a dual-input PMIC must arbitrate sources of very different voltage and current characteristics while keeping its own quiescent overhead low (Vullers et al., 2009; Kansal, Hsu, Zahedi, & Srivastava, 2007). Separately, radio transmission is consistently identified as the largest energy cost in a WSN duty cycle (Williams et al., 2021; Kansal et al., 2007), motivating edge intelligence, in which lightweight inference models run directly on constrained microcontrollers so that only actionable results are transmitted; the tinyML community has formalized benchmarking practice for exactly this class of workload (Banbury et al., 2020, preprint). Combining hybrid harvesting with on-node inference, rather than treating them as separate research threads, is the specific gap this paper addresses.

2.3 IoT-Enabled Precision Agriculture and the Research Gap

Precision agriculture built on networked sensing has an extensive evidence base in developed economies, where grid power and technician access are largely assumed rather than engineered around (Ojha et al., 2021; Friha, Ferrag, Shu, Maglaras, & Wang, 2021). A joint assessment by the Food and Agriculture Organization and International Telecommunication Union (2022) across 47 Sub-Saharan African countries found digital-agriculture adoption concentrated in donor-funded pilots rather than sustained, farmer-financed deployments, with unreliable rural electricity and recurring battery-replacement cost named among the most common reasons pilots fail to scale. Reviewed individually, solar harvesting, RF/backscatter harvesting, hybrid power management, and edge intelligence are each reasonably mature; what is missing, and what this paper contributes, is their combination into a single, voltage-referenced, leakage-inclusive design specifically budgeted for the solar and RF conditions, cost constraints, and deployment logistics of Nigerian smallholder farmland.

3. PROPOSED SYSTEM AND METHODOLOGY

3.1 System Architecture

The proposed node architecture comprises four functional layers: a dual-source energy-harvesting front end, a power-management and storage stage, a sensing and edge-intelligence compute stage, and a low-power wide-area communication stage, as shown in Fig. 1.

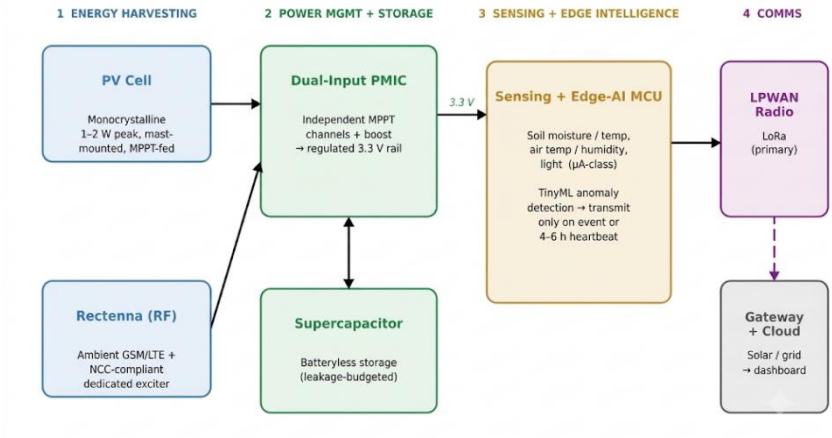

Figure 1: *Batteryless hybrid solar–RF agricultural monitoring node: dual-source harvesting, supercapacitor storage, on-node edge inference, and event-driven LPWAN uplink.*

The solar subsystem uses a small monocrystalline PV cell (1–2 W peak) mounted above the crop canopy, feeding a maximum-power-point-tracking (MPPT) charge stage chosen for low quiescent current; a simpler direct-charge path serves as a fallback where MPPT overhead would approach the harvested surplus under low irradiance. The RF subsystem uses a rectenna tuned to ambient GSM/LTE bands as a supplementary trickle source; in low-signal areas, a low-cost dedicated exciter co-located at the gateway provides a supplementary RF source, operating within the equivalent-isotropically-radiated-power limits and licence-exempt conditions set by the Nigerian Communications Commission (NCC, 2003). Both sources are merged through a dual-input PMIC into a regulated 3.3 V rail feeding a supercapacitor rather than a chemical battery, eliminating replacement and disposal; supercapacitor self-leakage is included explicitly in the energy budget rather than neglected.

Each node integrates capacitive soil-moisture, soil- and ambient-temperature, humidity, and light sensors selected for microampere-range operating currents. A microcontroller with a low-power neural-network accelerator runs a lightweight tinyML anomaly-detection model that flags soil-moisture stress or abnormal microclimate signatures; the node transmits only when the model flags a condition, or on a coarse scheduled heartbeat, which is the principal mechanism keeping average power draw within the harvestable budget. The 4–6 h heartbeat interval shown in Fig. 1 is chosen as a conservative upper bound on the time between updates an extension officer needs for irrigation and pest-risk decisions under normal conditions; because the heartbeat, rather than the event-triggered path, sets the guaranteed minimum transmit rate, it is also the primary lever for keeping the LPWAN radio-transmit contribution in Table 1 near its lower bound, with event-triggered transmissions adding to that baseline only when the edge model flags a condition. Communication uses LoRa for its low transmit-energy per message; a solar-plus-optional-grid gateway, far fewer in number than the nodes, aggregates data over cellular backhaul to a dashboard accessible to extension officers and cooperative managers.

3.2 Energy Budget Analysis

The core constraint of a batteryless design is that average harvested power must meet or exceed average consumed power, including storage leakage, over a representative operating cycle. Because the present study is at the framework and design stage, the budget below is an analytical estimate based on component-level operating ranges rather than the output of a completed simulation or prototype. Table 1 summarizes the node energy budget, referenced to the regulated 3.3 V rail.

Table 1: *Node energy budget (referenced to a 3.3 V rail).*

Node Subsystem	Active Current	Duty Cycle	Avg. Power @3.3 V
Sensor suite (soil, temp/humidity, light)	0.3–1.0 mA	~1%	~10–33 µW
Edge-inference MCU (active compute)	4–8 mA	<0.5%	~66–132 µW
MCU sleep/idle state	2–5 µA	~98%	~7–16 µW
LPWAN radio transmit burst	30–120 mA	<0.1%	~100–400 µW
Harvesting/PMIC quiescent overhead	10–20 µA	Continuous	~33–66 µW
Supercapacitor leakage	10–50 µA	Continuous	~33–165 µW
TOTAL (average)	~75–245 µA	—	~250–810 µW

Based on the component-level ranges and engineering assumptions summarized in Table 1, the projected average node power consumption is approximately 0.25–0.8 mW at the regulated 3.3 V rail. The estimate includes sensor, processing, radio, power-management, and supercapacitor-leakage contributions. On an engineering-estimate basis, this projected load is substantially below the nominal peak output of the proposed 1–2 W PV source; however, actual energy sufficiency will depend on irradiance, canopy shading, dust, conversion losses, RF-harvesting yield, and storage losses. The ambient RF subsystem is therefore treated as a supplementary source rather than the primary energy supply. These values represent a design-stage energy budget and have not yet been experimentally validated. Because leakage is comparable to the load, the supercapacitor is sized from the net (harvest-minus-leakage) surplus rather than from nominal harvest current alone.

3.3 Phased Deployment Methodology

Deployment proceeds in four phases. Phase 1, bench validation, characterizes the harvesting front end and trains the edge model on locally collected soil and microclimate data at a university research farm. Phase 2, pilot cluster, deploys 10–20 nodes across a single cooperative farm cluster, paired with extension-officer dashboard training, to validate energy sufficiency and inference accuracy across a full cropping season. This range is selected as a practical pilot size that permits deployment across a single cooperative farm cluster while remaining sufficiently large to observe node-to-node variation in canopy shading, soil type, and RF signal strength within the cluster, providing a spread of operating conditions for validating inference accuracy before committing to the larger capital and logistics outlay of Phase 3. Phase 3, cooperative-scale rollout, expands to a full cooperative or local government area, incorporating feedback on mechanical housing durability, livestock interference, and gateway placement. Phase 4, local manufacturing transition, partners with Nigerian electronics-assembly capacity, including university engineering workshops, to localize PCB assembly, antenna fabrication, and enclosure production, reducing per-node cost and import dependence.

4. DISCUSSION AND IMPLICATIONS

4.1 National Impact and Alignment with the Conference Theme

Continuous, low-cost soil and microclimate monitoring closes the information gap identified in Section 1: the precision-agriculture literature consistently associates timelier, data-informed irrigation and input decisions with reduced water waste and improved yield consistency relative to calendar-based scheduling (Ojha et al., 2021; Friha et al., 2021). Because the proposed framework reduces dependence on grid electricity and recurring battery replacement, it could extend digital-agriculture monitoring to

smallholder cropland where conventional powered networks are difficult or costly to maintain, with implications for national food-price volatility and import dependence that scale with the phased rollout of Section 3.3.

Reliable grid electricity does not reach most Nigerian farmland, and the Rural Electrification Agency's own capital-project reporting indicates that closing this gap through conventional grid extension remains a multi-year, capital-intensive undertaking rather than a near-term certainty (Rural Electrification Agency [REA], 2024). Because the proposed node requires neither grid connection nor battery replacement, it decouples digital-agriculture adoption from the pace of electrification rollout, consistent with the energy-access priorities documented jointly by the Food and Agriculture Organization and International Telecommunication Union (2022). The framework also touches several Sustainable Development Goals simultaneously: affordable and clean energy (SDG 7) through reliance on ambient renewable sources; responsible consumption and production (SDG 12) through reduced dependence on recurring battery use and associated waste; industry, innovation, and infrastructure (SDG 9) through the local-manufacturing pathway of Section 3.3; and zero hunger (SDG 2) through anticipated yield and input-efficiency gains.

4.2 Economic Scalability and Local Capacity

The phased local-manufacturing transition is the primary lever for reducing per-node cost over time, compressing the import duties, shipping, and currency-conversion overheads on imported sensor and radio modules as production scales from tens of units in Phase 2 toward hundreds or low thousands in Phase 3. Eliminating recurring battery-purchase and replacement logistics further shifts the node's cost profile from a recurring operating expense toward a one-time capital expense, easier for cooperatives and financing partners to plan around. Localizing PCB assembly, antenna fabrication, and enclosure production also builds domestic RF, photovoltaic, and embedded-systems expertise transferable well beyond agriculture, and each deployment phase creates rural technical employment in calibration, maintenance, and assembly. As a rough order-of-magnitude planning estimate rather than a costed bill of materials, imported-component sourcing at Phase 2 pilot volumes is estimated at approximately $25–35 (about ₦33,750–₦47,250 at a reference planning rate of ₦1,350/$) per node, inclusive of estimated freight, applicable duties and import charges, and currency-conversion costs, with the local-manufacturing transition of Phase 4 projected to reduce this toward approximately $15–20 (about ₦20,250–₦27,000) per node as deployment scales beyond Phase 3 volumes by substituting domestically assembled PCBs, antennas, and enclosures for imported equivalents; these figures should be treated as planning estimates to be refined once Phase 2 procurement data and applicable Nigerian import tariff classifications are available, not as validated costings. The estimate does not constitute a detailed bill of materials and excludes project-level costs such as gateway infrastructure, installation, field labour, testing equipment, software development, and long-term maintenance.

4.3 Limitations

The energy budget in Section 3.2 is derived from component-level datasheet ranges and engineering estimates rather than from a simulated, prototyped, or field-measured system, so the projected multi-day autonomy remains an unvalidated design target rather than a demonstrated performance result. RF harvesting yield is highly location-dependent and marginal far from cellular infrastructure, necessitating the NCC-compliant exciter fallback of Section 3.1, which adds gateway-side cost. Supercapacitor storage exhibits self-leakage comparable to the node load and capacitance fade at elevated ambient temperatures common in Nigeria, so multi-year node lifetime is bounded by temperature-derated ageing rather than open-ended. Mechanical durability of externally mounted PV and antenna elements against dust, humidity, livestock, and theft requires robust, low-cost enclosure design, and edge-model accuracy depends on training data representative of local soil types and crop varieties. Sustained adoption also depends on extension-service capacity to act on the data produced; the technology is necessary but not sufficient without complementary agricultural-advisory infrastructure.

5. CONCLUSION

This paper has proposed a hybrid solar–RF energy-harvesting framework for batteryless, edge-intelligent agricultural monitoring nodes designed around the infrastructural and economic conditions of rural Nigeria. A voltage-referenced analytical energy budget suggests an average node draw of a few hundred microwatts when radio bursts and supercapacitor leakage are included. This projected load is substantially below the nominal peak rating of the proposed 1–2 W PV source, but actual energy sufficiency remains to be established through simulation, prototype testing, and field measurements. By combining complementary harvesting sources with on-node inference intended to reduce the energy cost of communication, the framework is designed to reduce the recurring power and maintenance burden associated with conventional battery-dependent precision-agriculture IoT deployments. The phased deployment and local-manufacturing methodology further provides a pathway for the technology to mature from a research prototype into a domestically buildable national asset, supporting food security, energy justice, local industrial capacity, and rural technical employment simultaneously. Key limitations include the absence of prototype and field validation of the energy budget, location-dependent RF yield, temperature-related supercapacitor ageing, and dependence on complementary extension-service capacity. Future work will report field-validated energy-harvest yields, supercapacitor-ageing data, and edge-model accuracy from the Phase 1–2 deployments described in Section 3.3.

ABSTRACT
Modification of forward and reverse Electric Motor Starters is designed to reduce the numbers of Electrical component used in conventional Electric Motor Starters. The modified forward and reverse Direct-On-Line Starter is designed to use one Contactor, one Start Push Button, one Stop Push Button, one Miniature Circuit Breaker, one Control Breaker, one Overload Relay and Three-Phase Selector Switch. The modified forward and reverse Star/Delta Starter is designed to be implemented with two Contactors, one Start Push Button, one Stop Push Button, one Timer Relay, one Miniature Circuit Breaker, one Control Breaker and one Three-Phase Selector Switch. The designed Circuit diagrams are then subjected to test by using a software called CADe-SIMU to simulate the circuit diagrams. The modification reduces the cost of number of Contactors and some other Electrical components used as well as reducing the cross-sectional area of the Electrical panel.
Keywords: *Contactors; Overload Relay; Timer Relay; Forward and Reverse*

1.1 Introduction

Electric Motor Starters incorporate some Electrical components with safety devices to start the operation of the Electric Motor. There are two major types of such Starters, namely, Direct-On-Line Starter and Star/Delta Starter. The Electric Motor is either connected as Star or Delta at the Electric Motor terminals when using the DOL Starter. The Star/Delta Starter is another type of Electric Motor Starter having three Contactors, one Overload Relay, one Timer Relay, one Miniature Circuit Breaker, one Control Breaker, Indicating lamps and Push Button Switches. The three Contactors are tagged as Main Contactor, Star Contactor and Delta Contactor. If the Timer Relay is set at ten seconds, the Main Contactor and the Star Contactor are energized simultaneously for ten seconds. After ten seconds the Star Contactor disengage to give way to the Delta Contactor and the Main Contactor to continue the operation of the Electric Motor (Ifiok, 2024). The Star/Delta Starter is for soft starting of the Electric Motor. Changing the direction of Three-Phase Induction motor is carried out by interchanging two of the three phases.

2.1 Brief review of similar work

Forward and reverse operation of Electric Motor DOL Starter is realized with two contactors (Uduak Okoa, 2024). One Contactor for forward movement while the other Contactor for the reverse movement. The Control and Power line diagrams are as shown in figure 1.0.

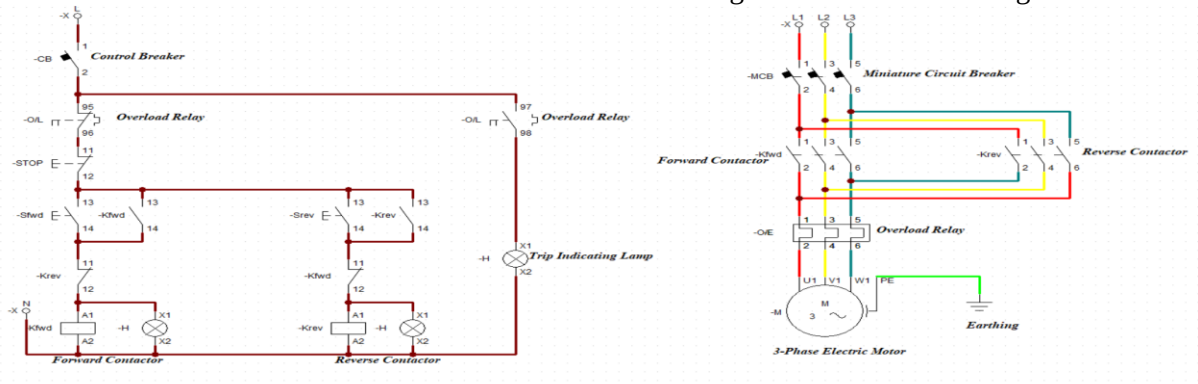

Figure 1.0: Forward and reverse Motor Starter

The software CADe-SIMU (CADe-SIMU Version 4.2, 2024) was used to draw and simulate the circuit diagrams. The result of the simulation for the forward operation is as shown in figure 1.1. If the forward Contactor is energized, the reverse Contactor remains open because the NC Contact from the forward Contactor which is connected in series with reverse Contactor coil is opened. Similarly, If the reverse Contactor is energized, the forward Contactor remains open because the NC Contact from the reverse Contactor which is connected in series with forward Contactor coil is opened. These operations were tested with the software and it works satisfactorily. The present research work is to use one Contactor, one Start Push Button and other electrical components to achieve the same aim.

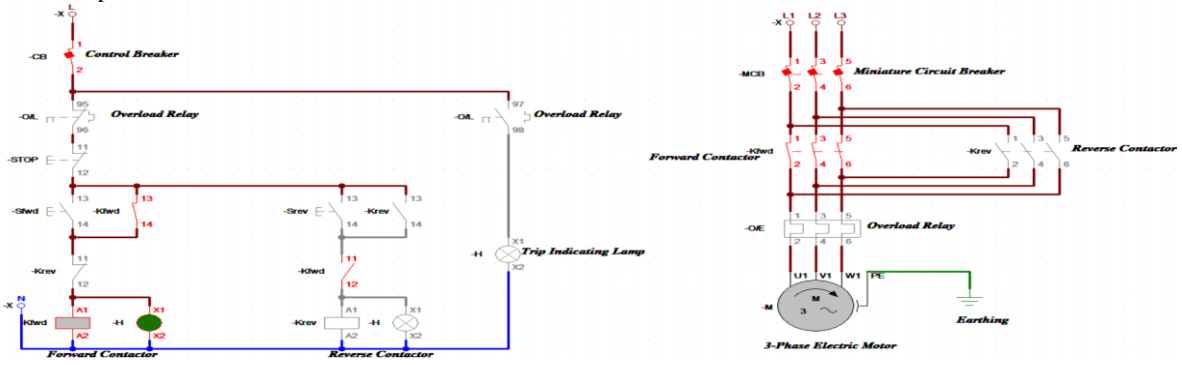

Figure 1.1: Forward and reverse Motor Starter (forward mode operation)

The result of the simulation for the reverse operation is as shown in figure 1.2

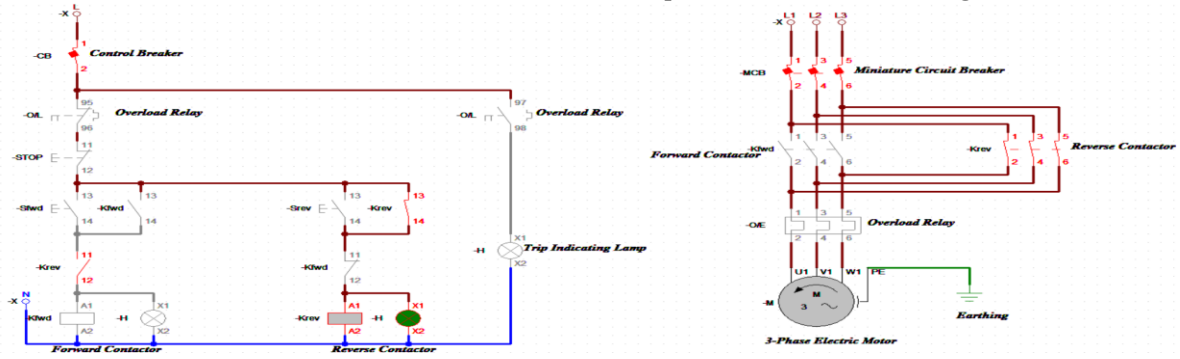

Figure 1.2: Forward and reverse Motor Starter (reverse mode operation)

The conventional Star/Delta Starter forward and reverse operation involves four contactors, one Overload Relay, one Timer Relay, one Miniature Circuit Breaker, one Control Breaker, Indicating Lamps and Push Button Switches. Use of Arduino Based Star/Delta Starter with forward and reverse control is equally another research work (Nigar Sultana, 2023). The Control and Power line diagrams are as shown in figure 1.3. The present research work is to use just two Contactors, one Start Push Button with other electrical components to realize the operation of the forward and reverse Star/Delta Starter. The starting torque and starting current in Delta connection is higher than that of Star connection (Jayswal, 2018).

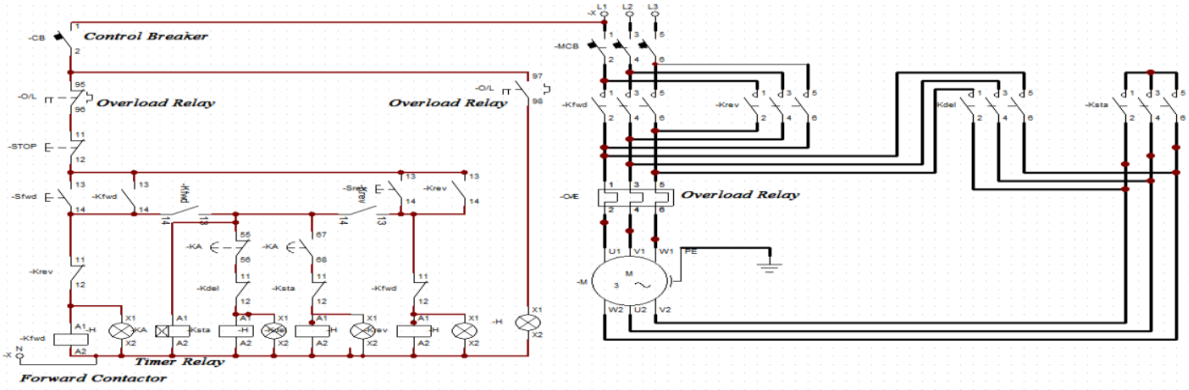

Figure 1.3: Control and Power line diagrams of forward and reverse Star/Delta Starter

The result of the simulation of the circuit diagram in forward Star mode is as shown in figure 1.4

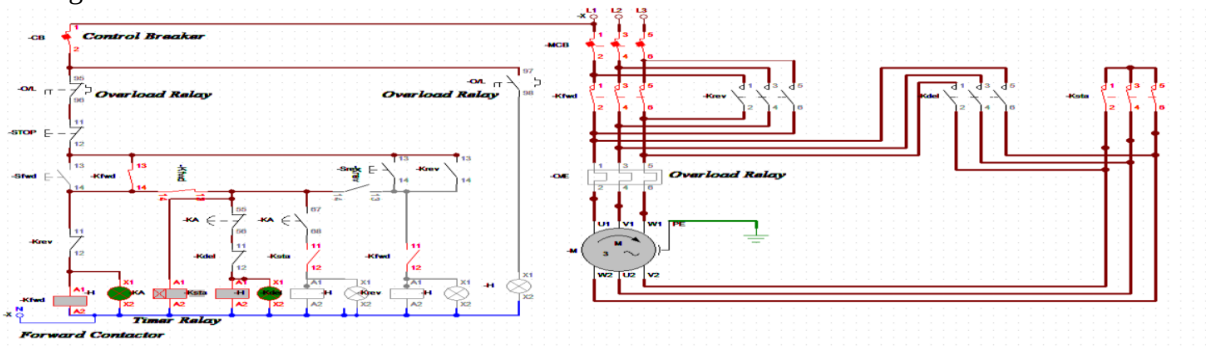

Figure 1.4: Control and Power line diagrams of forward and reverse Star/Delta Starter (forward Star mode)

The result of the simulation of the circuit diagram in forward Delta mode is as shown in figure 1.5

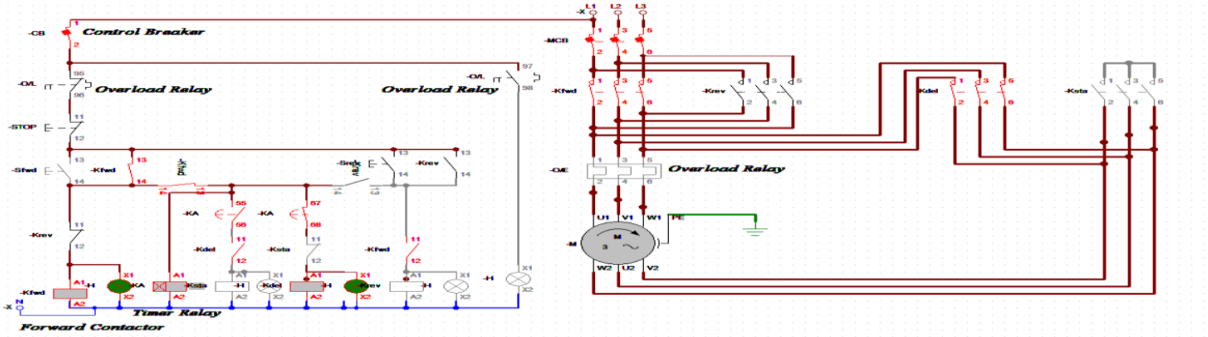

Figure 1.5: Control and Power line diagrams of forward and reverse Star/Delta Starter (forward Delta mode)

The result of the simulation of the circuit diagram in reverse Star mode is as shown in figure 1.6

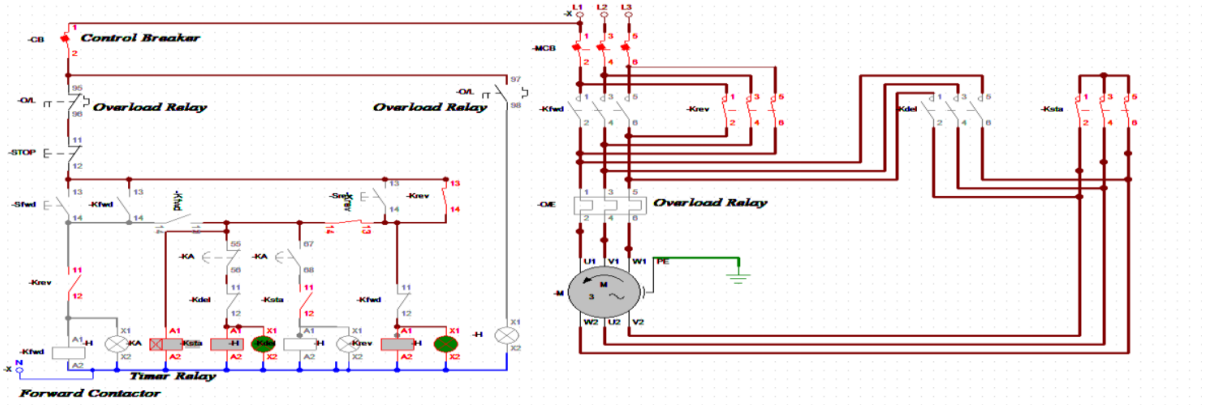

Figure 1.6: Control and Power line diagrams of forward and reverse Star/Delta Starter (reverse Star mode)

The result of the simulation of the circuit diagram in reverse Delta mode is as shown in figure 1.7

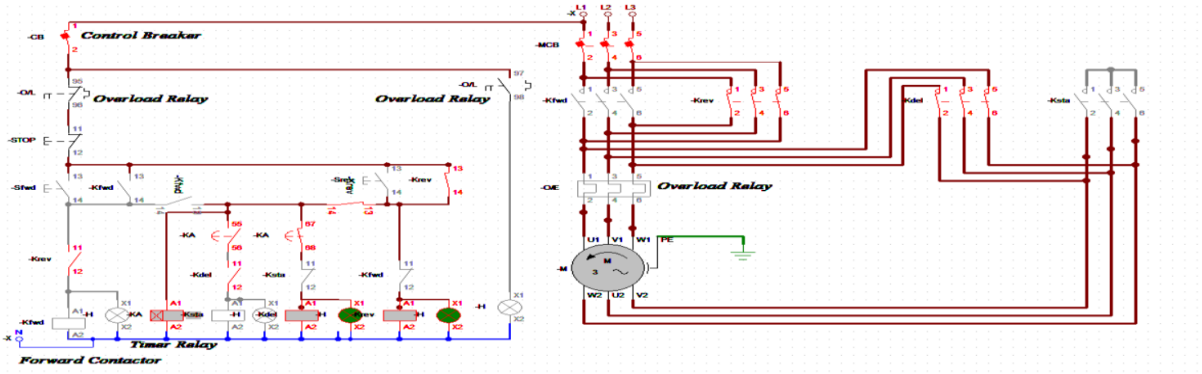

Figure 1.7: Control and Power line diagrams of forward and reverse Star/Delta Starter (reverse Delta mode)

Use of relays to realize the operation of Star/Delta Starter is another research work carried out by (Ayibapreye, October, 2022). This idea is practically not realizable on Electric Motors of high power capacity. Safety measures like Miniature Circuit Breaker and Overload Relay were excluded in the research work. The idea of Star connection and then Delta connection is to reduce the inrush starting current (Apoorva, June, 2017).

The connection involving three Contactors with other Electrical Components is as shown in figure 1.8.

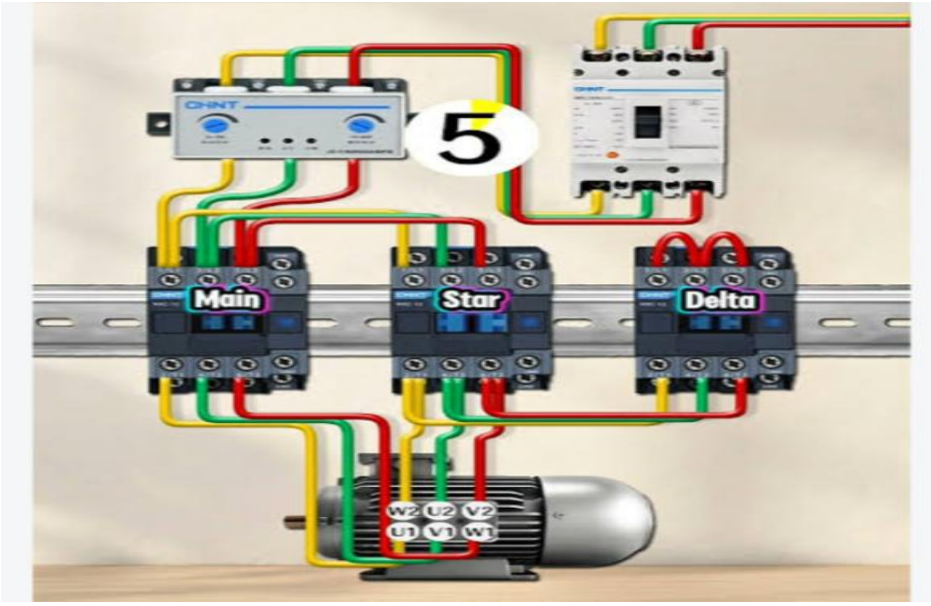

Figure 1.8: Star/Delta Starter

2.2 Problem Statement

Forward and reverse operation of Electric Motor in Industries is very vital in some product processing. The change of direction in three-phase induction Motor is realized by changing two of the phases. Hence there is need to make such changing more flexible and within the shortest period of time. Reducing the number of Electrical components will not only save cost but as well reduces the space within the Electrical panel.

2.3 Aim & Objective

The aim of this research work is to demonstrate implementation of Electric Motor Starters by reducing the numbers of Contactors involved.

3.1 Methodology

The conventional forward and reverse Starter incorporates two Contactors, one Overload Relay, one Miniature Circuit Breaker, one Control Breaker, two Start Push Buttons, one Stop Push Button and Indicating lamps. The modification is the utilization of such operation with just one Contactor, one Overload Relay, one Selector Switch, one Start Push Button, one Stop Push Button and Indicating Lamps. One contactor performs both the forward direction and the reverse direction. The change of direction is carried out on the Selector Switch. When changing the direction of the Electric Motor, the Operator must make sure the Stop Push Button on the Control Circuit is pressed.

The major reason for such step is to avoid arching within the Three-Phase Rotary Contacts. A position is OFF position while the remaining two positions are configured to change the sequence of the 3-Phase power supply.

The conventional forward and reverse Star/Delta Starter involves four Contactors, one Overload Relay, one Timer Relay. This research work is to use just two Contactors, namely, Star Contactor and Delta Contactor. The forward and reverse operations are configured on the Selector Switch with three positions. The Selector Switch is as shown in figure 2.0.

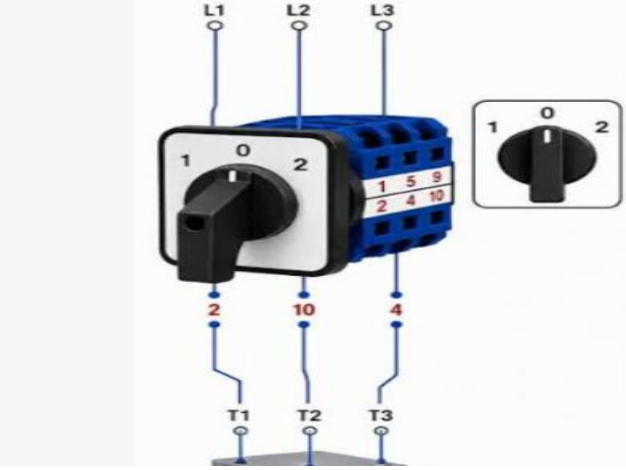

Figure 2.0: 3-Phase Selector Switch

4.1 Result

The results of modifications as carried out are as displayed as follows;

4.1.1 Modified forward and reverse DOL Starter

The operational mode of the modified forward and reverse Electric Motor Starter in forward direction is as shown in figure 2.1. When the Start Push Button is engaged as shown on the Control line diagram of figure 2.1 the Contactor is energized. The power supply to the Electric Motor terminal is obtained through the Three-Phase Selector Switch.

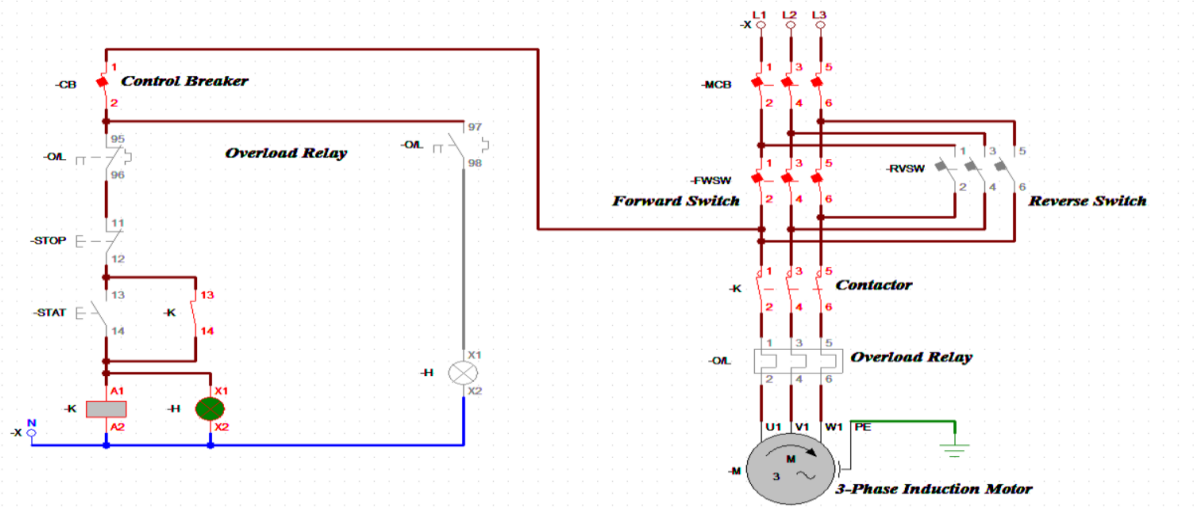

Figure 2.1: The operational mode of the Electric Motor in forward direction.

The operational mode of the modified Electric Motor Starter in reverse direction is as shown in figure 2.2.

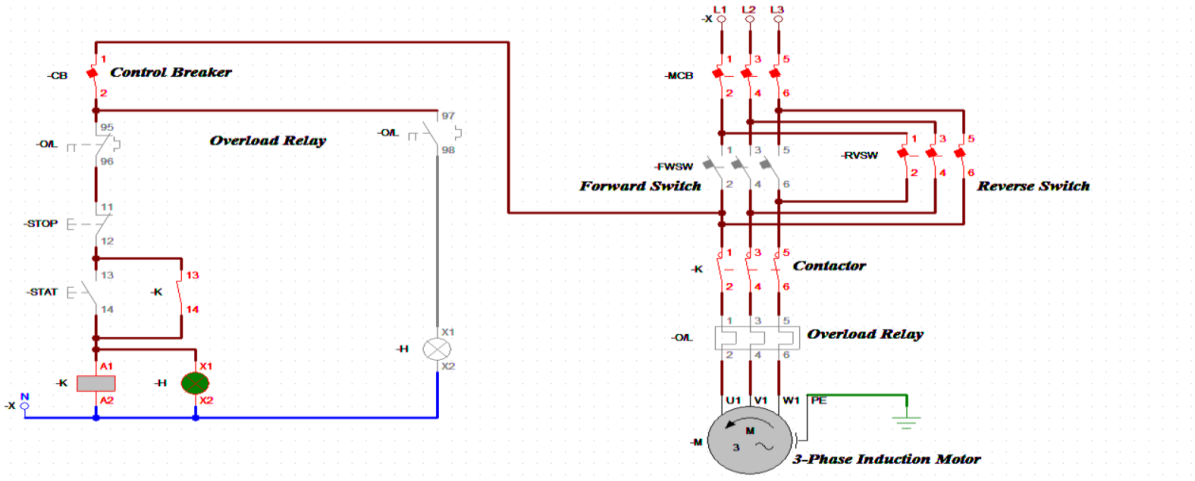

Figure 2.2: The operational mode of the modified Electric Motor Starter in reverse direction.

The diagram in figure 2.3 illustrates the connection of the Three-Phase Rotary Switch to implement the phase reversal.

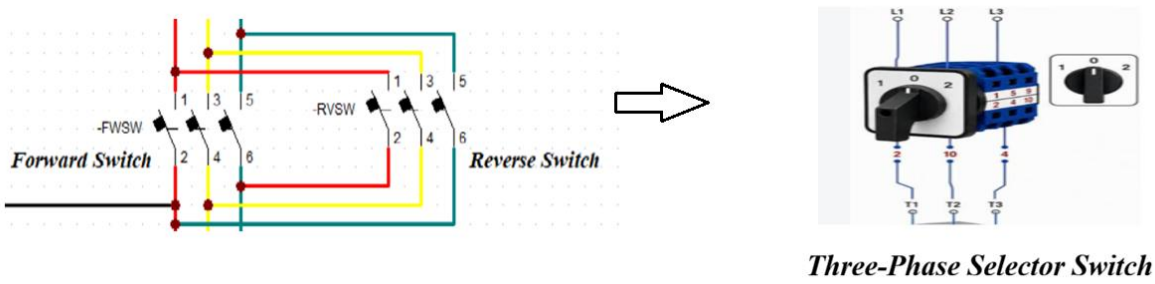

Figure 2.3: Diagram for the Three-Phase Selector Switch

The incorporation of Three-Phase Selector Switch for the modified Forward and reverse DOL is as shown in figure 2.4. the Selector Switch has three positions. Position labelled as ‘0’ is the OFF position. Position labelled as ‘1’ is to be connected power supply as Red, Yellow and Blue. This position ‘1’ is for forward direction. Position labelled as ‘2’ is to be connected to power supply as Red, Blue and Yellow. This position ‘2’ is for the reverse direction.

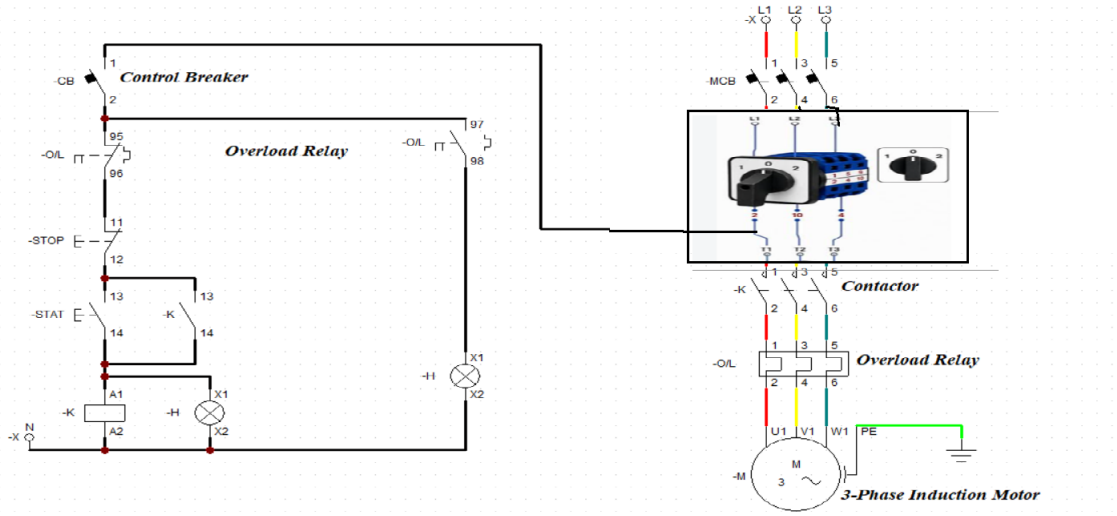

Figure 2.4: Use of Three-Phase Selector Switch for the modified Starter.

Safety

The safety measure when using the Selector Switch is to tap supply to the Control Breaker from the Contactor Main Contact. With this type of connection, the Contactor will only be energized via the Start Push Button when the Selector Switch is ON. The Main Circuit Breaker and the Overload Relay if well selected will protect the entire Circuit against any envisaged short circuit that might occur when the 3-Phase Selector Switch is operated.

4.1.2 Modified forward and reverse Star/Delta Starter

The control line diagram for the Modified Forward and reverse Star/Delta Starter is as shown in figure 2.5. The NC Contact and NO Contact of the Timer Relay are connected to the Star Contactor and Delta Contactor respectively to avoid operating the two contactors at the same time.

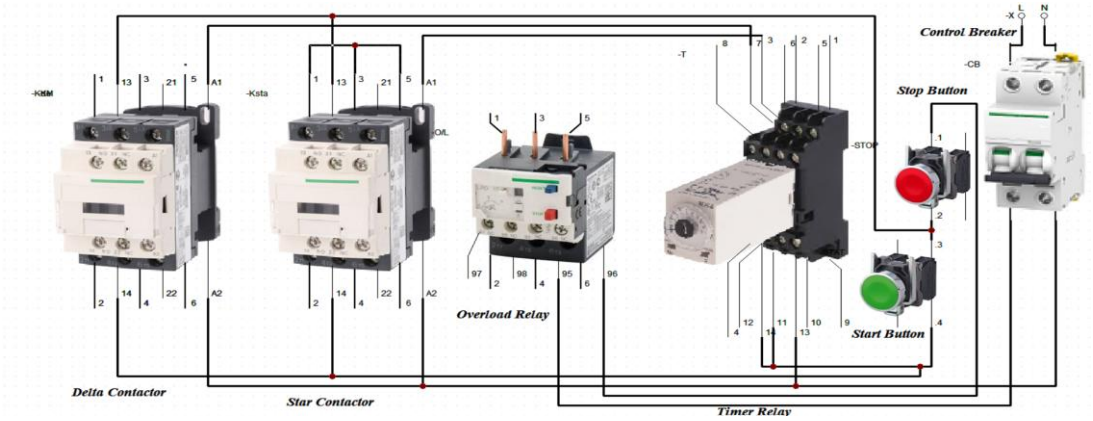

Figure 2.5: Control line diagram for the Modified Forward and reverse Star/Delta Starter

The operation of the control line diagram for the Modified Forward and reverse Star/Delta Starter in Star mode is as shown in figure 2.6. The Normally Close (NC) Contact of the Timer Relay labelled as terminal '3' is linked to the Star Contactor while the Normally Open Contact (NO) of the Timer Relay labelled '7' is linked to the Delta Contactor.

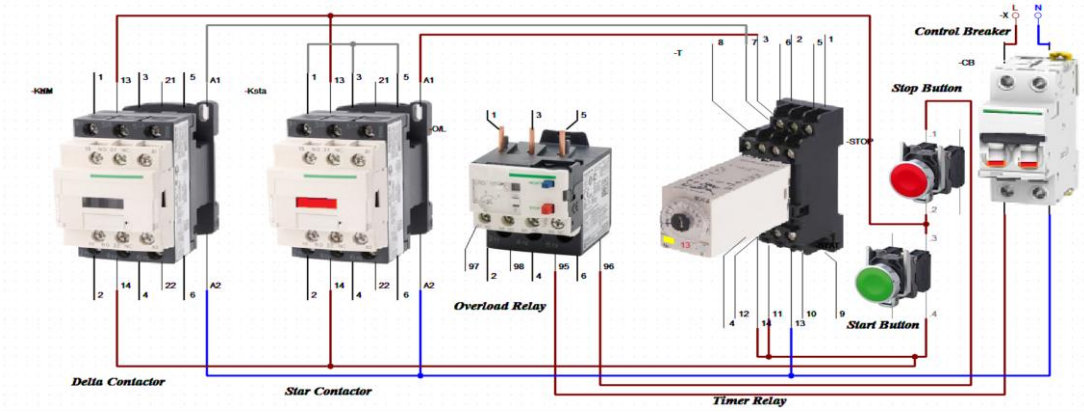

Figure 2.6: Control line diagram for the Modified Forward and reverse Star/Delta Starter (Star mode operation or simulation)

The operation or simulation of the control line diagram for the Modified Forward and reverse Star/Delta Starter in Delta mode is as shown in figure 2.7. The Normally Open (NO) Contact of the Timer Relay labelled as terminal '7' is now supplying current to the Delta Contactor. Under normal condition the NC and NO Contacts of the Timer Relay are neither close nor open simultaneously. That is, when the NO Contact is closed the NC Contact is opened.

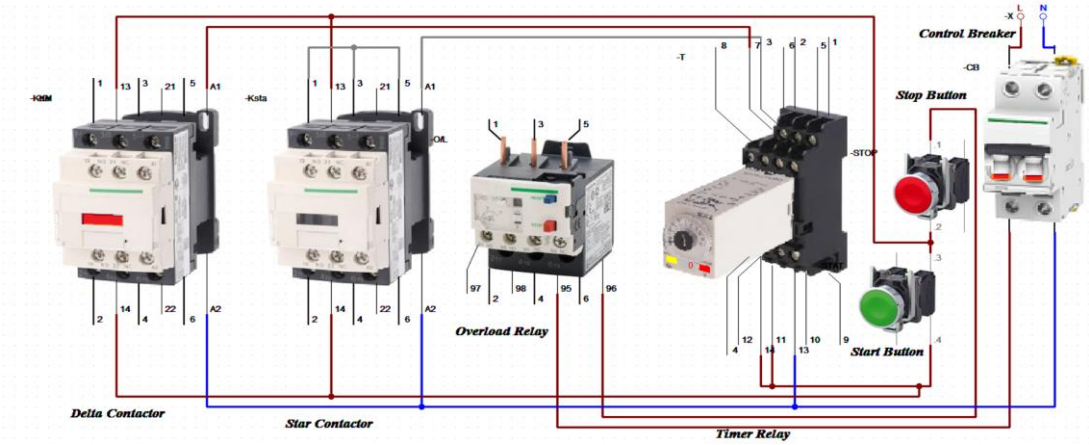

Figure 2.7: Control line diagram for the Modified Forward and reverse Star/Delta Starter (Delta mode operation or simulation)

The complete line diagrams for the modified Star/Delta Starter is as shown in figure 2.8. This design as shown in figure 2.8 do not need additional interlocking Contacts because the normally open and normally close contacts of the Timer Relay are connected respectively to the Star and Delta Contactor Coils.

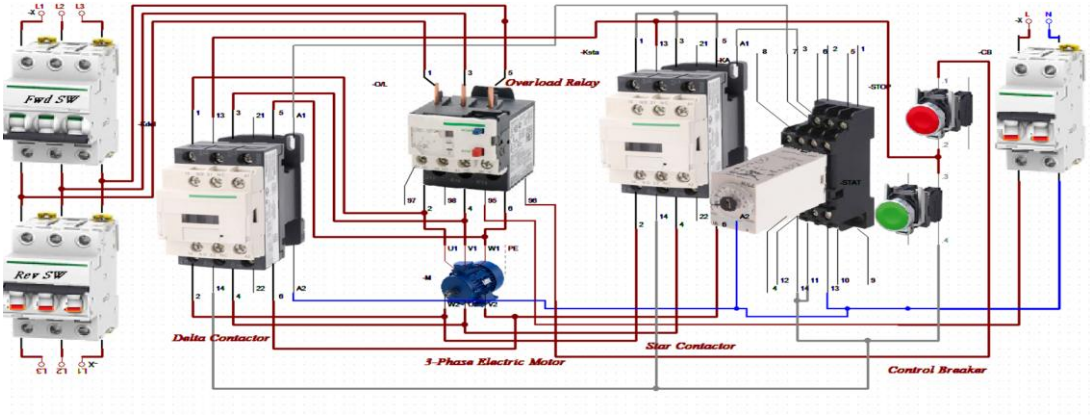

Figure 2.8: Complete line diagrams for the modified Star/Delta Starter

The operation or simulation of the motor as Star connected Motor in forward direction is as shown in figure 2.9. Current now flows through the NC Contact of the Timer Relay to the Star Contactor Coil. The Star Contactor is now energized to convey power supply to the Electric Motor. The Star Contactor remains ON for the period at which the Timer Relay is set. After the period the NC Contact open while the NO Contact of the Timer Relay close to convey current to the Delta Contactor Coil.

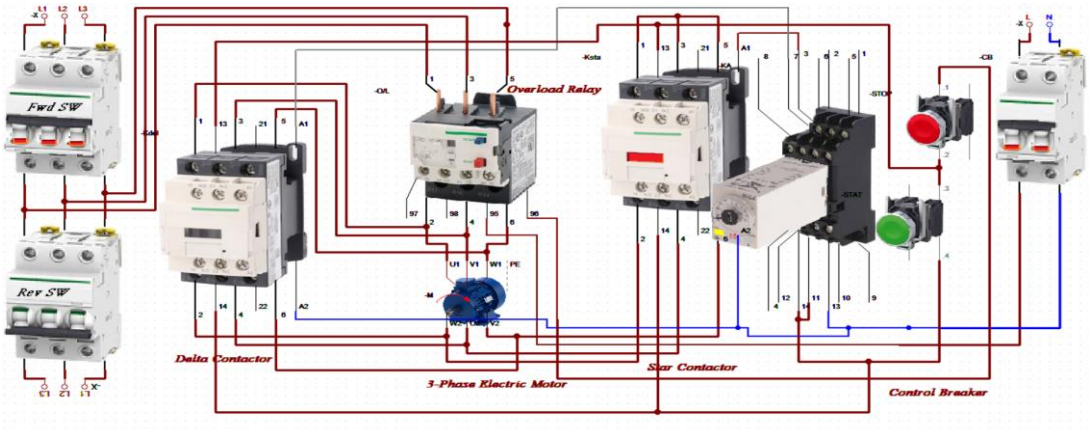

Figure 2.9: The operation or simulation of the motor as Star connected Motor in forward direction.

The operation or simulation of the motor as Delta connected Motor in forward direction is as shown in figure 2.10. Current now flows through the NO Contact of the Timer Relay to the Delta Contactor Coil. The Delta Contactor is now energized to convey power supply to the Electric Motor.

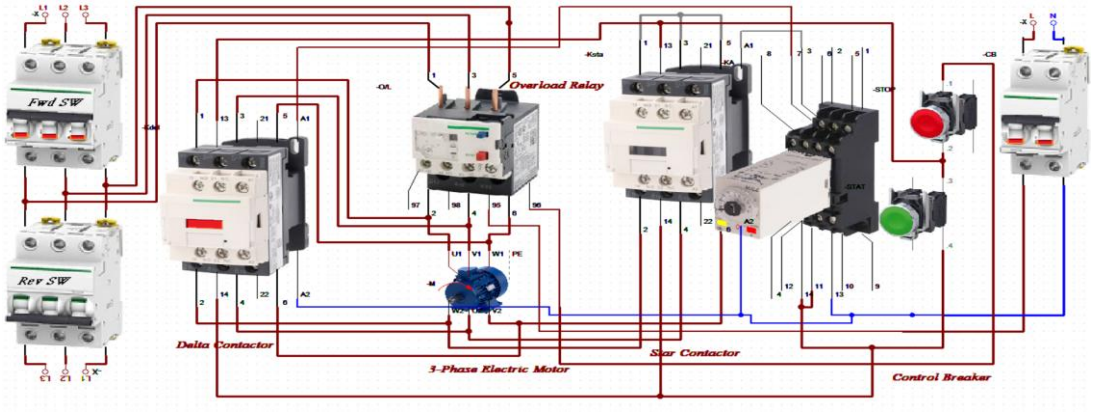

Figure 2.10: The operation or simulation of the motor as Delta connected Motor in forward direction.

The operation or simulation of the motor as Star connected Motor in reverse direction is as shown in figure 2.11. The Star Contactor is now energized to convey power supply to the Electric Motor.

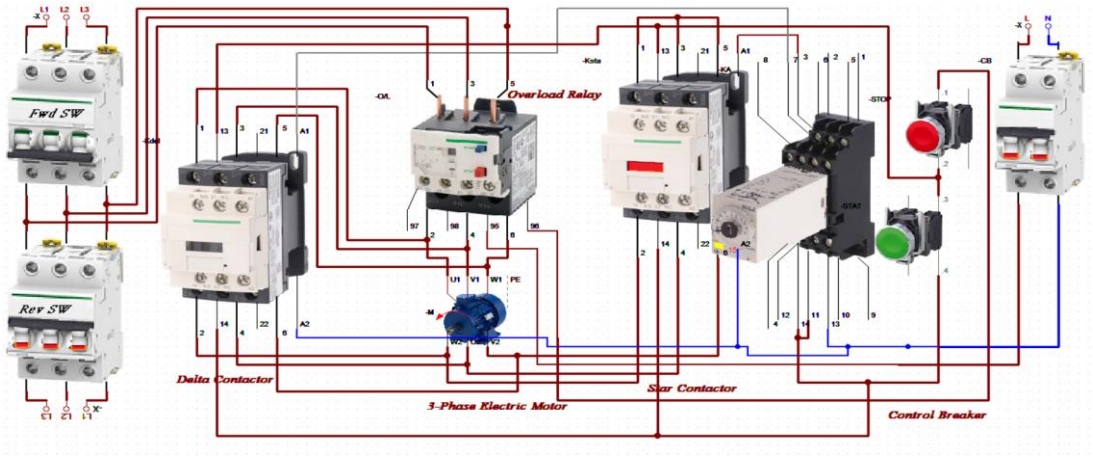

Figure 2.11: The operation or simulation of the motor as Star connected Motor in reverse direction.

The operation or simulation of the motor as Delta connected Motor in reverse direction is as shown in figure 2.12. The Delta Contactor is now energized to convey power supply to the Electric Motor.

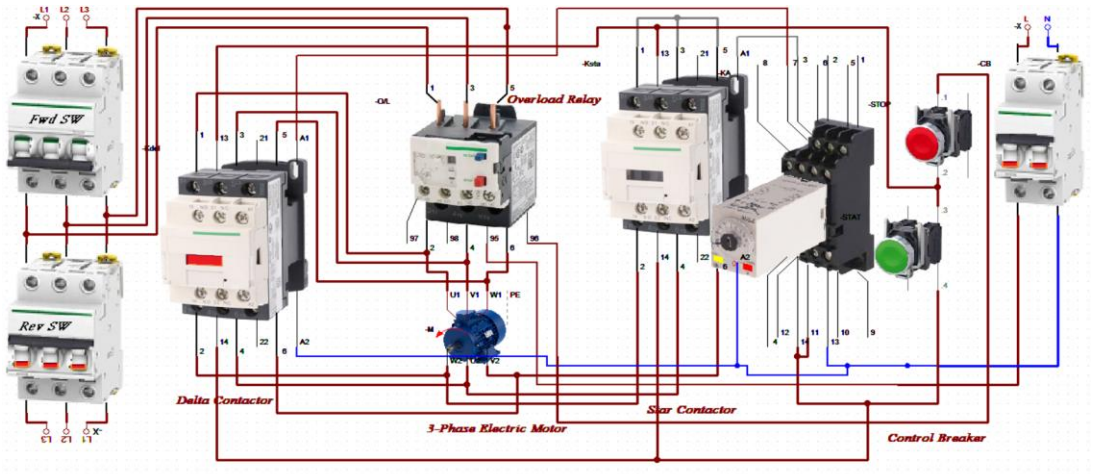

Figure 2.12: The operation or simulation of the motor as Delta connected Motor in reverse direction.

The Selector Switch as shown in figure 2.13 can be utilized to replace the two Miniature Circuit Breakers as used in figure 2.12.

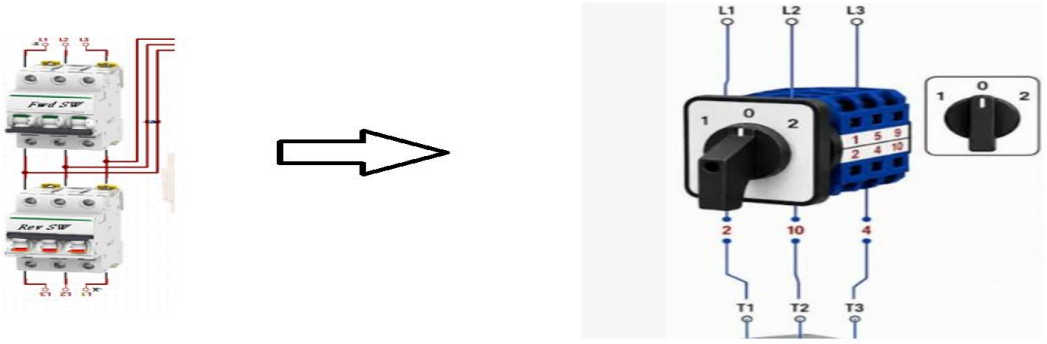

Figure 2.13: Three-Phase Selector Switch

The circuit diagram in figure 2.14 depicts incorporation of Three-Phase Selector Switch. The position (0) is OFF, the position (1) is connected to power supply as Red, Yellow and Blue. At this position '1' the Electric Motor is rotating in clockwise direction. The position (2) is connected to power supply as Red, Blue and Yellow. At position '2' the Electric Motor rotates in anti-clockwise direction.

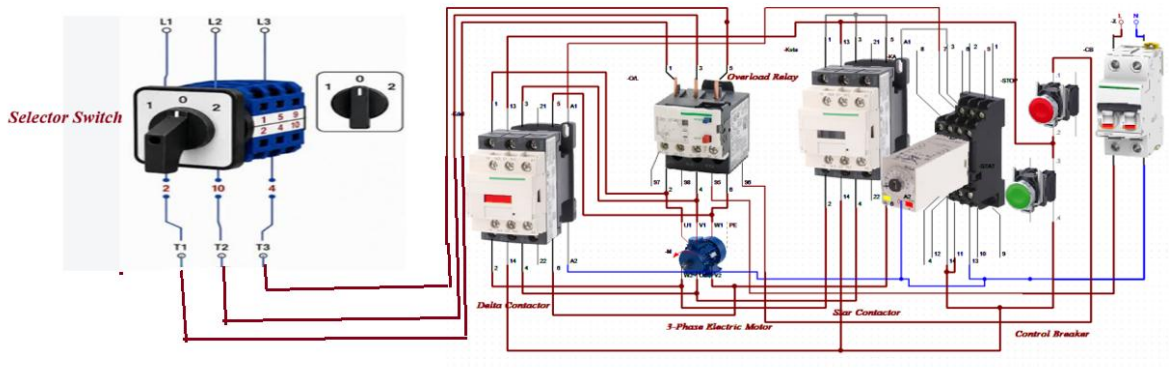

Figure 2.14: Incorporation of the Three-Phase Selector Switch on the modified Star/Delta Starter forward and reverse

4.1.3 Comparative Analysis

The comparative Analysis between the conventional Circuit diagrams and the modified Circuit diagrams for the two type of Starters are as estimated on Table 1.1. The estimated cost was obtained at market survey Kaduna on 30th September, 2026.

Table 1.1 (Kaduna)

Name of Starter	Materials required for the Conventional Circuit diagrams	Materials required for the Modified Circuit diagrams	Estimated Cost of Materials for the conventional Circuit	Estimated Cost of Materials for the Modified Circuit
Forward and reverse Direct-On-Line	(1) Two Contactors (2) Two Start Push Buttons (3) One Stop Push Button (4) Interlocking Contacts (5) One Overload Relay (6) One Miniature Circuit Breaker (7) One Control Breaker	(1) One Contactor (2) One Start Push Button (3) One Stop Push Button (4) 3-Phase Selector Switch. (5) One Overload Relay (6) One Miniature Circuit Breaker (7) One Control Breaker	(1) N2000 (2) N1000 (3) N500 (4) N1000 (5) N1500 (6) N2000 (7) N1500 Total N9500	(1) N1000 (2) N500 (3) N500 (4) N1500 (5) N1500 (6) N2000 (7) N1500 Total N8500

Name of Starter	Materials required for the Conventional Circuit diagrams	Materials required for the Modified Circuit diagrams	Estimated Cost of Materials for the conventional Circuit	Estimated Cost of Materials for the Modified Circuit
Forward and reverse Star/Delta	(1) Four Contactors (2) One Overload Relay (3) Two Start Push Buttons (4) One Stop Push Button (5) One Timer Relay (6) Interlocking Contacts (7) One Control Breaker (8) One Miniature Circuit Breaker	(1) Two Contactors (2) One Overload Relay (3) One Start Push Button (4) One Stop Push Button (5) One Timer Relay (6) 3-Phase Rotary Switch. (7) One Control Breaker (8) One Miniature Circuit Breaker.	(1) N4000 (2) N1500 (3) N1000 (4) N500 (5) N1500 (6) N1000 (7) N1500 (8) N2000 Total N13000	(1) N2000 (2) N1500 (3) N500 (4) N500 (5) N1500 (6) N1500 (7) N1500 (8) N2000 Total N11000

The circuit diagram in figure 2.15 further demonstrates the reduction of space and numbers of Electrical components between the conventional Star/Delta Starter forward/reverse and the modified Starter.

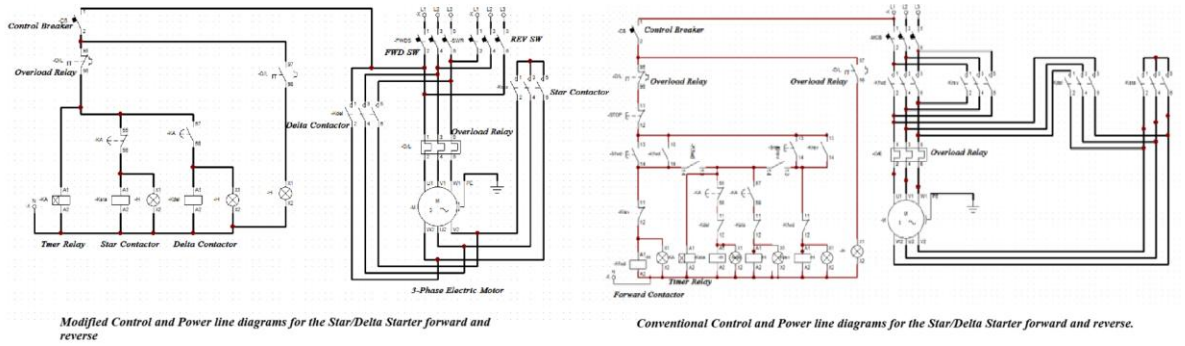

Figure 2.15: Modified and conventional forward and reverse Star/Delta Starter.

4.2 Conclusion

The research work provides another circuit connection schemes to realize the operation of Electric Motor Starters in Industries. The numbers of contactors used in conventional method was reduced. Where it involves two Contactors and two Start Push Buttons for the forward and reverse operations, one Start Push Button and one Contactor with other Electrical components were used. The four Contactors and two Start Push Buttons required for the forward and reverse Star/Delta Starter was equally reduced to two Contactor and one Start Push Button. This has greatly reduced the cost of numbers of Contactors in conventional method as well as reducing the space in the Electrical panel. The four Contactors for the conventional Star/Delta was equally reduced to two Contactors as well. The use of software CADe-SIMU shows the effective performances of the modified Electric Motor Starters. The only limitation with the modification for the forward and reverse DOL is the absence of indicating signal if the Electric Motor is in forward direction or reverse direction.

ABSTRACT

Self-healing materials represent one of the most significant paradigm shifts in modern materials engineering, offering the ability to autonomously detect and repair internal or external damage without human intervention, thereby extending service life, improving safety, and reducing maintenance costs across engineering applications. This review synthesizes recent advances in smart self-healing materials, covering the three principal design philosophies that underpin the field: capsule-based (extrinsic), vascular and intrinsic self-healing systems. It examines the healing agents, encapsulation strategies, and activation mechanisms employed across polymeric composites, cementitious materials and hydrogel-based systems, and evaluates their translation into real-world sectors including aerospace, automotive, construction, biomedicine, and flexible electronics. Particular attention is given to emerging technologies such as microencapsulated healing agents for structural and cement-based composites, dynamic covalent and supramolecular chemistries that enable repeated intrinsic healing, bio-mediated systems such as bacterially induced self-healing concrete and stimuli-responsive hydrogels for tissue engineering, wound care, and drug delivery. The review further considers how data-driven approaches, including machine learning and artificial intelligence, are beginning to accelerate the discovery, formulation optimization, and predictive modelling of healing efficiency. Despite considerable progress, the field remains constrained by challenges of production scalability, healing-agent depletion after repeated cycles, trade-offs between healing efficiency and mechanical performance, high cost, and the absence of standardized testing protocols. This review contributes to the growing body of knowledge by providing a comprehensive synthesis of emerging technologies and identifying research priorities for future development of smart self-healing materials.

Keywords: *self-healing materials; smart materials; microencapsulation; vascular networks*

1. INTRODUCTION

Advanced engineering materials have shifted from conventional passive systems toward smart materials that sense environmental changes and respond through controlled property alterations. Smart materials respond to stimuli including temperature, stress, pressure, moisture, pH, electric or magnetic fields, light, and chemical environments, enabling adaptive behaviour difficult to achieve with conventional materials (Mrinalini & Prasanthkumar, 2019). This broader field encompasses stimuli-responsive polymers, shape-memory materials, electroactive and magnetically responsive systems, hydrogels, nanocomposites, and self-healing materials (Srivastav et al., 2025; Jain et al., 2025).

Among these, self-healing materials (SHMs) have attracted particular interest because they introduce autonomous repair into engineering systems. A SHM restores structural integrity or functional performance following damage through autonomous or stimulus-assisted processes (El Choufi et al., 2022; Kontiza & Kartsonakis, 2024). Inspired by biological systems, where damage activates localized transport, molecular recognition, chemical reactions, and reconstruction; the engineering translation treats damage not as irreversible failure but as a trigger for programmed repair (White et al., 2001; Srivastav et al., 2025).

Material degradation often begins at microscopic scales before progressing to visible cracks, delamination, corrosion, leakage, conductivity loss, or catastrophic failure. Conventional maintenance

requires detection followed by external intervention. SHMs reduce this dependence by embedding healing mechanisms within the material architecture itself (White et al., 2001; Zhu et al., 2015). The landmark work of White et al. (2001) demonstrated an autonomic polymer composite in which crack propagation ruptured embedded microcapsules, released a healing agent, and initiated polymerization—establishing a foundational concept that stimulated extensive research into encapsulation, healing-agent chemistry, catalyst distribution, and matrix compatibility.

The field has evolved through successive generations: early extrinsic capsule-based systems (White et al., 2001), intrinsic reversible-bond polymers and advanced vascular and multi-stimuli systems inspired by biological circulatory networks (Blaiszik et al., 2010; Hager et al., 2010). Progress spans polymers, polymer-matrix composites, protective coatings, cementitious materials, metals, and soft materials. Market projections place the global SHM market in the multi-billion-USD range in the mid-2020s, with continued expansion toward 2030–2035 driven by construction, automotive, aerospace, electronics, and biomedical demand (Jose et al., 2026; Kontiza & Kartsonakis, 2024).

Reviews classify systems according to whether healing functionality is stored separately from the matrix (extrinsic: microcapsules, hollow fibres, vascular networks) or incorporated directly into the material network (intrinsic: reversible interactions or dynamic bonds) (El Choufi et al., 2022; Kontiza & Kartsonakis, 2024; Srivastav et al., 2025; Zhu et al., 2015; Jain et al., 2025). Figure 1 organizes the design space along three axes—Strategy (Intrinsic, Extrinsic, Stimuli-responsive), Mechanism (supramolecular interactions, dynamic covalent bonds, vascular/capsule architectures), and Target Functions (mechanical integrity, barrier properties, conductivity, biological compatibility)—and underpins the organization of this review.

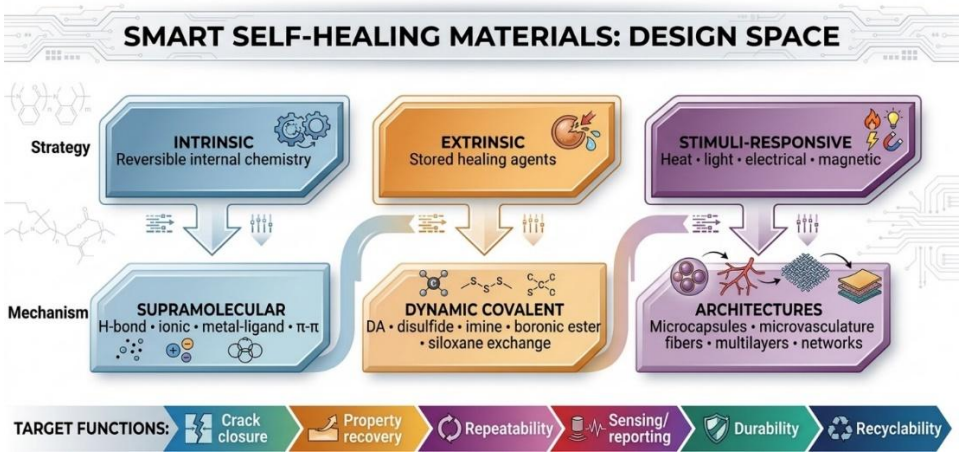

Figure 1: Author-generated design-space map of smart self-healing materials, synthesized from the reviewed literature (Song et al., 2021; Rai et al., 2023; Dallaev, 2024; Jose et al., 2026).

2. METHODOLOGY

2.1 Review Design and Search Strategy

This study employed a structured integrative review design rather than a formal systematic review or meta-analysis. Searches spanned Web of Science, Scopus, Google Scholar, PubMed/PMC, and publisher platforms (MDPI, Elsevier, Wiley, RSC, Springer). Search strings combined terms such as "smart materials," "self-healing materials," "self-healing polymers," "autonomous healing," "microcapsule self-healing," "vascular self-healing," "intrinsic self-healing," "dynamic covalent," "supramolecular self-healing," "self-healing concrete," "bacteria-based self-healing," and "stimuli-responsive hydrogels." Emphasis was placed on 2010–2026 while retaining seminal pre-2010 studies that established foundational mechanisms.

2.2 Eligibility and Evidence Selection

Priority was given to peer-reviewed reviews and original research reporting mechanisms, healing agents, fabrication routes, healing efficiency or mechanical recovery, conditions, durability, scalability, or application evidence. Non-peer-reviewed, purely speculative, out-of-domain, or non-

English studies were excluded. Citation chaining from seminal works and recent reviews identified influential experimental and sector-specific literature.

2.3 Data Extraction and Synthesis

Extracted data included material class, healing architecture, agent or reversible interaction, activation stimulus, healing time, recovery metric, environmental conditions, repeatability, and application context. Because healing efficiency is defined differently across studies, via fracture toughness, tensile strength, modulus, crack closure, permeability, conductivity or other metrics; reported percentages are presented as representative values only and are not treated as directly equivalent. Synthesis is qualitative and comparative rather than a pooled meta-analysis (Bekas et al., 2016; Geng et al., 2023).

3. SYNTHESIZED FINDINGS AND DISCUSSION

3.1 Extrinsic Capsule-Based Self-Healing Systems

Extrinsic capsule systems remain among the most mature autonomous-repair approaches because they separate the healing agent from the host matrix until damage occurs. A propagating crack ruptures microcapsules; the liquid agent wets crack faces; polymerization or solidification restores the damaged region. Healing chemistry can be optimized independently of the structural matrix, and capsules can be distributed throughout a component (White et al., 2001; Zhu et al., 2015).

The original dicyclopentadiene/Grubbs-catalyst system recovered approximately 75% of fracture toughness (White et al., 2001). Dual-microcapsule epoxy–amine chemistry achieved about 91% average healing efficiency in an optimized formulation (Jin et al., 2012). More recent work shows strong dependence on capsule size and concentration; one study reported up to 68% load recovery while demonstrating that larger capsules can reduce unhealed-matrix mechanical performance (Mousavi et al., 2019). These results underscore the central trade-off between adequate healing-agent delivery and preservation of matrix strength.

The principal limitation of single-use capsules is finite local healing capacity: once ruptured and consumed, a location cannot generally be healed again without another reservoir. Multicore and multicapsule systems distribute this limitation, yet increased loading may introduce defects, reduce matrix continuity, and complicate manufacturing (Zhu et al., 2015; Kontiza & Kartsonakis, 2024). Capsule shell chemistry, permeability, interfacial adhesion, size distribution, core fraction, catalyst stability, and environmental compatibility therefore require simultaneous optimization.

3.2 Vascular and Microvascular Self-Healing Architectures

Vascular systems address finite healing-agent supply by embedding interconnected channels that deliver agents to multiple damage events. Toohey et al. (2007) demonstrated a microvascular network supplying reactive components to damaged regions. Subsequent architectures enable repeated healing via network refill. Early systems achieved multiple healing events; later designs using separate networks for agents and catalysts extended repeatability—reported examples include 16 cycles with ~60% fracture-toughness recovery and >30 cycles with recovery ranging from ~50% to 100%, depending on architecture and test conditions (Toohey et al., 2007; Patrick et al., 2014).

3.3 Intrinsic Self-Healing: Dynamic Covalent and Supramolecular Mechanisms

Intrinsic systems incorporate the healing mechanism directly into the material network, permitting repeated damage and repair without a separate reservoir. Healing is enabled by reversible covalent bonds (disulfide, imine, boronate ester, Diels–Alder, and related dynamic chemistries) or by reversible non-covalent interactions (hydrogen bonding, ionic association, π–π interactions, metal coordination, host–guest recognition) (El Choufi et al., 2022; Zafeer & Bhat, 2024).

A major advantage is repeatability: because healing functionality is distributed throughout the network, repair can occur at multiple locations and over multiple cycles provided network chemistry remains viable. Supramolecular polymers can heal under relatively mild conditions via reversible

intermolecular interactions that enable chain rearrangement. Optically activated supramolecular systems combine stimulus response with repair, while thermoreversible rubber-like systems established the importance of dynamic association for repeated recovery (Burnworth et al., 2011; Cordier et al., 2008).

3.4 Stimuli-Responsive and Multifunctional Self-Healing Systems

Stimuli-responsive systems extend self-healing beyond passive damage-triggered repair by coupling healing to external or environmental cues—heat, light, pH, moisture, electrical or magnetic fields, ionic conditions, and chemical environments (Mrinalini & Prasanthkumar, 2019). The stimulus can accelerate diffusion, activate reversible reactions, soften a matrix temporarily, initiate photochemical healing, or alter network association.

Value is clearest in demanding environments: heat accelerates bond exchange; light provides spatial/temporal control; pH or enzyme responsiveness suits biomedical settings. Dependence on an external stimulus, however, can reduce autonomy if the stimulus is unavailable in service. Genuinely smart materials therefore increasingly combine damage sensing with a locally available stimulus, enabling repair only where and when needed (Jain et al., 2025; Morris et al., 2025).

3.5 Cementitious and Bio-Mediated Self-Healing Materials

Self-healing cementitious materials address a different service problem: sealing cracks, reducing transport of water and aggressive agents, and preserving durability rather than restoring original fracture toughness. Autogenous healing occurs through continued hydration, calcium carbonate precipitation, or related natural processes; autonomous systems employ capsules, mineral agents, polymers, shape-memory elements, or microorganisms (Amran et al., 2022; Meraz et al., 2023; Nguyen et al., 2023).

Bacteria-based self-healing concrete offers a distinct bio-mediated route in which suitable microorganisms promote mineral precipitation—particularly calcium carbonate—within cracks. Performance depends on bacterial viability, nutrient availability, pH, temperature, moisture, crack geometry, and protection of microorganisms from the highly alkaline cementitious environment. Recent reviews emphasize that environmental conditions and crack width strongly influence outcomes, and that laboratory results under ideal conditions should not be interpreted as direct evidence of field reliability (Gruyaert & De Belie, 2023; Meraz et al., 2023).

Sustainability potential lies in extended service life and reduced repeated repair. Durability of the biological component, long-term viability, compatibility with local construction practices, encapsulation/nutrient cost, and performance under African climatic conditions require additional field-scale evidence. For Nigeria, locally available mineral precursors and biologically compatible carriers could provide lower-cost routes to autonomous crack sealing, provided structural and environmental safety are demonstrated.

3.6 Self-Healing Hydrogels for Biomedical Applications

Self-healing hydrogels combine self-repair, injectability, flexibility, biocompatibility, and controlled transport within hydrated polymer networks. Biomedical designs use dynamic covalent and reversible non-covalent associations to restore network integrity after mechanical damage, supporting wound dressings, tissue engineering, drug delivery, biosensing, and regenerative medicine (Bhuvaneswari et al., 2025; Xue et al., 2025).

Stimuli-responsive hydrogels are particularly relevant to wound care because physiological environments supply cues such as pH, temperature, ionic strength, reactive oxygen species, glucose, and enzyme activity that can control drug release, antimicrobial activity, tissue adhesion, and regeneration. Composite hydrogels can respond to pH, temperature, light, and enzyme activity while supporting controlled therapeutic delivery and tissue repair (Ding et al., 2025). Reported mechanical recovery ranges from approximately 40% to >90% depending on network chemistry and conditions, illustrating the same strength–mobility trade-off observed in structural polymers (Khan et al., 2022). High laboratory efficiency alone does not establish clinical suitability; cytocompatibility, degradation behaviour, sterilization stability, reproducibility, and long-term physiological performance must also be demonstrated (Xue et al., 2025).

3.7 Comparative Synthesis of Representative Healing Performance

Table 1 summarizes representative reported performance values. Values are intentionally not ranked because healing efficiency depends on the property measured, damage geometry, healing time, stimulus, and test protocol.

Table 1: Summary of representative reported performance values

System	Material / architecture	Representative recovery	Healing condition	Key strength	Key limitation
Extrinsic capsule	DCPD/Grubbs epoxy	≈75% fracture toughness	Room-temp; seminal	Simple autonomous activation	Finite local agent supply
Extrinsic dual capsule	Epoxy–amine microcapsules	≈91% avg. efficiency	Optimized ratio; RT	High single-cycle recovery	Complexity; finite reservoir
Vascular	Microvascular epoxy	≈60% over 16 cycles	Repeated refill	Repeatable healing	Fabrication complexity
Vascular (adv.)	Advanced architecture	Up to 100% recovery	Architecture-dependent	Many cycles possible	Channel reliability
Cementitious	Microbial / autonomous	Varies with crack/env.	Moisture, nutrients	Crack sealing; durability	Viability; field robustness
Hydrogel	Dynamic covalent / supra.	Tens of % to >90%	Min–days; stimulus-dep.	Soft, injectable, multi-func.	Biocompatibility; strength

Note. Values drawn from White et al. (2001), Jin et al. (2012), Toohey et al. (2007), Patrick et al. (2014), Amran et al. (2022), Meraz et al. (2023), and Xue et al. (2025). Percentages are not directly comparable across material classes.

4. SECTOR-SPECIFIC APPLICATIONS AND TRANSLATION

4.1 Aerospace and Wind-Energy Structures

Aerospace structures demand low mass, high damage tolerance, fatigue resistance, environmental stability, and predictable certification performance. Self-healing composites are attractive because cracks and delamination can initiate below easy visual detection. Capsule-based and vascular approaches can delay damage growth; intrinsic matrices can provide repeated repair. Wind-turbine blades present a related application: large composite structures under cyclic loading with difficult maintenance access. Koralagundi Matt et al. (2015) demonstrated self-healing polymer composites for wind-turbine blade applications. Translation to flight-critical aerospace components, however, requires stringent evidence on fatigue, impact, ageing, repair repeatability, inspection compatibility, and certification.

4.2 Automotive Applications

Automotive uses include structural composites, protective coatings, sealants, interior components, and conductive materials. The principal benefit is reduced degradation from repeated mechanical, thermal, and environmental loading. Intrinsic polymers suit repeated low-level damage; extrinsic systems are useful in coatings or localized composite regions. Commercial implementation depends on cost, high-volume processing compatibility, temperature resistance, recyclability, and compatibility with existing joining and painting processes (El Choufi et al., 2022; Kontiza & Kartsonakis, 2024).

4.3 Construction and Infrastructure

Construction offers one of the strongest arguments for self-healing because inspection and repair of distributed microcracks are expensive and disruptive. Self-healing concrete can reduce water ingress and improve durability via autogenous, mineral, capsule-based, or microbial mechanisms.

Realistic exposure conditions, crack width, sustained loading, wet–dry cycling, and environmental aggressiveness can substantially alter performance; laboratory crack closure should not be the sole indicator of field effectiveness (Gruyaert & De Belie, 2023; Nguyen et al., 2023).

4.4 Biomedical and Healthcare Applications

Biomedical self-healing systems must repair while remaining biocompatible and functionally compatible with living tissue. Self-healing hydrogels support wound dressings, drug delivery, tissue engineering, biosensing, and injectable systems. Stimuli-responsive designs can exploit physiological cues to regulate drug release or healing activity; dynamic networks preserve functionality after deformation (Ding et al., 2025; Xue et al., 2025). Principal translation barriers are biocompatibility, sterilization, biodegradation control, reproducibility, long-term safety, and clinical validation.

4.5 Flexible Electronics and Bioelectronics

Flexible and stretchable electronics require recovery of both mechanical and functional properties after repeated deformation or damage. Self-healing conductive polymers, elastomers, and hydrogels can restore electrical pathways while maintaining flexibility—relevant to wearable sensors, soft interfaces, and bioelectronic devices where mechanical damage can interrupt signal transmission (He et al., 2024; Liu et al., 2024; Mashkoor et al., 2022). Future systems will need simultaneous recovery of mechanical, electrical, optical, and sensing functions rather than structural repair alone.

5. RESEARCH GAPS AND SUSTAINABILITY

5.1 Healing Efficiency versus Mechanical Performance

A central unresolved problem is simultaneous optimization of healing efficiency, strength, toughness, stiffness, environmental resistance, and processing stability. Increased molecular mobility generally improves healing but can reduce mechanical integrity; rigid crosslinked structures restrict healing kinetics (El Choufi et al., 2022; Jain et al., 2025). Future studies should report multidimensional performance rather than a single healing percentage.

5.2 Repeatability and Healing-Agent Depletion

Extrinsic capsule systems are limited by finite agent availability; vascular systems require reliable fluid transport and refillability. Intrinsic systems offer better theoretical repeatability but may suffer from fatigue of dynamic bonds or environmental sensitivity. Meaningful comparison should report number of healing cycles, retained recovery after cycling, and fraction of original functionality restored after repeated damage (Toohey et al., 2007; Patrick et al., 2014).

5.3 Standardization of Evaluation

Cross-literature comparisons remain difficult because studies vary in damage geometry, crack width, healing temperature and duration, stimulus intensity, loading configuration, environmental exposure, and definition of recovery. Future research should report both crack-level metrics and functional recovery, together with standardized damage and healing histories—particularly important when translating laboratory results into structural applications (Bekas et al., 2016; Morris et al., 2025).

5.4 Sustainability and Circular Materials Design

Self-healing can contribute to sustainability by extending service life and reducing replacement and maintenance, but healing chemistry itself must be assessed. Capsule shells, catalysts, nanoparticles, synthetic monomers, and complex processing routes may create environmental burdens. A sustainable design framework should consider embodied energy, toxicity, recyclability, end-of-life processing, local material availability, and life-cycle service extension rather than assuming inherent sustainability (Srivastav et al., 2025).

5.5 Relevance to Nigeria and Africa

For Nigeria and other African economies, the most relevant pathway is not simply to reproduce high-cost laboratory systems developed for advanced industrial markets, but to adapt self-healing principles to locally available materials, manufacturing capabilities, climate conditions, and infrastructure needs. Priorities include mineral-based healing agents for cementitious materials, bio-mediated crack sealing using locally adaptable microorganisms, natural or agricultural-derived polymer components, and low-cost encapsulation routes. Such research should be coupled with local durability testing under high temperature, humidity, wet–dry cycling, and aggressive environmental conditions. Scale-up requires affordable feedstocks, reproducible processing, quality control, skilled personnel, and standards that support local manufacturing and construction adoption.

The Nigerian context also creates opportunity for application-driven research in infrastructure, water systems, transportation, energy, and composite components. A locally grounded agenda could integrate materials characterization, design of experiments, life-cycle assessment, digital modelling, and machine learning to identify formulations that balance performance with cost and availability—aligning SHM research with broader priorities of infrastructure durability, resource efficiency, local manufacturing, and sustainable industrial development.

6. FUTURE PERSPECTIVES

6.1 Artificial Intelligence and Data-Driven Materials Design

AI and machine learning are increasingly relevant because healing performance depends on interacting formulation, processing, microstructural, and environmental variables. Data-driven models can relate polymer composition, crosslink density, capsule concentration, healing temperature, damage history, and kinetics to final performance. The most useful direction is not to replace experiments but to reduce trial-and-error and identify promising combinations for targeted validation (Jain et al., 2025).

6.2 Additive Manufacturing and Architected Healing Networks

Additive manufacturing provides spatial control over composition and architecture. Three-dimensional printing can enable controlled placement of healing reservoirs, vascular networks, dynamic polymer regions, and multifunctional structures—moving design from homogeneous formulations toward architectures tailored to predicted damage locations and load paths (Andreu et al., 2024). Remaining challenges include printability, interlayer bonding, healing-agent compatibility, scale-up, process repeatability, and long-term stability of printed architectures.

6.3 Multifunctional and Autonomous Systems

The next generation is expected to integrate sensing, actuation, repair, and communication. A truly smart material could detect damage, identify severity, trigger a suitable healing mechanism, verify recovery, and communicate condition to a monitoring system. Combining self-healing with structural health monitoring, embedded sensors, conductive networks, and digital models could create materials that participate actively in predictive maintenance rather than merely responding after damage.

6.4 Industrial Scale and Circularity

Industrial adoption will depend on reproducible manufacturing, affordable raw materials, environmental stability, standardized testing, and compatibility with existing production systems. Dynamic covalent networks may be especially important where healing and reprocessing can be combined, potentially reducing material waste (Maes et al., 2025). Claims of circularity must be validated through life-cycle assessment and end-of-life studies. For developing economies, low-cost and locally sourced healing systems deserve particular attention because economic accessibility is part of sustainability.

7. CONCLUSIONS

Smart self-healing materials have progressed from the original capsule-based concept to a broad family of extrinsic, vascular, intrinsic, stimuli-responsive, bio-mediated, and multifunctional systems.

No single architecture is universally superior. Capsule systems offer relatively simple autonomous activation but finite local healing capacity; vascular networks improve repeatability at the expense of architectural complexity; intrinsic systems offer distributed and potentially repeated repair but face the strength–mobility trade-off; stimuli-responsive systems provide additional control but may depend on environmental or external stimuli.

Comparative evidence demonstrates why healing-efficiency percentages must be interpreted within their test context. Representative polymer systems have achieved approximately 75–91% recovery in selected fracture-toughness tests; vascular architectures have demonstrated repeated healing over many cycles; hydrogel systems can achieve high mechanical recovery under selected conditions. Cementitious and bio-mediated systems are better evaluated through crack closure, permeability reduction, durability, and service-life indicators. Across all classes, standardized testing, repeatability, environmental durability, and life-cycle assessment remain critical.

For Nigeria and Africa, the strategic opportunity is to adapt self-healing principles to local materials, infrastructure needs, climate conditions, and manufacturing capacity. Research should prioritize affordable and environmentally responsible healing agents, scalable processing, realistic durability testing, and data-driven optimization. The long-term objective should be materials that do not merely heal damage but sense, respond, recover, and operate sustainably over extended service lives.

ABSTRACT

Deep learning-based plant disease recognition achieves strong benchmark results, but data scarcity and class imbalance consistently limit its reliability when deployed on real field imagery. This study comparatively evaluates four Coordinate Attention-enhanced lightweight CNNs, ShuffleNetV2, MobileNetV3-Small, GhostNet, and EfficientNet-B0, trained with Conditional GAN (cGAN) augmentation on the OSFmaize dataset across four disease categories and five data configurations. Generative quality assessment confirmed acceptable synthetic image quality, with best average FID of 198.57 at epoch 700 and best IS of 3.32 at epoch 1,000. In the primary Real + cGAN configuration, MobileNetV3-Small achieved the highest accuracy at 94.06% with 1.11M parameters, 0.061G FLOPs, 5.10ms inference, and 4.43MB storage, representing the best accuracy-efficiency trade-off among all four models. GhostNet recorded 80.07%, attributed directly to shortcut learning caused by training from scratch without pretrained weights, producing a 19.93 percentage point accuracy drop when real data was added to synthetic-only training. Traditional augmentation outperformed cGAN in all combined training scenarios. Ablation confirmed Coordinate Attention contributes up to 12.24 percentage points accuracy gain. These results provide practical guidance for architecture and augmentation selection in resource-constrained maize disease recognition systems.

Keywords: *Maize leaf disease recognition; Conditional GAN; Lightweight CNN; Coordinate Attention; Data augmentation; MobileNetV3-Small*

1. Introduction

Deep Deep learning has substantially changed how plant diseases are detected and classified, enabling automated diagnostic systems that work directly from digital leaf images without manual feature engineering (Li et al., 2021; Ouhami et al., 2021; Pardede et al., 2020). In precision agriculture, this shift matters practically: early disease identification reduces crop losses, cuts unnecessary pesticide use, and gives farmers actionable information before infections spread across a field. Maize (Zea mays L.) is one of the crops where this need is most acute. It is among the most widely grown cereals globally, with annual production exceeding 1.2 billion tonnes, yet it remains persistently vulnerable to foliar infections that can reduce yields by more than 50% in severe outbreaks (FAOSTAT, 2024; Solaimalai et al., 2020; USDA, 2024). Gray Leaf Spot (GLS), Northern Leaf Blight (NLB), and Northern Leaf Spot (NLS) are the primary culprits, and distinguishing between them accurately from leaf imagery is a non-trivial classification problem given their overlapping visual characteristics (Jasrotia et al., 2023; Langemeier et al., 2017).

Large-capacity architectures such as VGGNet (Simonyan & Zisserman, 2014), ResNet (He et al., 2016), and EfficientNet (Tan & Le, 2019) have demonstrated strong performance on plant disease benchmarks, but their practical utility depends on large, balanced training datasets. In real agricultural settings, assembling such datasets is consistently difficult. Seasonal variation, uneven disease incidence across fields, and inconsistent imaging conditions all produce small, class-imbalanced collections that push well-trained models toward overfitting (Li et al., 2021; Ouhami et al., 2021; Pardede et al., 2020).

Traditional augmentation methods, including rotation, flipping, color jittering, and random cropping, partially offset this by expanding dataset size, but they only introduce geometric and photometric variation. They do not produce new lesion morphologies, novel color gradients, or previously unseen severity patterns (Li et al., 2021). Models trained on traditionally augmented data can still fail to generalize when real field conditions differ from their training distribution.

Generative Adversarial Networks (GANs) address this limitation by learning the underlying distribution of real images and synthesizing new, semantically varied samples (Goodfellow et al., 2014). The Conditional GAN (cGAN; Mirza & Osindero, 2014), which conditions both the generator and discriminator on class labels, enables targeted synthesis of disease-specific leaf images that preserve class-relevant texture and color characteristics. Studies applying GAN-based augmentation to plant disease tasks, including tomato leaf detection (Wu et al., 2020) and corn disease identification (Hu et al., 2020), have reported measurable accuracy gains. However, GAN training for agricultural data introduces its own challenges. Training instability, mode collapse, and the tendency of models to memorize synthetic distributions rather than learn generalizable features are known failure modes that require careful evaluation (Saad et al., 2024; Wani et al., 2025). Systematic comparison of cGAN augmentation across multiple lightweight architectures on maize disease data, with explicit documentation of these failure conditions, remains limited in the literature.

Lightweight CNN architectures have attracted growing research interest for deployment on resource-constrained hardware, where large models are impractical (Chen et al., 2022; Le et al., 2024; Lu et al., 2023). ShuffleNetV2 (Ma et al., 2018), MobileNetV3, GhostNet, and EfficientNet-B0 each represent distinct trade-offs between parameter count, computational cost, and classification accuracy. Direct comparison of these models under identical training conditions provides useful guidance for practitioners who must select an architecture for edge deployment in agricultural settings. A recurring weakness across lightweight models is reduced sensitivity to spatially subtle lesions, since standard architectures apply attention uniformly across feature maps without discriminating between lesion and background regions (Bhujel et al., 2022). Coordinate Attention (Hou et al., 2021; Saminu et al., 2026) addresses this directly by encoding positional information along both horizontal and vertical spatial dimensions into the channel attention mechanism, allowing the model to localize fine-grained disease features without significant added computation. Prior work confirms attention-based improvements in lightweight plant disease classifiers (Bhujel et al., 2022; Ibrahim et al., 2025), but systematic multi-architecture comparisons under the same GAN-augmented training setup remain scarce.

This study addresses these gaps through a targeted problem-solution structure. Four challenges motivate the experimental design:

Limited dataset diversity. Small, imbalanced maize disease datasets cause overfitting and poor generalization across unseen field conditions. Traditional augmentation adds volume but not semantic variety. Solution: A cGAN trained for 1,000 epochs synthesizes class-conditioned maize leaf images for Healthy, GLS, NLB, and NLS categories, expanding both the size and visual diversity of the training set.

Inadequate spatial attention in lightweight models. Standard lightweight CNNs do not selectively attend to lesion regions, reducing their discriminative capacity when disease symptoms are subtle or unevenly distributed. Solution: Coordinate Attention is integrated at the final feature stage of each model, encoding directional spatial context into channel-wise feature recalibration without substantially increasing parameter count (Hou et al., 2021).

Absence of multi-architecture comparison under controlled conditions. Most existing studies evaluate a single model or compare architectures trained on different datasets and protocols, making it difficult to isolate the effect of architectural choice from training setup. Solution: Four lightweight CNNs ShuffleNetV2, MobileNetV3-Small, GhostNet, and EfficientNet-B0 are trained and evaluated under an identical protocol using a 70/15/15 stratified split with seed=42 across five data scenarios.

Deployment feasibility gap. Reporting accuracy alone is insufficient for field deployment decisions. Model size, inference speed, and parameter count must be evaluated alongside accuracy to determine practical suitability. Solution: All models are benchmarked on inference time, FLOPs, parameter count, and storage size to determine practical suitability for edge deployment.

This explicit problem-solution mapping ensures that each architectural and experimental decision addresses a specific, identified limitation rather than being arbitrarily assembled. The study represents a methodologically grounded comparison of cGAN augmentation and attention-enhanced

lightweight CNNs, not an additive combination of techniques.

To systematically evaluate this design, the study is guided by the following research questions:

a) Which lightweight CNN architecture, enhanced with Coordinate Attention, achieves the best accuracy-efficiency trade-off when trained with cGAN-augmented maize disease data?
b) Under what conditions does cGAN augmentation improve classification performance, and when does combining synthetic and real data degrade generalization?
c) Does Coordinate Attention consistently improve classification performance across different lightweight architectures when applied under identical training conditions?

To answer these questions, this paper presents a comparative evaluation of four Coordinate Attention-enhanced lightweight CNNs trained across five data scenarios on the OSFmaize dataset. The experimental design incorporates cGAN-based augmentation with GAN quality evaluation using Fréchet Inception Distance (FID) and Inception Score (IS), and ablation studies isolating the Coordinate Attention contribution.

The main contributions of this work are as follows:

1. Multi-architecture comparison under controlled conditions: A systematic evaluation of ShuffleNetV2, MobileNetV3-Small, GhostNet, and EfficientNet-B0, each enhanced with Coordinate Attention, trained under an identical 70/15/15 stratified protocol across five data scenarios, enabling fair and reproducible architecture comparison.
2. cGAN augmentation analysis with failure documentation: An empirical characterization of cGAN augmentation behavior across five training scenarios, including explicit analysis of shortcut learning failure in architectures trained from scratch without pretrained weights, providing practical guidance for GAN-based augmentation in small agricultural datasets.
3. GAN quality evaluation across training checkpoints: Quantitative FID and IS evaluation at epochs 300, 500, 700, and 1,000, providing transparent evidence for the epoch selection decision used in downstream augmentation and documenting the trade-off between FID-optimal and IS-optimal checkpoints.

The remainder of this paper is organized as follows. Section 2 reviews related work on GAN-based augmentation and attention-enhanced lightweight CNNs for agricultural image classification. Section 3 describes the dataset preparation, cGAN training protocol, classifier architectures, and evaluation setup. Section 4 presents comparative results and ablation studies. Section 5 concludes with findings, limitations, and directions for future work.

2. Literature Review

A. GAN-Based Augmentation for Plant Disease Recognition

Data scarcity and class imbalance are persistent obstacles in agricultural image classification. Standard augmentation techniques such as rotation, flipping, and color jittering expand dataset volume but do not introduce new disease morphologies or lesion patterns. Generative Adversarial Networks, introduced by Goodfellow et al. (2014), address this by training a generator to produce synthetic images that a discriminator cannot reliably distinguish from real ones. The resulting synthetic samples add semantic variety that geometric transforms cannot provide.

For class-conditioned synthesis, the Conditional GAN (Mirza & Osindero, 2014) extends the original GAN by feeding class label information into both the generator and discriminator, allowing targeted generation of disease-specific images. This architecture is particularly suitable for small, imbalanced datasets where certain disease classes have insufficient training examples. Wu et al. (2020) applied DCGAN-based augmentation to tomato leaf disease classification and reported measurable accuracy improvements over models trained without generative augmentation. Mohana et al. (2022) reviewed GAN-based augmentation across multiple agricultural domains and confirmed that synthetic data consistently improves classifier performance when real data is limited, though they noted that image quality and training stability vary considerably across GAN architectures and dataset sizes.

In maize-specific tasks, Hu et al. (2020) demonstrated that GAN-augmented training data improved corn leaf disease identification accuracy by reducing inter-class confusion caused by visually

similar lesion patterns. Cap et al. (2020) introduced LeafGAN, a domain-adapted GAN for plant disease augmentation that achieved lower FID scores than standard cGAN on leaf datasets, confirming that domain-specific generator design improves synthetic image fidelity. Despite these advances, most existing studies evaluate a single GAN architecture on one downstream classifier. Systematic comparison of GAN augmentation behavior across multiple lightweight classifiers under identical training conditions remains absent, leaving practitioners without clear guidance on which architecture combinations generalize reliably.

A further concern with GAN-augmented training is the risk of shortcut learning, where models trained on synthetic-only data learn distributional shortcuts specific to the generator rather than true disease discriminators (Saad et al., 2024). This failure mode is particularly pronounced in architectures trained from scratch without pretrained weights, where the model has no prior visual knowledge to anchor feature learning. Saad et al. (2024) reviewed training challenges in GANs for biomedical image analysis and identified distribution mismatch between synthetic and real data as one of the most common causes of downstream classification degradation. Documenting these failure conditions explicitly is necessary for any study that proposes GAN augmentation as a practical tool.

B. Lightweight CNN Architectures for Agricultural Image Classification

Deploying disease recognition models in field conditions requires architectures that balance accuracy with computational efficiency. Standard deep networks such as VGGNet (Simonyan & Zisserman, 2014) and ResNet (He et al., 2016) deliver strong benchmark performance but carry parameter counts and inference times that are impractical on embedded or mobile hardware. Lightweight CNN architectures address this through structural innovations that reduce computation without sacrificing discriminative capacity.

ShuffleNetV2 (Ma et al., 2018) achieves efficiency through channel splitting and element-wise addition rather than computationally expensive group convolutions, resulting in fast inference and low memory usage. Chen et al. (2021) applied an improved ShuffleNetV2 to apple leaf disease recognition and confirmed that the architecture maintains competitive accuracy under resource constraints. MobileNetV3 builds on depthwise separable convolutions and incorporates hard-swish activations and squeeze-and-excitation blocks to improve accuracy per parameter. Abubakar et al. (2026) demonstrated the effectiveness of MobileNetV2 features compressed with PCA for maize disease recognition, achieving competitive accuracy with substantially reduced feature dimensionality, which reflects the broader utility of MobileNet-family architectures in agricultural classification tasks.

GhostNet reduces redundant feature map computation by generating additional feature maps from cheap linear operations applied to a small set of intrinsic features, cutting FLOPs without proportionally reducing representational capacity. EfficientNet-B0 (Tan & Le, 2019) applies compound scaling across network depth, width, and input resolution simultaneously, producing a model that achieves strong accuracy with fewer parameters than comparably performing architectures. Evangelista et al. (2023) evaluated EfficientNet V2 variants on maize disease classification and reported consistently high accuracy across disease categories, confirming EfficientNet-family models as reliable baselines for this task.

Lu et al. (2023) reviewed lightweight methods for plant disease identification and found that models with fewer than 5M parameters can match or approach the accuracy of larger networks when training data is sufficient and augmentation is applied effectively. Le et al. (2024) reached a similar conclusion using hybrid lightweight architectures for tomato disease detection, noting that inference speed and model size are as important as accuracy for real-world deployment. These findings collectively establish the four architectures used in this study as appropriate and well-motivated choices for comparative evaluation under cGAN-augmented training conditions.

C. ATTENTION MECHANISMS IN LIGHTWEIGHT PLANT DISEASE CLASSIFIERS

Lightweight CNNs process all spatial regions of a feature map with equal weight by default, which limits their ability to focus on diagnostically relevant areas such as lesion boundaries, color

transitions, or specific texture patterns. Attention mechanisms address this by learning to weight feature map regions according to their relevance to the classification task.

Squeeze-and-Excitation networks (Wang et al., 2020) introduced channel-wise attention by globally pooling spatial information and using a small fully connected network to recalibrate channel responses. Efficient Channel Attention (Wang et al., 2020) improved on this by replacing the fully connected layer with a lightweight 1D convolution, reducing parameter overhead while maintaining recalibration quality. Coordinate Attention (Hou et al., 2021) extends the spatial awareness of channel attention by decomposing global pooling into two directional pooling operations along the horizontal and vertical axes separately, encoding precise positional context into the attention weights. This directional encoding allows the model to localize spatially distributed features such as scattered lesions more accurately than standard channel attention, which discards spatial information entirely during pooling.

Bhujel et al. (2022) integrated a lightweight attention mechanism into a CNN for tomato leaf disease classification and reported consistent accuracy gains over the baseline without attention, particularly for visually similar disease classes. Ibrahim et al. (2025) combined depthwise separable convolutions with hybrid attention in EDANet for tomato disease recognition, confirming that attention improves both accuracy and feature discriminability in compact architectures. Rachman et al. (2024) applied attention-enhanced vision transformers to rice disease detection and found that cross-scale attention improved generalization to underrepresented disease classes. Jasrotia et al. (2023) evaluated CNN-based maize disease identification and noted that models lacking spatial attention mechanisms showed reduced performance on classes with fine-grained lesion textures, supporting the rationale for integrating CA into each architecture in this study.

Wang et al. (2020) confirmed through ablation that channel attention mechanisms consistently contribute to accuracy in lightweight CNNs across diverse visual classification tasks, with the contribution being largest when the model backbone has limited depth and therefore limited implicit spatial selectivity. This finding directly motivates applying CA at the final feature stage of each model in this study, where spatial selectivity has the greatest impact on downstream classification.

D. GAN Quality Evaluation: FID and Inception Score

Evaluating the quality of GAN-generated images requires metrics that go beyond visual inspection. Two quantitative measures are standard in the literature: Fréchet Inception Distance (FID) and Inception Score (IS). FID measures the distance between the distribution of real images and generated images in the feature space of a pretrained Inception-v3 network. Lower FID indicates that the synthetic distribution is closer to the real one, reflecting better perceptual realism and structural fidelity (Mohana et al., 2022). IS measures both image quality and class diversity within the generated set: a high IS means individual generated images are recognizable and the full set covers multiple distinct categories (Mohana et al., 2022).

Han et al. (2018) used FID to evaluate GAN-generated brain MRI images for data augmentation and found that lower FID correlated with better downstream classifier performance, establishing FID as a reliable proxy for augmentation utility in medical imaging. Cap et al. (2020) applied IS alongside FID to evaluate LeafGAN outputs on plant disease datasets, finding that IS scores above 2.0 were acceptable for domain-specific agricultural GANs where the total number of classes is small relative to ImageNet. Tang et al. (2019) similarly used FID to select optimal GAN training checkpoints for CT image augmentation, demonstrating that FID-based checkpoint selection is a practical and reproducible evaluation strategy.

In domain-specific datasets with few classes, IS values are expected to be considerably lower than those reported on ImageNet-scale benchmarks, since class diversity is inherently bounded by the number of categories in the dataset (Mohana et al., 2022). This distinction is important for interpreting IS results on the OSFmaize dataset, which contains only four classes. FID and IS together provide complementary evidence: FID captures distributional similarity to real data while IS captures per-image quality and intra-set diversity. When the two metrics favor different training checkpoints, as occurs in this study where FID is lowest at epoch 700 and IS is highest at epoch 1,000, the selection decision requires explicit justification rather than mechanical optimization of a single metric.

Existing work in agricultural GAN augmentation rarely reports both FID and IS across multiple training checkpoints, making it difficult to assess how generative image quality evolves during training and how checkpoint selection affects downstream classifier performance. This study addresses that gap by evaluating both metrics at epochs 300, 500, 700, and 1,000, providing a transparent basis for the augmentation epoch decision used across all five training scenarios.

3. PROPOSED FRAMEWORK

3.1 Overview

This section describes the dataset, preprocessing pipeline, cGAN implementation, classifier architectures, Coordinate Attention integration, and experimental configuration adopted for the comparative evaluation of four lightweight CNNs under cGAN-augmented training conditions for maize leaf disease recognition. The overall workflow integrates synthetic data generation using a Conditional GAN (cGAN) with four independently evaluated CA-enhanced lightweight classifiers to enable a controlled and fair multi-architecture comparison. The general framework is illustrated in Figure 3.

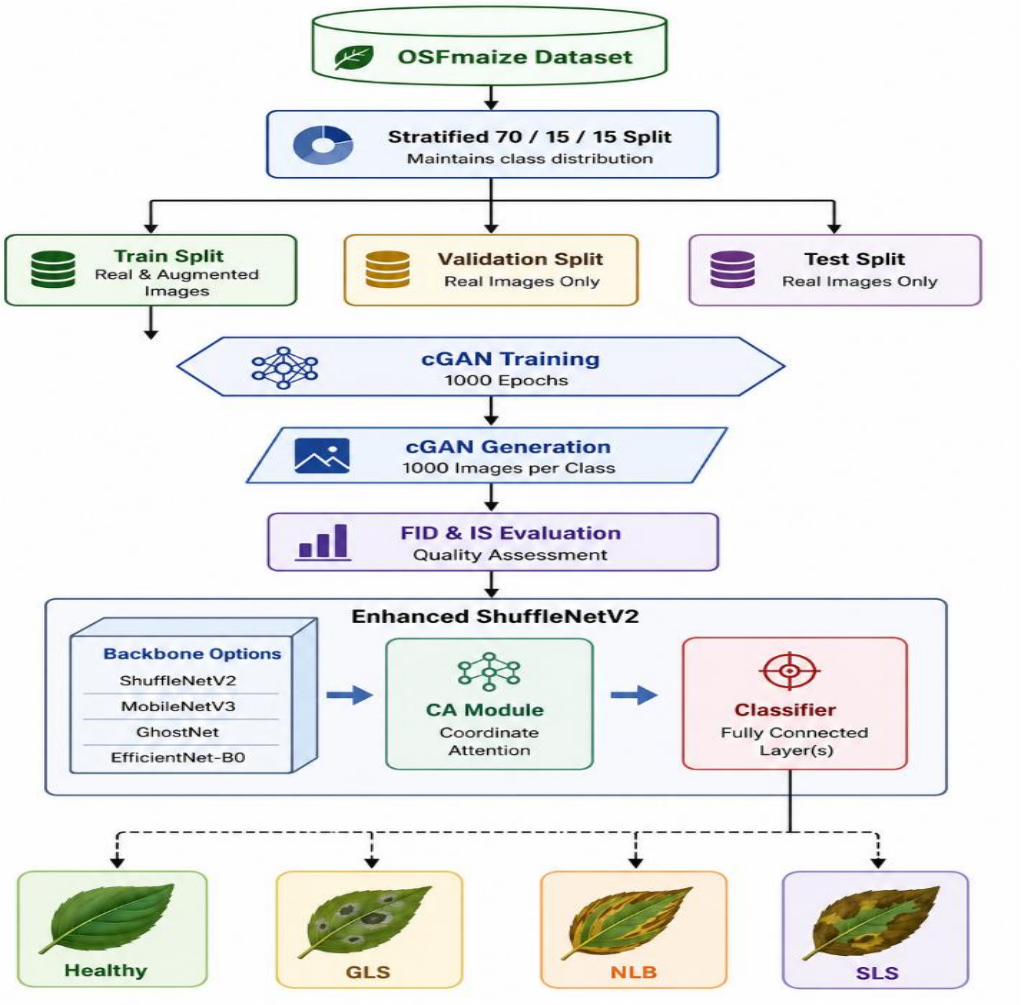

Figure 3: Developed DL Framework

The workflow trains a single cGAN on the training partition of the OSFmaize dataset and uses the generated images across all four classifier training scenarios. By holding the augmentation strategy, dataset split, evaluation protocol, and Coordinate Attention placement constant across all models, any observed performance differences can be attributed directly to architectural characteristics rather than experimental variation.

All experiments were implemented in Python 3.13 with PyTorch 2.10 on a local Ubuntu 24.04 workstation with the following hardware: HP Omen 16 laptop; Intel Core i9 14th-generation processor; 32 GB RAM; NVIDIA GeForce RTX 5070 GPU; CUDA 12.8. GAN training and classifier fine-tuning used the RTX 5070 GPU for acceleration. FID and IS evaluation was performed on CPU due to CUDA sm_120 architecture constraints with the installed PyTorch version, which does not affect metric correctness.

3.2 Dataset and Preprocessing

The dataset used in this study is the publicly available OSFmaize Leaf Disease dataset (https://osf.io/s6ru5/, accessed 17 September 2025). It comprises four classes representing distinct foliar conditions: Healthy, Gray Leaf Spot (GLS), Northern Leaf Blight (NLB), and Northern Leaf Spot (NLS), with a total of 1,902 real images across all classes.

After stratified splitting, the test set contains 286 images (15% of 1,902), with per-class counts proportional to the original class distribution.

Initial inspection revealed notable class imbalance, with Healthy and NLB containing substantially more samples than GLS and NLS. The images also exhibited visible heterogeneity in illumination, leaf orientation, and background clutter, reflecting the conditions of real-field acquisition. These factors can introduce bias into model learning if not addressed through principled dataset handling.

Data split and leakage prevention. The dataset was first partitioned into training (70%), validation (15%), and test (15%) subsets using stratified random sampling with a fixed random seed (seed = 42), prior to any synthetic generation. This three-way stratified split ensures class distribution is preserved across all partitions and that the test set provides an unbiased performance estimate independent of training decisions. The cGAN was trained exclusively on the training subset. Synthetic images were generated after cGAN training convergence and combined solely with the training partition to form the augmented training pool. The validation and test sets remained composed entirely of real, unseen images throughout all experiments. This procedure eliminates data leakage and ensures that all reported metrics reflect genuine generalization to unseen real-world data.

Each class received 1,000 cGAN-generated images. When combined with the real training partition, this produced a balanced augmented training corpus for the Real + cGAN scenario. All images were resized to 128 × 128 × 3 pixels and normalized to the range [−1, 1]. No additional geometric augmentation was applied to the cGAN-generated images, since the generative process inherently introduces morphological diversity across samples.

The five experimental data configurations evaluated in this study are summarized in Table 3.1.

Table 3.1: Summary of the five experimental data configurations. Validation and test sets consist exclusively of real images in all configurations.

Configuration	Training Data	Val.	Test
Real Only	Real train split	Real only	Real only
cGAN Only	cGAN-generated images	Real only	Real only
Real + cGAN	Real train + cGAN images	Real only	Real only
Real + cGAN (no CA)	Real train + cGAN, no CA module	Real only	Real only
Real + TradAug	Real train + traditional augmentation	Real only	Real only

The 'Real + cGAN (no CA)' row represents an architectural ablation under the Real + cGAN data configuration, not an independent data scenario. The training data is identical to Real + cGAN; only the Coordinate Attention module is removed. It is included in this table for completeness but is discussed separately in Section 4.5.

3.3 Interpretation of FID and IS Metrics

Raw Frechet Inception Distance (FID) and Inception Score (IS) were used to quantify the perceptual realism and diversity of cGAN-generated images across training checkpoints. FID measures

the statistical distance between the feature distributions of real and synthetic images in the activation space of a pretrained Inception-V3 network. Lower FID indicates closer alignment with the real data distribution and higher visual fidelity. IS evaluates image quality and class diversity within the synthetic set alone; higher scores indicate more varied and semantically confident outputs.

FID is computed as:

$$FID = \| \mu_r - \mu_g \|^2 + \mathrm{Tr}\left(\Sigma_r + \Sigma_g - 2\left(\Sigma_r \Sigma_g\right)^{\frac{1}{2}}\right) \quad (2.1)$$

where u_r, S_r are the mean and covariance of real image features, and u_g, S_g are the corresponding statistics for generated images extracted from the Inception-V3 pool3 layer.

IS is computed as:

$$IS = \exp\left(\mathbb{E}_{x\sim pg}\left[D_{\mathrm{KL}}\left(p(y \mid x) \parallel p(y)\right)\right]\right) \quad (2.2)$$

where p(y|x) is the conditional class distribution predicted by Inception-V3 for a generated image x, and p(y) is the marginal class distribution over all generated images. Higher IS reflects both high individual image confidence and diversity across the generated set.

Since Inception-V3 was pretrained on ImageNet rather than agricultural data, absolute FID and IS values are not directly comparable to benchmarks from natural image datasets. All FID and IS values reported here are used strictly for relative comparison across cGAN training checkpoints under identical evaluation conditions. Before computing FID and IS, all generated and real images at 128 × 128 resolution were resized to 299 × 299 pixels using bilinear interpolation to match the standard Inception-V3 input size, and pixel values were normalized to the range [0, 1] prior to feature extraction.

3.4 Conditional GAN Implementation

The Conditional GAN (cGAN) (Miraz et al., 2024) generates class-specific maize disease images by conditioning both the generator and discriminator on class label information. The generator accepts a 100-dimensional random noise vector concatenated with a learned class label embedding, enabling synthesis of disease-specific leaf textures, colors, and lesion patterns. The discriminator receives real and generated image-label pairs and learns to distinguish genuine samples from synthetic ones, with the class label serving as an additional conditioning signal.

The adversarial objective is:

$$\mathcal{L}_{\mathrm{cGAN}} = \mathbb{E}_{(x,y)}[\log D(x \mid y)] + \mathbb{E}_{(z,y)}\left[\log\left(1 - D\left(G(z \mid y)\right)\right)\right] \quad (2.3)$$

where x is a real image, y is the class label, z is a noise vector sampled from a prior distribution, G is the generator, and D is the discriminator. The generator minimizes this objective while the discriminator maximizes it, driving the generator toward producing class-consistent images that the discriminator cannot reliably reject.

The full cGAN training configuration is summarized in Table 3.2.

Table 3.2. cGAN training configuration.

Parameter	Setting	Description
Latent dimension	z = 100	Random noise vector input to generator
Batch size	64	Mini-batch per training iteration
Learning rate	0.0002	Adam optimizer (b1 = 0.5, b2 = 0.999)
Epochs	1,000	Total training epochs
Checkpoint epochs	300, 500, 700, 1,000	Epochs at which 1,000 images/class generated
Image size	128 x 128 x 3	Standardized RGB resolution
Optimizer	Adam	Used for both generator and discriminator
Hardware	NVIDIA RTX 5070 (HP Omen 16)	Ubuntu 24.04 local environment

3.5 Lightweight CNN Architectures with Coordinate Attention

Four lightweight CNN architectures were selected for comparative evaluation based on their distinct computational designs and demonstrated performance in resource-constrained classification tasks(Chen et al., 2022; Lu et al., 2023; Le et al., 2024). Each model was enhanced with a Coordinate Attention module inserted at the final convolutional feature stage, and each was independently trained and evaluated across the five data configurations. The classifier head was kept identical across all models: a fully connected layer (256 units) with ReLU activation, Dropout (p = 0.4) for regularization, and a final linear projection to four output classes.

3.4.1 ShuffleNetV2

ShuffleNetV2 (Ma et al., 2021) achieves computational efficiency through channel splitting and element-wise addition rather than group convolutions, which carry higher memory access costs. At each basic block, the input channels are split into two branches. One branch passes through unchanged while the other applies a sequence of 1x1 convolution, 3x3 depthwise convolution, and 1x1 convolution. The outputs are concatenated and shuffled to maintain cross-channel information flow. The variant used in this study is ShuffleNetV2 x1.0, which contains 1.62M parameters and operates at 0.153G FLOPs at 128 x 128 input resolution after CA integration. Pretrained ImageNet weights were loaded from local storage and used for full fine-tuning from epoch 1.

3.4.2 MobileNetV3-Small

MobileNetV3-Small [12] extends the MobileNet family with hard-swish activations, a redesigned last stage, and built-in Squeeze-and-Excitation (SE) blocks within its inverted residual structure. The hard-swish activation approximates the swish function with lower computational cost:

$$\text{h-swish}(x) = \frac{x \cdot \text{ReLU6}(x + 3)}{6} \tag{2.3}$$

The architecture is optimized through neural architecture search for minimal latency on mobile hardware. After CA integration and classifier replacement, the effective parameter count is 1.11M, operating at 0.061G FLOPs. Pretrained ImageNet weights were loaded locally and used for full fine-tuning.

3.4.3 GhostNet

GhostNet reduces feature map redundancy by generating additional feature maps from a small set of intrinsic features using cheap linear operations rather than computing all feature maps through standard convolutions. Given an input feature map X, the Ghost module produces:

$$Y' = \text{Conv}(X), \quad Y'' = \Phi(Y'), \quad Y = \text{concat}(Y', Y'') \tag{2.4}$$

where Y' is the set of intrinsic feature maps produced by a standard convolution, Phi represents the cheap linear transformation, and Y is the full output. GhostNet is implemented in this study using a native PyTorch implementation without the timm library or external pretrained weights, since no publicly available pretrained GhostNet weights matched the exact native configuration. The model is therefore trained from scratch across all experiments. After CA integration, the effective parameter count is 1.17M at 0.135G FLOPs.

3.4.4 EfficientNet-B0

EfficientNet-B0 (Tan et al., 2019) applies compound scaling, simultaneously increasing network depth, width, and input resolution according to a fixed scaling coefficient, to maximize accuracy per unit of computation. The compound scaling rule is:

$$d = \alpha^{\varphi}, \quad w = \beta^{\varphi}, \quad r = \gamma^{\varphi} \quad \text{s.t.} \quad \alpha \cdot \beta^2 \cdot \gamma^2 \approx 2 \tag{2.5}$$

where d, w, and r denote depth, width, and resolution scaling factors respectively, phi is the compound coefficient, and alpha, beta, gamma are constants determined by grid search. After CA integration and classifier replacement, the effective parameter count is 4.49M at 0.416G FLOPs. Pretrained ImageNet weights were loaded locally and used for full fine-tuning.

3.6 Coordinate Attention Integration

Coordinate Attention (CA) (Hou et al., 2021) extends standard channel attention by preserving spatial location information along both the horizontal and vertical axes. CA decomposes global pooling into two directional operations:

$$z_h^c(h) = \frac{1}{W} \sum_{0 \le i < W} x^c(h, i) \tag{2.6}$$

$$z_w^c(w) = \frac{1}{H} \sum_{0 \le j < H} x^c(j, w) \tag{2.7}$$

where x^c is the c-th channel of the input feature map with height H and width W. The two directional descriptors are concatenated and passed through a shared transformation:

$$f = \delta\left(F_1([z^h, z^w])\right) \tag{2.8}$$

where delta is a non-linear activation and F_1 is a 1x1 convolution that reduces channel dimensionality by a reduction ratio r. The resulting embedding is split and projected back to generate attention weights along each spatial direction:

$$g^h = \sigma\left(F_h(f^h)\right), \qquad g^w = \sigma\left(F_w(f^w)\right) \tag{2.9}$$

The final attended output is:

$$y^c(i, j) = x^c(i, j) \cdot g_c^h(i) \cdot g_c^w(j) \tag{2.10}$$

The CA module is inserted at the output of the final convolutional stage in each backbone, immediately before the global average pooling and classifier head, where spatial feature refinement has the greatest effect on downstream classification.

3.7 Experimental Configuration and Training Protocol

All four models were trained using cross-entropy loss with stochastic gradient descent (SGD), learning rate = 0.01, momentum = 0.9, and early stopping with patience = 7 epochs monitored on validation accuracy. Pretrained ImageNet weights were loaded locally for ShuffleNetV2, MobileNetV3-Small, and EfficientNet-B0. GhostNet was initialized randomly and trained from scratch. All experiments used a fixed seed of 42 for stratified splitting and reproducibility. Each model was evaluated on five data configurations as defined in Table 3.1, producing 20 main experimental runs in total. Ablation experiments removing the CA module were conducted for all four models on the Real + cGAN configuration to isolate the CA contribution.

All 20 main experimental runs and ablation experiments represent single training runs without repeated trials. Given the small dataset size (1,902 real images), results are sensitive to random initialization and split variance. Small percentage-point differences, particularly the 0.70 percentage point CA ablation result for ShuffleNetV2, should be interpreted with caution as they may not be distinguishable from random variation without repeated trials with variance reporting.

The Real + TradAug configuration applied the following augmentation pipeline to the real training images: random horizontal flip (p = 0.5), random vertical flip (p = 0.5), random rotation within ±30 degrees, color jitter with brightness = 0.2, contrast = 0.2, saturation = 0.2, and hue = 0.1, and random resized crop to 128 × 128 with scale range [0.8, 1.0]. No synthetic images were used in this configuration.

3.8 Evaluation Criteria

Model performance was evaluated using accuracy, precision, recall, and F1-score computed on the real test set as in (Saminu et al., 2026; Bawa et al., 2026). Let TP, FP, TN, and FN denote true positives, false positives, true negatives, and false negatives respectively:

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}} \quad (2.11)$$

$$\text{Precision} = \frac{\text{TP}}{\text{TP} + \text{FP}} \quad (2.12)$$

$$\text{Recall} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (2.13)$$

$$\text{F1-Score} = \frac{2 \times \text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}. \quad (2.14)$$

Weighted-average metrics were used across all four classes to account for class distribution differences in the test set. GAN image quality was assessed using FID and IS as described in Section 3.3**.** Inference time was measured as the average time per image on the RTX 5070 GPU across the full test set.

4. RESULTS AND ANALYSIS

This section presents and discusses the experimental results across all five data configurations for the four CA-enhanced lightweight CNN architectures. Results are organized as follows: cGAN training and image quality evaluation, main classification results, ablation analysis of Coordinate Attention, augmentation strategy comparison, convergence analysis, per-class classification analysis, and efficiency benchmarking.

4.1 cGAN Training Quality Evaluation

Figure 4.1 shows the cGAN training loss curve over 1,000 epochs. The discriminator loss stabilized near zero early in training and remained consistently low throughout, indicating that the discriminator learned a reliable decision boundary quickly. The generator loss increased gradually over training epochs, reflecting the expected adversarial dynamic where a stronger discriminator forces the generator to produce progressively harder-to-reject samples. No mode collapse was observed across the 1,000-epoch run.

Table 4.1 summarizes the FID and IS scores computed at epochs 300, 500, 700, and 1,000 across all four disease classes.

Table 4.1: FID and IS evaluation across cGAN training checkpoints

.

Epoch	Health FID	GLS FID	NLB FID	NLS FID	Avg FID	Combined IS
300	171.23	241.84	257.66	225.24	223.99	2.98
500	144.58	223.26	245.76	210.57	206.04	3.06
700	142.55	213.53	233.48	204.73	198.57	3.28
1,000	129.83	228.31	238.33	207.66	201.03	3.32

FID improved consistently from epoch 300 (avg 223.99) to epoch 700 (avg 198.57), then rose slightly at epoch 1,000 (avg 201.03). IS increased monotonically across all checkpoints, reaching its highest value of 3.32 at epoch 1,000. This creates a trade-off: epoch 700 produces synthetic images with better distributional similarity to real data, while epoch 1,000 produces images with higher individual quality and intra-set diversity.

The Healthy class consistently achieved the lowest FID across all checkpoints, reaching 129.83 at epoch 1,000. This is expected given that healthy leaf images are visually more uniform than diseased ones. GLS, NLB, and NLS showed higher FID values throughout, reflecting the greater visual

complexity and inter-class similarity of disease lesion patterns. All IS values above 2.0 across all epochs are consistent with the reference threshold reported by Cap et al. [21] for domain-specific agricultural GANs, though this threshold was derived from a different dataset and serves here as a heuristic reference point rather than a universally established benchmark.

Epoch 1,000 was selected for downstream augmentation experiments because it produced the highest IS (3.32), indicating superior image diversity, and its FID (201.03) remained comparable to epoch 700 (198.57), with a difference of only 2.46 points. Given the small FID gap and the meaningful IS gain, epoch 1,000 represents the better overall trade-off for augmenting a small, imbalanced dataset where intra-class diversity directly affects classifier generalization.

It should be noted that the downstream classifier accuracy using epoch-700-generated images was not separately evaluated. The epoch 1,000 selection is based on the FID/IS trade-off analysis above rather than a direct empirical comparison of downstream classification performance between the two checkpoints.

4.2 Main Classification Results: Real + cGAN ep1000

Table 4.2 presents the main classification results for all four models trained on the Real + cGAN ep1000 configuration. Figure 4.2 shows the model comparison across accuracy, F1-score, inference time, and parameter count.

Table 4.2: Main classification results: Real + cGAN ep1000 with Coordinate Attention

Model	Acc (%)	Prec (%)	Rec (%)	F1 (%)	Params (M)	FLOPs (G)	Inf (ms)	Size (MB)
MobileNetV3-Small	94.06	94.68	94.06	93.99	1.11	0.061	5.10	4.43
ShuffleNetV2	93.36	93.45	93.36	93.35	1.62	0.153	9.17	6.46
EfficientNet-B0	88.81	89.15	88.81	88.87	4.49	0.416	30.83	17.96
GhostNet	80.07	80.98	80.07	79.89	1.17	0.135	15.86	4.66

MobileNetV3-Small achieved the best overall result at 94.06% accuracy and 93.99% F1-score, with the smallest parameter count (1.11M), lowest FLOPs (0.061G), fastest inference (5.10ms), and second-smallest model size (4.43MB). ShuffleNetV2 followed closely at 93.36% accuracy with a 9.17ms inference time and 1.62M parameters. The 0.70 percentage point accuracy gap between the two is small, but MobileNetV3-Small's inference speed advantage (5.10ms vs 9.17ms) is practically significant for real-time field applications.

EfficientNet-B0 achieved 88.81% accuracy despite having the largest parameter count (4.49M), highest FLOPs (0.416G), and slowest inference time (30.83ms) among the four models. Its larger capacity did not translate to better performance under cGAN-augmented training on this dataset size, suggesting that the additional model complexity was not justified by the available training data. GhostNet recorded the lowest accuracy at 80.07%, a result directly explained by its training-from-scratch condition, discussed further in Section 4.4.

4.3 Results Across All Five Data Scenarios

Table 4.3 presents the complete accuracy results across all five configurations for all four models.

Table 4.3: Classification accuracy (%) across all five data configurations

Model	Real Only	cGAN Only	Real + cGAN	Real + cGAN (no CA)	Real + TradAug
MobileNetV3-Small	93.01	99.83	94.06	81.82	98.60
ShuffleNetV2	32.87	99.67	93.36	94.06	98.25
EfficientNet-B0	95.45	99.83	88.81	85.66	97.20
GhostNet	91.61	100.00	80.07	74.83	96.15

Several patterns emerge across scenarios. All four models achieved near-perfect or perfect accuracy under cGAN-only training (99.67% to 100.00%). This result does not reflect genuine generalization. When trained on synthetic data alone and tested on real images, the high accuracy indicates the models learned the synthetic data distribution effectively, but the real test set happened to be classifiable from features the generator had already encoded. The collapse in performance when real data is added in the Real + cGAN scenario, particularly for GhostNet (100.00% to 80.07%), confirms that synthetic-only accuracy does not predict real-world generalization.

Traditional augmentation outperformed cGAN augmentation in the Real + Aug comparison for all four models. MobileNetV3-Small reached 98.60% with TradAug versus 94.06% with cGAN. ShuffleNetV2 reached 98.25% with TradAug versus 93.36% with cGAN. Geometric and photometric augmentation of real images produces more in-distribution training samples than GAN-synthesized data, which can introduce distributional artifacts that partially conflict with real image statistics (Wu et al., 2020).

ShuffleNetV2 recorded only 32.87% accuracy in the Real Only scenario. The Real Only training set contains only 1,331 images split across four classes after stratified partitioning. ShuffleNetV2's channel-split architecture appears particularly sensitive to small dataset size without augmentation. The convergence analysis for the Real Only run indicates the model stopped early, suggesting it did not have sufficient data to learn stable class boundaries before convergence criteria were triggered; however, no dedicated training curve for this specific scenario is reported here, and this explanation should be treated as inferred rather than directly observed. The addition of 4,000 cGAN-generated images in the Real + cGAN scenario resolved this, confirming that ShuffleNetV2 requires a minimum data volume to function effectively.

4.4 GhostNet Shortcut Learning Analysis

GhostNet's result in the cGAN-only scenario warrants specific attention. A perfect 100.00% accuracy on the real test set when trained exclusively on synthetic data is not a sign of a strong model. It indicates shortcut learning: the model memorized the cGAN output distribution so effectively that the features it learned aligned with the real test set by coincidence rather than genuine disease discrimination.

When real images were added in the Real + cGAN configuration, accuracy dropped to 80.07%, a 19.93 percentage point decline. Adding real images introduced a second, conflicting distribution that the model could not reconcile without pretrained weights. The other three models, all initialized from ImageNet weights, showed no such collapse. MobileNetV3-Small, ShuffleNetV2, and EfficientNet-B0 all performed stably when moving from cGAN-only to Real + cGAN training. The contrast confirms that pretrained initialization is a necessary condition for stable generalization under combined real and synthetic training on small agricultural datasets.

The GhostNet confusion matrix (Figure 4.3b) shows the clearest evidence of this failure: 31 of 79 GLS samples were misclassified as NLB, and 12 of 75 NLB samples were misclassified as GLS. These two classes share streak-like lesion textures, and without pretrained low-level feature representations, GhostNet could not learn sufficiently discriminative boundaries between them from the

combined dataset.

A methodological limitation of this comparison should be acknowledged: GhostNet was trained from scratch due to the absence of publicly available pretrained weights compatible with the native PyTorch implementation used, while ShuffleNetV2, MobileNetV3-Small, and EfficientNet-B0 were initialized from ImageNet weights. This pretraining difference is an uncontrolled variable in the multi-architecture comparison. GhostNet's lower performance should therefore be interpreted as initialization-dependent rather than a property of the Ghost module architecture in isolation. A fairer architectural comparison would require pretrained GhostNet weights, which are available via timm for some configurations and should be explored in future work.

4.5 Coordinate Attention Ablation

Table 4.4 presents the ablation results comparing each model with and without the Coordinate Attention module on the Real + cGAN ep1000 configuration.

.

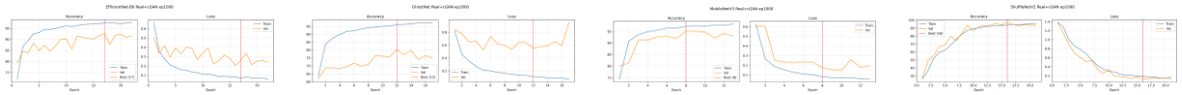

Table 4.4: Coordinate Attention ablation results: Real + cGAN ep1000

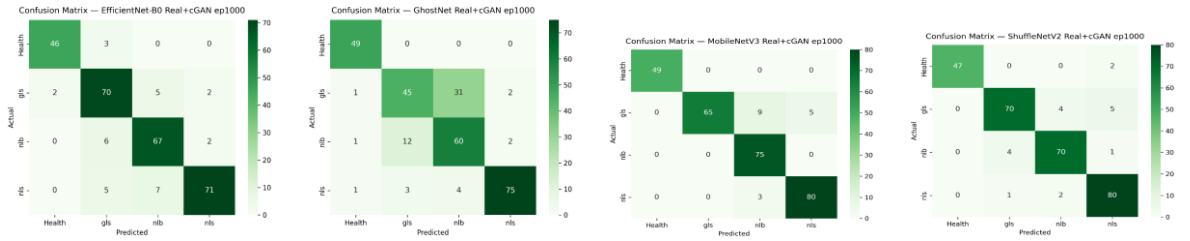
Model	With CA (%)	Without CA (%)	CA Gain (pp)
MobileNetV3-Small	94.06	81.82	+12.24
GhostNet	80.07	74.83	+5.24
EfficientNet-B0	88.81	85.66	+3.15
ShuffleNetV2	93.36	94.06	-0.70

Overall, Coordinate Attention produced consistent accuracy gains for three of the four models. The largest gain was in MobileNetV3-Small, where removing CA caused a 12.24 percentage point drop from 94.06% to 81.82%. MobileNetV3-Small's built-in SE blocks operate on global channel statistics and discard spatial position information. CA's directional pooling recovers this spatial context, allowing the model to attend to localized lesion regions rather than treating all spatial positions equally. The combination of SE and CA in MobileNetV3-Small thus provides complementary rather than redundant attention.

GhostNet gained 5.24 percentage points with CA, and EfficientNet-B0 gained 3.15 points. Both results confirm that directional spatial attention improves lesion localization across architectures with different internal structures. ShuffleNetV2 showed a marginal 0.70 percentage point decrease with CA compared to without. The channel-shuffle operation in ShuffleNetV2 already promotes cross-channel information mixing, which may partially substitute for the recalibration that CA provides in architectures without such mixing

4.6 Convergence Analysis



Figures 4.5 through 4.8 show the training and validation accuracy and loss curves for each model under the Real + cGAN ep1000 configuration. MobileNetV3-Small (Figure 4.7) converged fastest, reaching its best validation accuracy of 95% at epoch 8 before early stopping triggered at epoch 13. Both train and validation loss decreased smoothly and in close alignment, with no sign of overfitting.

ShuffleNetV2 (Figure 4.8) showed a longer convergence trajectory, reaching its best validation accuracy at epoch 16 out of 21 total epochs. The training and validation curves tracked closely throughout, with both loss curves descending steadily. EfficientNet-B0 (Figure 4.5) reached its best validation accuracy at epoch 17, with training accuracy exceeding 97% while validation accuracy stabilized around 91-93%. The visible gap between training and validation accuracy from epoch 10 onward suggests mild overfitting, attributable to EfficientNet-B0's larger capacity relative to the effective training set size.

GhostNet (Figure 4.6) displayed the most unstable convergence pattern. Validation accuracy peaked at 80% at epoch 12, after which validation loss began rising sharply while training loss continued to decrease. This divergence between training and validation loss is the signature of overfitting, directly attributable to the absence of pretrained weights. Without ImageNet initialization, GhostNet must learn feature representations entirely from the training data, and the distribution mismatch between real and synthetic images creates optimization instability that pretrained models avoid.

4.7 Per-Class Classification Analysis

Figures 4.3a through 4.3d show the confusion matrices for all four models on the Real + cGAN ep1000 test set. MobileNetV3-Small (Figure 4.3c) produced the cleanest classification pattern. It correctly classified all 49 Healthy samples, all 75 NLB samples, and 80 of 83 NLS samples. The only notable errors were 9 GLS samples misclassified as NLB and 5 GLS samples misclassified as NLS, out of 79 total GLS samples. GLS was the only class where the model showed consistent confusion, expected given that GLS lesion textures share angular streak characteristics with NLB at certain disease stages.

ShuffleNetV2 (Figure 4.3d) correctly classified 47 of 49 Healthy samples, 70 of 79 GLS samples, 70 of 75 NLB samples, and 80 of 83 NLS samples. Errors were distributed relatively evenly across classes, with no single class dominating the misclassification pattern. EfficientNet-B0 (Figure 4.3a) correctly classified 46 of 49 Healthy samples and 71 of 83 NLS samples. Its GLS-NLB misclassifications (11 total) are comparable to MobileNetV3-Small (14 total), and its lower overall accuracy relative to the other pretrained models is distributed across multiple class boundaries rather than concentrated at a single pair.

GhostNet (Figure 4.3b) showed the highest concentration of errors at the GLS-NLB boundary. Thirty-one of 79 GLS samples were predicted as NLB, representing a 39.2% error rate for that class. This single failure accounts for a large portion of GhostNet's overall accuracy deficit and confirms that the GLS-NLB boundary is the primary point of failure for models without stable pretrained feature representations.

4.8 Efficiency Analysis

Table 4.5 summarizes the efficiency profile of all four models under the Real + cGAN ep1000 configuration

.

Table 4.5: Model efficiency comparison: Real + cGAN ep1000 with Coordinate Attention.

Model	Params (M)	FLOPs (G)	Inf (ms)	Size (MB)	Acc (%)
MobileNetV3-Small	1.11	0.061	5.10	4.43	94.06
GhostNet	1.17	0.135	15.86	4.66	80.07
ShuffleNetV2	1.62	0.153	9.17	6.46	93.36
EfficientNet-B0	4.49	0.416	30.83	17.96	88.81

MobileNetV3-Small achieves the best accuracy-efficiency trade-off across all four metrics simultaneously. Its FLOPs of 0.061G are 2.2 times lower than GhostNet (0.135G), 2.5 times lower than ShuffleNetV2 (0.153G), and 6.8 times lower than EfficientNet-B0 (0.416G). Its inference time of 5.10ms is the fastest in the group and its 4.43MB storage footprint is the smallest. EfficientNet-B0's 4.49M parameters and 17.96MB storage size make it the least suitable for edge deployment, and its 30.83ms inference time is six times slower than MobileNetV3-Small while delivering 5.25 percentage points lower accuracy in this scenario.

5. CONCLUSION

This study comparatively evaluated four Coordinate Attention-enhanced lightweight CNNs under cGAN augmentation for maize leaf disease recognition. MobileNetV3-Small achieved the best result at 94.06% accuracy with 1.11M parameters, 0.061G FLOPs, and 5.10ms inference, making it the most suitable architecture for resource-constrained deployment. GhostNet's performance collapsed from 100.00% under synthetic-only training to 80.07% when real data was added, confirming that pretrained initialization is necessary for stable generalization under combined real and synthetic training. Traditional augmentation outperformed cGAN in all combined scenarios, establishing that synthetic generation is most valuable when real data is severely limited. Ablation confirmed Coordinate Attention contributes consistent gains across three of four architectures, with the largest improvement of 12.24 percentage points in MobileNetV3-Small, where CA's directional spatial encoding complements the model's built-in global channel attention. The primary finding is that no single architecture dominates across all criteria: MobileNetV3-Small leads on accuracy and efficiency, while ShuffleNetV2 offers competitive accuracy at moderate cost. Future work will evaluate WGAN-GP and StyleGAN2-ADA as alternative augmentation strategies, test robustness on UAV-captured field imagery, and explore structured pruning of MobileNetV3-Small for low-power edge deployment.

ABSTRACT

Environmental sound recognition has become increasingly important in applications ranging from smart surveillance to health monitoring and intelligent urban systems. Although recent deep learning models have improved the ability to classify complex acoustic events, many of them still struggle with redundant features in audio embeddings or rely on heavy architectures that limit deployment on resource-constrained devices. To address these challenges, we developed a lightweight framework that combines YAMNet's pre-trained audio embeddings with a simple one-dimensional self-attention mechanism. This design helps the model focus on the most informative parts of each audio segment while avoiding unnecessary computational overhead. The enhanced embeddings are then processed through a compact fully connected network for final classification. Experiments on two benchmark datasets, ESC-10 and BDLib, demonstrate the effectiveness of the proposed approach, achieving test accuracies of 96% and 97%, respectively. The model outperforms an Xception-based transfer learning baseline on ESC-10 by 2.7% while using roughly 45× fewer parameters and provides competitive performance to MobileNetV2 on BDLib with only a fraction of its complexity. Though, the model was developed by utilizing small datasets with few classes of sounds, the results obtained indicate that applying self-attention directly to pre-trained audio embeddings can significantly improve environmental sound classification and offers a solution for real-time acoustic monitoring in noisy environments.

Keywords: *Environmental sound classification; Neural Networks; Self-Attention Mechanism; transfer learning*

I. INTRODUCTION

Environmental sound classification (ESC) is increasingly becoming an integral component of intelligent systems, particularly in applications such as automated surveillance, health monitoring, smart homes, and smart cities. These intelligent systems rely on the ability to recognize and interpret everyday acoustic events such as; natural sounds like rain or ocean waves and critical events such as alarms, sirens, or human activities. Also, ESC has found applications in smart surveillance systems, health monitoring, and environmental sensing in urban areas (Piczak, 2015a). For instance, in a security system, detecting a glass-breaking sound could help raise an alarm even in the absence of video data (Hershey *et al*., 2017) .

Benchmark datasets such as ESC-10 and ESC-50 have played an important role in enabling systematic evaluation of ESC methods by providing curated collections of labeled environmental sounds (Mu *et al*., 2021). Compared with structured signals such as speech and music, environmental sounds often exhibit highly variable and complex time–frequency patterns, which makes them more challenging to model reliably (Mkrtchian & Furletov, 2022).

Early ESC approaches were largely based on hand-crafted features such as Mel-frequency cepstral coefficients (MFCC) combined with classical machine learning algorithms. Although these pipelines gave useful baselines, they typically struggled to capture richer temporal and spectral dependencies and often degraded in the presence of noise or overlapping events (Mushtaq & Su, 2020). The emergence of deep learning has significantly improved ESC performance. Convolutional neural networks (CNNs) operating on spectrograms or stacked acoustic features have been shown to outperform traditional models on ESC-10, ESC-50 and related corpora (Mun *et al*., 2017).

Recent works have further refined these architectures using multi-branch (Latifi *et al*., 2024) or pyramidal CNNs to better capture multi-scale time–frequency patterns (Demir *et al*., 2020; Fang *et al*.,

2022). A parallel line of research has focused on pre-trained audio models trained on large-scale datasets such as AudioSet. PANNs, for instance, provide large-scale pre-trained audio neural networks that have demonstrated strong transfer performance across a variety of audio pattern recognition tasks (Kong *et al*., 2020). Similarly, several studies have adopted YAMNet-based transfer learning for downstream audio tasks. The YAMNet-based transfer learning model, a 1024-dimensional embedding generator strategy, is derived from a MobileNet-like architecture trained on hundreds of sound event classes (Liu *et al*., 2025). This strategy has been particularly attractive in resource-constrained scenarios such as embedded anomaly detection in smart cities, where pre-trained models are retrained on ESC-10, BDLib, and related datasets and then deployed on Raspberry Pi or TPU platforms (Lamrini *et al*., 2023).

Despite these advances, two key limitations remain. First, embeddings produced by general-purpose pre-trained models may contain redundant or weakly relevant dimensions when applied to more specific ESC tasks. Second, CNN-based transfer learning architectures typically introduce millions of additional parameters, which increases memory consumption and computational latency. Thus, model developed may not be ideal for edge deployment. For instance, CNN-based transfer learning using Xception has achieved strong performance on ESC-10 and ESC-50 but at the cost of relatively large model sizes (Zhou *et al*., 2025). At the same time, work on lightweight ESC models, such as resource-adaptive CNNs (Binandeh Dehaghani et al., 2025; Fang *et al*., 2022), has highlighted the importance of carefully balancing accuracy with computational efficiency for practical deployment.

Motivated by these observations, this study explores a lightweight framework that applies a one-dimensional self-attention mechanism directly to YAMNet embeddings for environmental sound recognition. The central ideas is to refine the pre-trained embedding space by emphasizing the most informative dimensions before classification, rather than adding deeper convolutional or recurrent stacks. As detailed in the rest of this paper, the proposed model combines YAMNet-derived 1024-dimensional embeddings with a simple dense self-attention layer and a compact fully connected classifier, and is evaluated on ESC-10 and BDLib. The results show that this approach can achieve high accuracy while using substantially fewer parameters than typical CNN-based transfer learning baselines, making it a promising option for real-time ESC on embedded devices.

II. RELATED WORKS

A. Environmental Sound Classification with Deep Learning

Early deep learning studies showed that CNNs operating on log-Mel spectrograms can substantially outperform classical machine learning methods on these datasets. Piczak demonstrated that relatively shallow CNNs already capture useful local time–frequency patterns for ESC-50, while subsequent work improved robustness further using deeper architectures and data augmentation (Piczak, 2015b). The work of Mushtaq and Su (2020) proposed a regularized deep CNN with data augmentation, reporting improved performance on ESC-10, ESC-50 and UrbanSound8K by combining appropriate feature extraction with network regularization. Other studies have explored alternative CNN topologies such as concatenated or pyramidal architectures to capture richer multi-scale representations of environmental sounds (Mu *et al*., 2021).

At the same time, there has been a growing interest in models that can provide strong performance while remaining computationally efficient. The work of [8] introduced a resource-adaptive CNN (RACNN) that uses a lightweight convolutional module to reduce hardware requirements and speed up ESC, highlighting the importance of designing architectures explicitly for embedded deployment. Other efficient end-to-end architectures, such as AclNet (Huang & Alvarado Leanos, 2018), and SwishNet (Hussain & Haque, 2018), have explored 1D CNNs and compressed model designs to achieve high accuracy at significantly reduced complexity. These works collectively show that careful architectural design can strike a useful trade-off between accuracy and resource usage.

B. Pre-trained Audio Models and YAMNet-based Transfer Learning

Large-scale pre-trained audio models have become increasingly influential in ESC and related tasks. PANNs, trained on AudioSet, provide pre-trained CNN backbones that can be fine-tuned or used as feature extractors for various audio tagging, acoustic scene classification, and sound event detection problems (Kong *et al*., 2020). Building on this idea, several recent studies have adopted YAMNet as a

generic feature extractor. In their work, Liu *et al.* (2025) used YAMNet-based transfer learning to build a compact noise classifier. Their findings showed that its 1024-dimensional embeddings can be effectively reused in downstream tasks with relatively small additional networks. In the work of Wu (2025), a comprehensive approach for urban sound detection was developed using YAMNet obtain high-level embeddings and bidirectional LSTM as classification modules. The work of Mohino-Herranz *et al*. (2025) showed that the use of pretrained YAMNet for sound event classification on edge devices reduce training requirements and enable efficient deployment.

Lamrini *et al*. (2023) evaluated the performance of a pre-trained CNN for environmental sound recognition on multiple platforms, including laptops, Raspberry Pi, and Coral TPU, using ESC-10, BDLib, and UrbanSound datasets (Salamon *et al*., 2014). Their results showed that transfer learning with pre-trained audio networks can achieve up to 100% accuracy on BDLib while remaining feasible on embedded hardware. However, these systems often rely on relatively heavy CNN backbones with millions of parameters. Although pre-training reduces the amount of labeled data required, the resulting models may still be over-parameterized for low-power deployment and may not explicitly address redundancy within the pre-trained embedding space.

C. Attention Mechanisms for Environmental Sound Classification

Attention mechanisms have been widely adopted to improve the modeling of complex acoustic patterns. In their work, Mu *et al.* (2021) proposed a temporal–frequency attention-based CNN (TFCNN) that applies attention over log-Mel spectrograms to focus on informative time–frequency regions. The work of Qiao *et al*. (2021) compared sub-spectrogram segmentation with temporal–frequency attention mechanisms and showed that attention mechanisms can provide performance gains by adaptively weighting different spectrogram regions. More recently, attention has been integrated into residual architectures and multi-branch CNNs for ESC (Zhong *et al*., 2025). This further demonstrate its usefulness in refining spectro-temporal representations.

Beyond ESC, self-attention and multi-head attention have been explored in broader audio tasks. The work of Dong *et al.* (2023), applied multi-head attention to acoustic scene analysis and showed that attention over frame-level representations can yield competitive performance with only recording-level supervision. In the work of Wang *et al*. (2020), self-attention mechanism was assessed on learned features for joint sound event localization and detection. Findings demonstrated that self-attention can effectively replace or complement recurrent layers in CRNN-based architectures. Sudarsanam *et al*. (2021) developed an adaptive memory-controlled self-attention mechanism to improve polyphonic sound event detection by selectively emphasizing salient temporal patterns. These studies suggest that self-attention is a flexible tool for highlighting informative portions of audio representations; whether in time, frequency, or latent feature space.

Most attention-based ESC models, however, operate on spectrograms or intermediate CNN feature maps, which requires additional preprocessing and often increases model complexity. In contrast, the present work investigates a simpler alternative by applying a one-dimensional self-attention mechanism directly to pre-trained YAMNet embeddings and compact neural network classifier. As shown in our experiments, this embedding-level attention can yield competitive or superior ESC performance while maintaining a very small parameter budget. Thus, making our approach attractive for resource-constrained deployments.

III. METHODOLOGY

This section describes the proposed system for environmental sound classification; including data preprocessing, feature extraction using YAMNet, the application of a self-attention mechanism, and the final classification using fully connected layer. Fig. 1 shows the steps involved in process of audio classification.

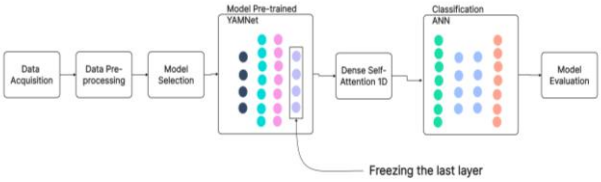

Figure 1: Proposed ESC framework

A. Dataset Aquisition and Preprocessing

Two benchmark datasets were used in this study: ESC-10 (Piczak, 2015a) and BDLib (Bountourakis *et al*., 2015; Bountourakis *et al*., 2019). The ESC-10 dataset was acquired from https://github.com/karoldvl/ESC-50/archive/master.zip. ESC-10 contains 400 audio samples across 10 environmental classes such as dog bark, clock ticking, and chainsaw. Each audio clip is 4 seconds long and sampled at 44.1 kHz. BDLib is a custom dataset collected for environmental monitoring applications. For this work, the BDLib dataset was acquired from https://research.playcompass.com/files/BDLib-2.zip. It includes sounds like rain, helicopter, sea waves, and sneezing, each stored as a .wav file in class-labelled folders.

To prepare the data, all audio files were first resampled to 16 kHz and converted to mono, matching the input requirements of YAMNet (Hershey *et al*., 2017). A sliding window of 4 seconds was applied to each clip with a 50% overlap (Lamrini *et al*., 2023). This resulted in more training samples from each audio file and ensured that important sound segments were not missed. Basic noise filtering was applied to remove silent frames. Fig. 2 shows the windowing process technique.

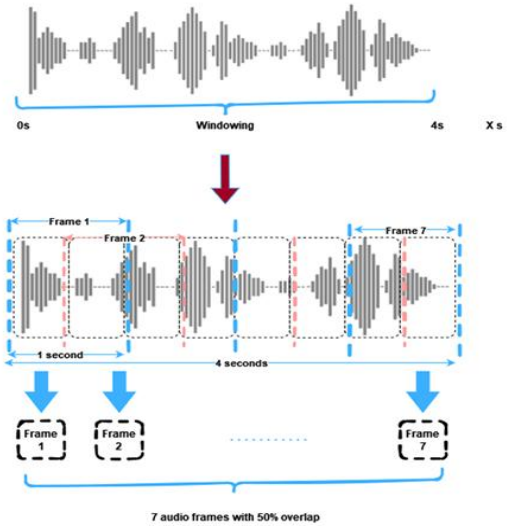

Figure 2: Windowing approach (Lamrini *et al*., 2023)

B. Feature Extraction Using YAMNet

In this work, the YAMNet pretrained model was used purely as a feature extractor. Its classification head was removed, and the last fully-connected layer was frozen. The output of the frozen fully connected layer serves as input to the dense self-attention module of Figure 1. A 4-second audio window was adopted. Fig. 3 shows the adopted YAMNet architecture.

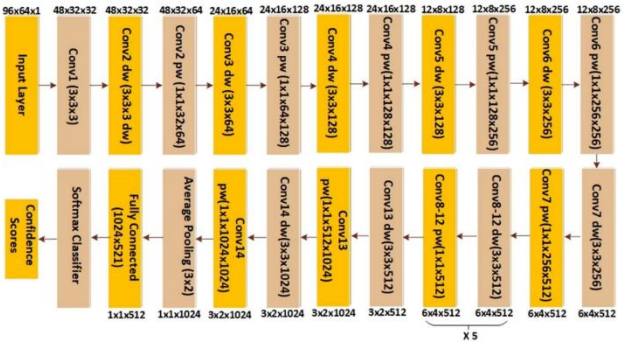

Figure 3: Adopted YAMNet architecture (Hershey *et al.*, 2017)

C. Self-Attention Mechanism Module

After feature extraction, a custom 1D self-attention layer was applied to the embeddings. This mechanism allows the model to assign different levels of importance to each dimension of the YAMNet output vector. The attention layer consists of a dense projection of the embedding followed by a SoftMax operation to compute attention scores. These scores are then multiplied element-wise with the original embeddings to produce an attention-weighted feature vector. Fig. 4 illustrate a single-head dense self-attention mechanism applied to 1D embeddings

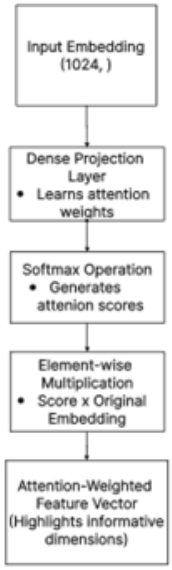

Figure 4: Single-headed dense self-attention module

This process enhances the most informative elements in the vector and suppresses those with little contribution to the final prediction. Unlike the temporal–frequency attention applied on spectrograms in earlier work (Kuzminykh *et al.*, 2020), this approach applies attention directly to a compact, pre-trained embedding. The goal is to reduce complexity while preserving performance.

D. Classification Module

The attention-enhanced embeddings generated by the single-headed dense self-attention module of Figure 4 are passed through a fully connected network consisting of two dense layers with 256 units each, using ReLU activation and dropout of 0.5 for regularization. Then, a final dense layer with 10 units and SoftMax activation was used to produce the probability distribution across the 10 sound classes. The summary of the architecture of the proposed model and parameter information used in each layer.

TABLE I. SUMMARY OF MODEL PARAMETERS

Type of Layer	Output Shape	Number of Parameters
Input_layer (InputLayer)	(None, 1024)	0
dense_self_attention1d (DenseSelfAttention1D)	(None, 1024)	131,329
dense_2 (Dense)	(None, 256)	262,400
dropout (Dropout)	(None, 256)	0
dense_3 (Dense)	(None, 256)	65,792
dropout_1 (Dropout)	(None, 256)	0
dense_4 (Dense)	(None, 10)	2,570
Total parameters	462,091	

E. Training Procedure

Two training scenarios were followed. First, the datasets were split into training (80%), validation (10%), and testing (10%) sets. The model was trained using the Adam optimizer with a learning rate of 0.001 and categorical cross-entropy as the loss function. Training was conducted on the ESC-10 and BDLib dataset for 10 and 20 epochs, respectively. Batch size was set to 32. The entire pipeline was implemented using TensorFlow and trained on a GPU-enabled environment.

Second, another training was conducted, using 5-fold cross validation (Zhou *et al*., 2025) on the ESC-10 dataset, to allow for precise evaluation of the proposed architecture in handling small dataset.

Performance was measured using accuracy, precision, recall, and F1-score. The evaluation was done on the test set to ensure generalization. A confusion matrix was also used to visualize per-class prediction accuracy.

IV. RESULTS

The model was evaluated on two datasets: ESC-10 and BDLib. Each dataset was divided into 80% training, 10% validation, and 10% testing splits.

A. ESC-10 Datasets Results

For the ESC-10 dataset, the model achieved a test accuracy of 96%, which shows that the proposed attention-based model can effectively classify environmental sounds using only the YAMNet embeddings. Table II shows the performance obtained based on the metrics for evaluation.

TABLE II. MODEL PERFORMANCE ON THE ESC-10 DATASET

Metric	Value
Accuracy	96%
Precision	98%
Recall	97%
f1-Score	97%

This result outperforms the recent transfer learning approach using the Xception CNN by Zhou *et al*. (2025); which reported 93.3% accuracy on the same ESC-10 dataset using mel-spectrogram-to-image conversion and a much larger model (~20.8 million parameters). In contrast, our lightweight architecture with only 462K trainable parameters achieves a 2.7% higher accuracy while being approximately 45 times more parameter-efficient. The confusion matrix for the ESC-10 dataset is presented in Fig. 5.

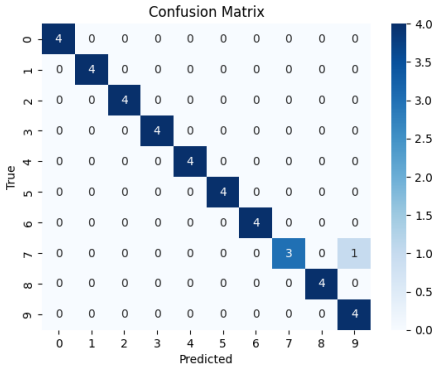

Figure 5: Developed model confusion matrix on the ESC-10 dataset

As seen in Figure 5, 9 classes were efficiently classifiedand only 1 test sample was misclassified; mostly in acoustically similar categories such as “clock ticking” and “crackling fire”.

Table III shows the cross-validation performance obtained based on the metrics for evaluation.

TABLE III. MODEL CROSS-VALIDATION PERFORMANCE ON THE ESC-10 DATASET

Metric	Value
Accuracy	95.40%
Precision	97.28%
Recall	96.29%
f1-Score	96.29%

Similarly, the cross-validation performance, in terms of accuracy, outperforms the recent transfer learning approach using the Xception CNN by Zhou *et al*. (2025) by 2.25%.

B. BDLib Dataset Results

The BDLib dataset yielded a test accuracy of 97% using the same model architecture. Table IV shows the performance obtained based on the metrics for evaluation.

TABLE IV. MODEL PERFORMANCE ON THE BDLIB DATASET

Metric	Value
Accuracy	97%
Precision	97%
Recall	97%
f1-Score	97%

Even though this dataset contains more real-world variations, the attention mechanism still performed well in learning meaningful embeddings from the YAMNet output. This result is competitive with the pre-trained MobileNetV2 transfer learning approach by Lamrini *et al.* (2023), which reported 100%, but required ~3.5 million parameters. Our lightweight design with only 462K trainable parameters achieves near-equivalent performance while being approximately 7.5 times more parameter-efficient. The confusion matrix for the BDLib dataset model is shown in Figure 6.

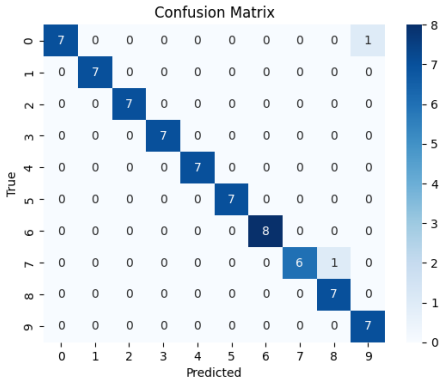

Figure 6: Developed model confusion matrix on the BDLib dataset

These results indicate strong generalization capability of the model on unseen, noisy samples.

V. DISCUSSION

The use of a self-attention mechanism on the YAMNet embedding played a key role in improving the classification performance. Compared to deeper CNN-based transfer learning models such as Xception used in the work of Zhou *et al*. (2025), which require over 20 million parameters to achieve 93.3% cross-validation accuracy on ESC-10 dataset, our YAMNet + self-attention model delivers superior performance with significantly lower computational overhead; proposed model shows 45 times smaller in size. Table V summarizes the comparison.

TABLE V. COMPARISON WITH BASELINE ON ESC-10 DATASET

Method	**Accuracy**	**Parameters**	**Parameter Ratio of baseline to Proposed Model**
Developed Model (YAMNet + Self-Attention) using 5-fold Cross-validation	95.4%	462K	~45
(Zhou *et al*., 2025) (Xception)	93.3%	~20.8M	

On the custom BDLib dataset, the 97% accuracy further validates the model's generalization to varied environmental sounds, closely approaching the 100% achieved by Lamrini *et al.* (2023) with MobileNetV2-based transfer learning under a matching 80/10/10 split. Table VI summarises the comparison.

TABLE VI. COMPARISON WITH BASELINE ON BDLIB DATASET

Method	**Accuracy**	**Parameters**	**Parameter Ratio of baseline to Proposed Model**
Proposed Model (YAMNet + Self-Attention)	97%	462K	~7.5
Lamrini et al. (2023) (BDLib-based MobileNetV2)	100%	~3.5M	

Similarly, from Table VI, the proposed model shows over 7.5 times improvement over the model developed in Lamrini *et al*. (2023), in terms of model size. This parameter efficiency gain, combined with high accuracy, positions the developed method as a practical solution for real-time audio-based environmental monitoring in edge environments. The network was able to highlight critical dimensions of the embedding vector while suppressing noise, resulting in a more discriminative feature space. This is consistent with previous works which have shown that attention can improve model performance. Additionally, the compact structure of the network with only 462K parameters makes it suitable for deployment on resource-constrained devices such as mobile phones or embedded systems for smart surveillance and monitoring.

VI. CONCLUSION

This study presented a lightweight and effective deep learning architecture for environmental sound classification. The approach combines YAMNet embeddings with a custom 1D self-attention mechanism followed by fully connected layers. The model was trained and evaluated on two datasets; ESC-10 and BDLib. A 5-fold cross-validation accuracy of 95.4 was obtained for the ESC-10 based model. And a test accuracy of 97% was obtained for the BDLib-based model. Thus the use of a pre-trained feature extractor allowed the model to learn high-level representations of audio without requiring complex spectrogram-based processing. Additionally, the attention mechanism significantly improved the model's ability to focus on the most informative parts of the audio embedding, leading to better classification performance. The architecture also remains computationally efficient compared with the baseline models. Therefore it can be a more suitable candidate for real-world applications where speed and resource constraints are critical.

Future work may explore the use of hybrid attention mechanisms, domain adaptation techniques, or lightweight convolutional variants to further improve robustness across a wider range of sound environments. Also, there is the need to deploy the developed model on embedded platforms, like Raspberry Pi, to evaluate it inference latency against existing works, because parameter efficiency alone may not translate to real-time feasibility. Finally, there is the need to further subject the developed technique on large and balanced datasets with more categories of sounds; to evaluate its generalization capability.

ABSTRACT
Weapon-related crimes pose significant threats to public safety and security, creating a growing need for intelligent surveillance systems capable of automatically identifying potential threats. Deep learning has demonstrated remarkable success in object recognition and image classification, making it well suited for automated weapon recognition. This study develops and evaluates a transfer learning-based approach for classifying two common weapon categories, AK-47 rifles, and knives, using a pretrained ResNet-50 convolutional neural network. A dataset comprising 2,001 labeled images was collected from Google Images, manually cleaned, preprocessed, and divided into training and validation sets using an 80:20 ratio. The pretrained ResNet-50 model was adapted using transfer learning and trained for 50 epochs. Model performance was evaluated using precision, recall, F1-score, and overall accuracy. Experimental results demonstrated high classification performance on the validation dataset, with the AK-47 class achieving a precision of 0.99, recall of 1.00, and F1-score of 0.99, while the Knife class achieved precision, recall, and F1-score values of 0.99, resulting in an overall classification accuracy of 0.99. Additional inference on previously unseen weapon images produced accurate predictions with consistently high confidence scores, providing supplementary evidence of the model's predictive capability beyond the validation samples. These findings demonstrate the effectiveness of the proposed approach as a proof-of-concept classification framework, highlighting its foundational potential for future integration into real-time intelligent surveillance and public safety applications.

1. INTRODUCTION

Video surveillance systems have become an integral component of modern public safety and security, playing a vital role in crime prevention and incident monitoring. Security cameras are widely deployed in transportation infrastructure, public housing complexes, shopping districts, border control areas, and public buildings to monitor activities and enhance security. Despite their widespread deployment, the monitoring of surveillance systems and the identification of potential threats still rely heavily on continuous human observation by security personnel. As the number of surveillance cameras continues to increase, maintaining effective real-time monitoring has become increasingly challenging, with operators often reviewing recorded footage only after incidents have occurred to reconstruct events and gather evidence. Furthermore, prolonged surveillance tasks can result in operator fatigue and human error, reducing the effectiveness of manual monitoring. These limitations highlight the growing need for intelligent and proactive surveillance systems capable of supporting timely threat identification (Kaya *et al.*, 2021).

Weapon-related violence remains a significant public safety concern worldwide, posing serious risks to human life and property. Early identification of dangerous weapons can significantly improve the ability of law enforcement and security agencies to respond promptly and mitigate potential harm. To overcome the limitations of manual surveillance, researchers have increasingly explored automated surveillance systems capable of recognizing weapons before violent incidents occur. Consequently, artificial intelligence (AI)-based surveillance solutions have been developed to detect and recognize dangerous objects within surveillance imagery. By providing faster and more consistent analysis than manual observation alone, AI can support security personnel, reduce operator workload, alleviate workforce shortages, and improve the overall efficiency of surveillance operations (Lim *et al.*, 2019; Xu & Hung, 2020; Mehta *et al.*, 2020; Gelana & Yadav, 2019; Dwivedi *et al.*, 2019).

Recent advances in artificial intelligence have been largely driven by deep learning, which has significantly improved the ability of computer systems to analyze and interpret visual information. Among deep learning models, Convolutional Neural Networks (CNNs) have demonstrated remarkable performance in image classification, object detection, and image segmentation by automatically learning hierarchical feature representations directly from image data. Their ability to extract discriminative visual features without relying on handcrafted feature engineering has made CNNs the dominant architecture for computer vision and intelligent surveillance applications (Verma & Dhillon, 2017; Burgaz & Budak, 2022; Kaya *et al*., 2021; Oura *et al*., 2021; Hashmi *et al.*, 2021; Ağdaş *et al*., 2021). Consequently, CNN-based approaches have substantially improved the automatic recognition of weapons and other dangerous objects, thereby enhancing situational awareness and supporting more effective security operations (Lim *et al.*, 2019).

A reliable weapon classification system can significantly enhance video surveillance, smart home security, intrusion detection, and smart city monitoring by providing timely alerts that support rapid decision-making and emergency response (Warsi *et al.*, 2019). Early recognition of dangerous weapons enables security personnel to intervene before situations escalate, thereby reducing potential risks to public safety (Yadav et al., 2023). Among commonly encountered weapons in security-related incidents, firearms such as the AK-47 and bladed weapons such as knives present significant security concerns because of their potential use in violent attacks. Consequently, this study focuses on the classification of AK-47 rifles and knives to support intelligent surveillance applications (Dwivedi *et al.*, 2019; Ingle & Kim, 2022).

One of the major advantages of modern CNN architectures is their ability to support transfer learning, whereby knowledge acquired from large-scale image datasets can be transferred to related tasks with limited training data. Rather than training a model from scratch, transfer learning enables pre-trained networks to be fine-tuned for specific applications, thereby reducing computational cost, shortening training time, and improving model performance when only modest datasets are available. These advantages make transfer learning particularly suitable for intelligent surveillance applications, where obtaining large, well-annotated weapon image datasets can be challenging (Dwivedi *et al*., 2019; Warsi *et al.*, 2019). Among the available deep learning architectures, ResNet-50 has become one of the most widely adopted models because of its ability to learn rich hierarchical feature representations while mitigating the vanishing gradient problem through residual learning (Kaya *et al*., 2021).

ResNet-50 has demonstrated excellent performance in image classification and surveillance applications because of its strong feature extraction capability and compatibility with transfer learning. Previous studies have successfully applied ResNet-50 to weapon recognition and firearm classification tasks, demonstrating robust performance under diverse operating conditions (Salido *et al*., 2021; Ahmed *et al.*, 2022; Kambhatla & Khaled, 2023). However, many existing studies have focused on object detection frameworks, larger datasets, or broader weapon categories, while comparatively fewer have investigated the effectiveness of transfer learning with ResNet-50 for the classification of specific weapon categories using relatively modest datasets. Therefore, this study develops and evaluates a transfer learning-based framework as a proof-of-concept classification study. Rather than real-time localization, this work establishes a diagnostic baseline for distinguishing AK-47 rifles and knives using clean web-scraped image repositories to evaluate supervised image classification performance prior to complex video stream deployment.

2. METHODOLOGY

The proposed methodology consists of four main stages: data acquisition, data preprocessing, model training, and weapon classification. Initially, a dataset containing images of AK-47 rifles and knives was collected and prepared for model development. The images were subsequently preprocessed to improve data quality and ensure compatibility with the deep learning model. During the training stage, a transfer learning approach based on the pre-trained ResNet-50 architecture was employed to learn discriminative features for weapon classification. Finally, the trained model was used to classify unseen query images into their respective weapon categories. The overall methodology is illustrated in Figure 1, while the detailed workflow of the proposed surveillance system is presented in Figure 2.

2.1 Proposed Surveillance System

The proposed intelligent surveillance system follows a sequential workflow comprising four major phases: data acquisition, data preprocessing, model training, and weapon classification. In the data acquisition stage, images representing the target weapon categories were collected to construct the dataset. The preprocessing stage involved resizing and normalizing the images to prepare them for deep learning. The processed images were then used to train the ResNet-50 model through transfer learning, enabling the extraction of discriminative visual features for accurate weapon classification. In the final stage, unseen query images were presented to the trained model, which predicted the corresponding weapon class. The individual stages of the proposed methodology are described in detail in the following subsections.

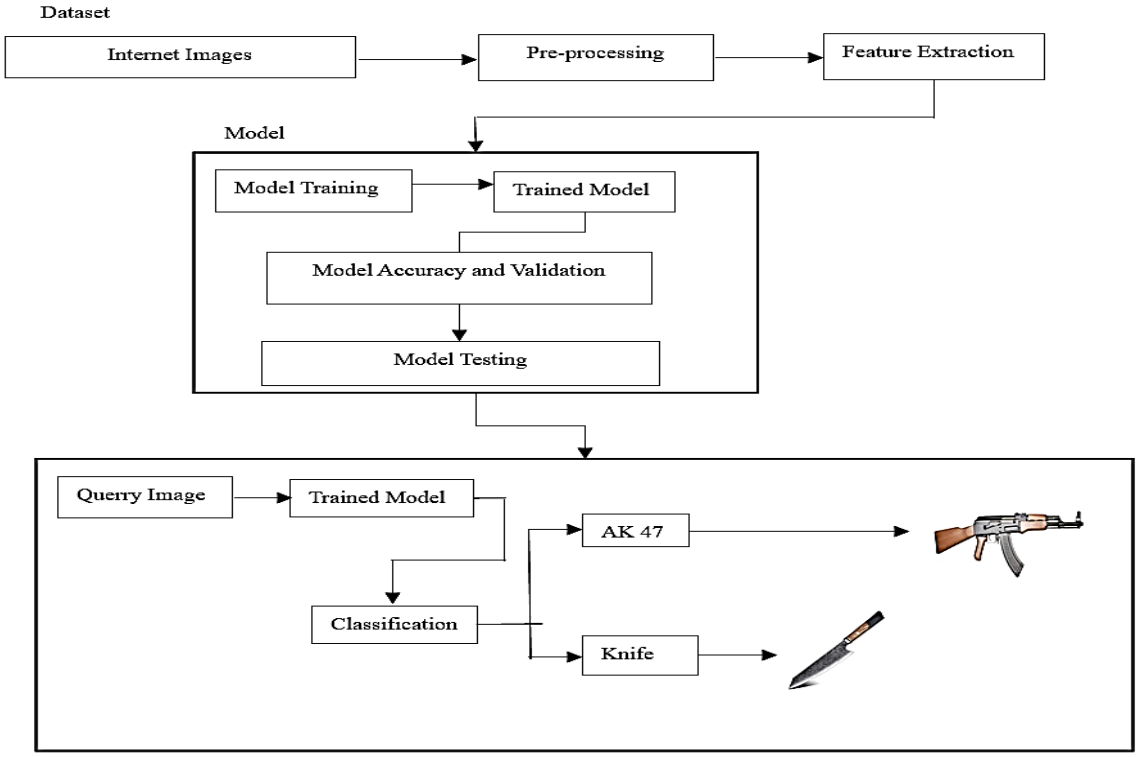

Figure 1: Block diagram of proposed methodology

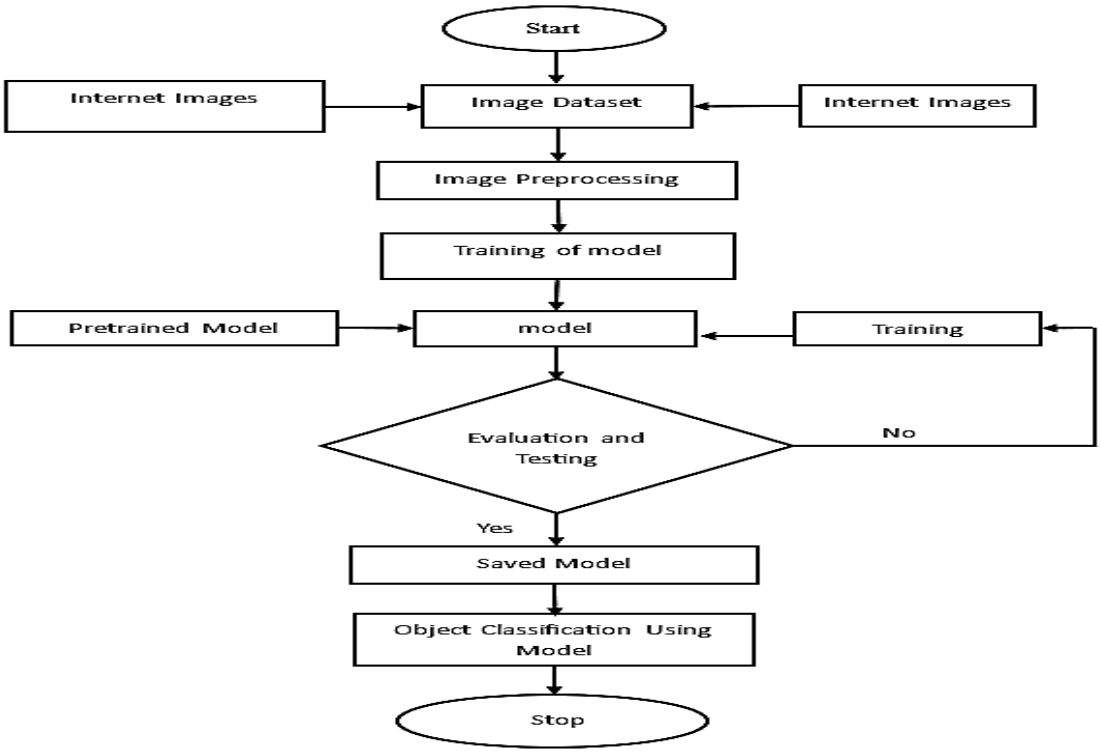

Figure 2: Methodology flowchart

2.2 Data Acquisition

During the data acquisition phase, a dataset comprising 2,001 images of AK-47 rifles and knives was collected from Google Images to support the development of the proposed weapon classification model. Search queries related to the two weapon categories were used to retrieve images captured under different viewpoints, backgrounds, lighting conditions, and object orientations in order to improve dataset diversity. The collected images were manually inspected to ensure their relevance

to the target classes before undergoing preprocessing. Representative samples of the acquired images are presented in Figure 3.

Figure 3: Image Dataset

2.3 Data Preprocessing

Before model training, the collected images underwent a series of preprocessing operations to ensure that the dataset was properly organized, standardized, and optimized for the ResNet-50 architecture. The preprocessing pipeline comprised image collection and cleaning, dataset organization, image resizing, image normalization, and dataset splitting. These operations improved data consistency, enhanced training efficiency, and supported stable model training.

2.3.1 Image Collection, Cleaning and Dataset Organization

The dataset comprised images belonging to two weapon categories: AK-47 rifles and knives. These images were collected from online sources, primarily Google Images, using search queries related to the target weapon categories. To ensure dataset quality and relevance, all collected images were manually inspected, and duplicate, irrelevant, corrupted, and low-resolution samples were removed. This cleaning process ensured that only clear and representative images of each weapon category were retained for model development.

Following the cleaning process, the images were organized into two class-specific subdirectories, namely AK47 and Knife, within a parent directory named ResNet_Dataset. This hierarchical directory structure enabled the PyTorch ImageFolder utility to automatically assign class labels during data loading, thereby facilitating supervised learning. Proper dataset organization also ensured that each image was correctly associated with its corresponding weapon category throughout the training and validation processes, providing a consistent and efficient data management framework for model development.

2.3.2 Image Resizing

All images were resized to 224 × 224 pixels, corresponding to the input dimensions required by the ResNet-50 architecture. Uniform image dimensions ensured consistency across all samples, reduced computational complexity, and enabled the direct use of ImageNet pre-trained weights without modifying the network architecture.

2.3.3 Image Normalization

Following image resizing, pixel values were normalized to improve training stability and enhance model convergence. The pixel intensities were first scaled to the range **[0, 1]** and subsequently standardized using the ImageNet mean and standard deviation values, consistent with the preprocessing requirements of the pre-trained ResNet-50 model. This normalization process reduced the effects of illumination and contrast variations across the dataset, improved numerical stability during optimization, and ensured compatibility with the feature representations learned from the ImageNet dataset.

2.3.4 Data Augmentation

To improve the variability of the training samples and enhance the model's ability to recognize weapons under different image conditions, data augmentation was applied dynamically during the training process. The augmentation operations included random resized cropping, random horizontal flipping, random rotation within a specified range, and colour-jitter adjustment of brightness and contrast. These transformations generated varied representations of the original training images during model training without creating or permanently storing additional image files. The validation images were not subjected to these random augmentation operations; instead, they were processed using deterministic resizing and centre cropping before normalization. Thus, the dataset remained at 2,001 original images, while augmentation increased the variability of the samples presented to the model during training.

2.3.5 Dataset Splitting

Following preprocessing, the prepared dataset of 2,001 images was randomly partitioned into training and validation subsets using an approximately 80:20 ratio to facilitate model development and performance evaluation. A total of 1,600 images were allocated to the training set, while the remaining 401 images were reserved for validation, as summarized in Table 1. The partitioning process maintained class representation between the AK-47 and Knife categories, with 800 AK-47 and 800 Knife images used for training, and 201 AK-47 and 200 Knife images used for validation.

The validation set was used to monitor model performance during training and to assess its classification performance after training. A separate held-out test set was not created because of the moderate dataset size of 2,001 images, allowing a larger proportion of the available data to be retained for model development. Consequently, the performance metrics reported in this study are based on the validation set and may be influenced by model-development and hyperparameter-selection decisions. The absence of an independent test set is therefore acknowledged as a limitation of the study. Future work should evaluate the model using a separate unseen test set or an external dataset to provide a more independent estimate of its generalization performance.

Table 1: Data Set Distribution

Classification	Training Set	Validation Set	Total
AK47	800	201	1001
Knife	800	200	1000
Total	1600	401	2001

2.4 Transfer Learning and ResNet-50 Architecture

The proposed weapon classification framework was developed using the ResNet-50 deep convolutional neural network through a transfer learning approach. This section describes the adopted ResNet-50 architecture and the transfer learning strategy employed to adapt the pre-trained network to the binary weapon classification task.

2.4.1 ResNet-50 Architecture

ResNet-50 was adopted as the backbone convolutional neural network for this study because of its strong feature extraction capability, computational efficiency, and proven performance in image classification tasks. The architecture comprises 50 learnable layers organized into residual blocks with skip connections that facilitate efficient gradient propagation during training. The model was initialized with ImageNet pre-trained weights to provide robust feature representations for the weapon classification task. The standard ResNet-50 architecture used in this study is summarized in Table 2 based on the architecture described by (He *et al.*, 2016).

Table 2: ResNet-50 Architecture

Layer Name	Output size	50-layer
Conv 1_×	112 x 112	7 x7, 64, stride 2
		3 x 3 max pool, stride 2
Conv 2_×	56×56	$\begin{bmatrix} 1\times1, 64 \\ 3\times3, 64 \\ 1\times1, 256 \end{bmatrix}\times3$
Conv 3_×	28×28	$\begin{bmatrix} 1\times1, 128 \\ 3\times3, 128 \\ 1\times1, 512 \end{bmatrix}\times4$
Conv 4_×	14×14	$\begin{bmatrix} 1\times1, 256 \\ 3\times3, 256 \\ 1\times1, 1024 \end{bmatrix}\times6$
Conv 5_×	7×7	$\begin{bmatrix} 1\times1, 512 \\ 3\times3, 512 \\ 1\times1, 2048 \end{bmatrix}\times3$
	1×1	average pool, 1000-d fc, softmax

2.4.2 Transfer Learning Strategy

A transfer learning strategy was employed to adapt the pre-trained ResNet-50 model to the binary weapon classification task. The model was initialized with ImageNet pre-trained weights, while the final fully connected layer was replaced with a new layer comprising two output neurons corresponding to the AK-47 and Knife classes. During transfer learning, the pretrained ResNet-50 feature-extraction layers were kept frozen, while the newly replaced fully connected classification layer was trained for the two-class weapon classification task. This approach reduced training time and supported efficient adaptation of the pretrained model to the target classification task.

2.5 Model Training

Following dataset preprocessing and configuration of the ResNet-50 architecture, the modified network was trained to classify images into the AK-47 and Knife categories. The training process involved configuring the model hyperparameters, optimizing the network using an appropriate loss

function and optimization algorithm, and monitoring its convergence throughout training. The training procedure and adopted hyperparameters are described in the following subsections.

2.5.1 Training Procedure

Following dataset preparation and partitioning, the modified ResNet-50 model was trained using the training subset, while the validation subset was used to monitor the model's learning progress and performance throughout the training process. The dataset was processed in mini batches of 32 images, and the model was trained for 50 epochs. During each epoch, both the training and validation losses were monitored to assess convergence, evaluate model stability, and minimize the risk of overfitting.

2.5.2 Training Parameters

The principal hyperparameters adopted during model training are summarized in Table 3. These parameters were selected to achieve stable convergence while maintaining computational efficiency throughout the training process.

Table 3: Training Parameters

Related Parameter	**Value**
Batch size	32
Learning rate	1×10^{-4}
Optimizer	Adam
Number of Epochs	50
Loss Function	Cross Entropy Loss
Backbone model	Pre-trained model, ResNet-50 (ImageNet)

2.6 Performance Evaluation

The performance of the proposed ResNet-50 model was evaluated using four widely adopted classification metrics: accuracy, precision, recall, and F1-score. These metrics provide complementary information regarding the model's overall classification performance, prediction reliability, and ability to correctly distinguish between the AK-47 and Knife classes. The mathematical expressions of the evaluation metrics are presented in Table 4.

In the evaluation process, True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) denote the correctly and incorrectly classified samples used in computing the performance metrics.

Table 4: Performance Evaluation Metrics. Source (Burgaz and Budak, 2022)

Metric	**Equation**
Precision	$\frac{TP}{TP + FP}$
Recall	$\frac{TP}{TP + FN}$
F1 score	$2 \times \frac{Precision \times Recall}{Precision + Recall}$
Accuracy	$\frac{TP + TN}{TP + TN + FP + FN}$

3. RESULTS AND DISCUSSION

This section presents and discusses the performance of the proposed ResNet-50-based weapon classification model. Following model training, the network was evaluated using the validation dataset to assess its ability to distinguish between the AK-47 and Knife classes. The experimental results are presented in terms of training performance, classification metrics, and prediction capability on unseen images, demonstrating the effectiveness of the proposed approach for intelligent surveillance applications.

3.1 Training and Validation Performance

The training and validation performance of the proposed ResNet-50 model was evaluated using the loss and accuracy recorded over 50 training epochs. The corresponding learning curves are presented in Figure 4, where Figure 4(a) illustrates the training and validation loss, while Figure 4(b) presents the training and validation accuracy.

As shown in Figure 4(a), both the training and validation loss decreased progressively throughout the training process, indicating that the model progressively learned discriminative features for the classification task. However, the validation loss remained lower than the training loss during most of the training epochs. Similarly, Figure 4(b) shows that both the training and validation accuracy increased progressively before stabilizing at high values, with the validation accuracy remaining higher than the training accuracy. This pattern is attributable, in part, to the different preprocessing procedures applied during training and validation. During training, random resized cropping, horizontal flipping, rotation, and colour-jitter augmentation were applied to the images, introducing additional variability into the samples presented to the model. In contrast, the validation images were processed using deterministic resizing and center cropping without random augmentation. Consequently, the training accuracy and loss reflect the model's performance on dynamically transformed training samples, whereas the validation metrics reflect performance on consistently processed validation samples. The higher validation performance therefore does not, by itself, indicate data leakage or overfitting, but reflects, in part, the different preprocessing conditions applied during training and validation. Overall, the learning curves indicate progressive convergence and high classification performance, with the difference between the training and validation curves being consistent with the different preprocessing conditions adopted in the experiment.

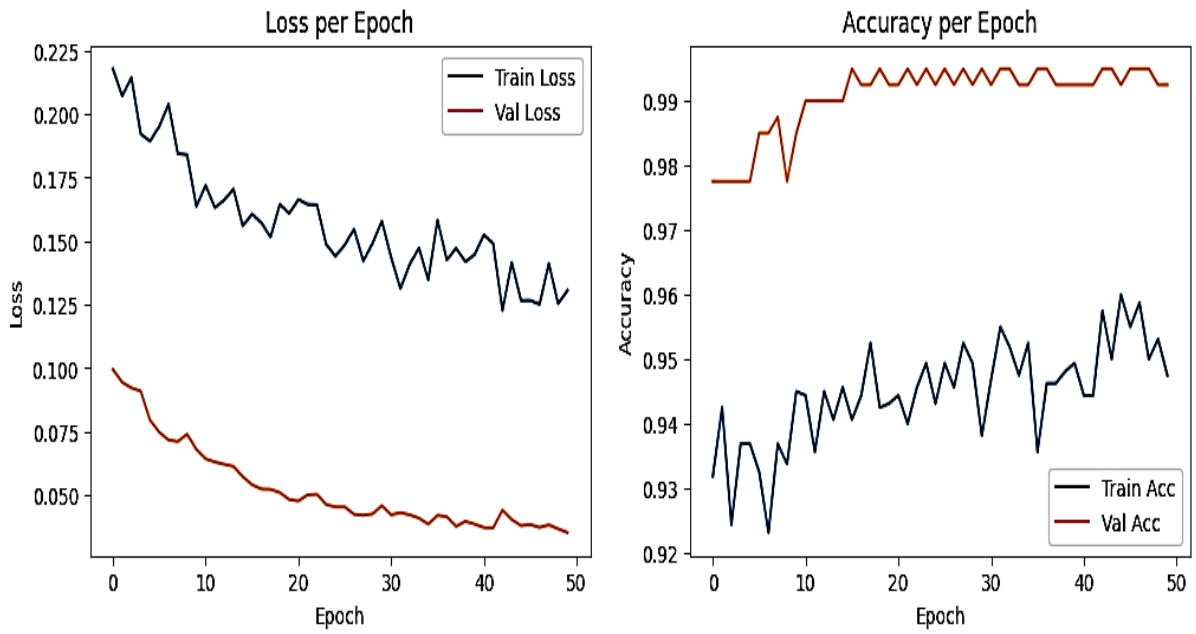

Figure 4: Training and Validation Loss Curves

3.2 Classification Performance

The classification performance of the proposed ResNet-50 model was evaluated using precision, recall, F1-score, and overall classification accuracy. The quantitative performance metrics are presented in Table 5, while the corresponding confusion matrix is shown in Figure 5.

As presented in Table 5, the proposed model achieved excellent classification performance for both weapon categories. For the AK-47 class, the model attained a precision of 0.99, recall of 1.00, and an F1-score of 0.99. Similarly, the Knife class achieved precision, recall, and F1-score values of 0.99, with an overall classification accuracy of 0.99. These results demonstrate that the fine-tuned ResNet-50 model effectively learned discriminative visual features that enabled accurate differentiation between the two weapon categories.

The confusion matrix shown in Figure 5 further validates the classification performance of the proposed model. The model correctly classified 200 AK-47 images and 198 Knife images, with only a small number of misclassifications. Specifically, one AK-47 image was incorrectly classified as a Knife, while two Knife images were misclassified as AK-47. The low number of false positive and false negative predictions is consistent with the high precision, recall, F1-score, and overall accuracy obtained during evaluation. The low number of misclassifications is consistent with the high precision, recall, F1-score, and overall accuracy obtained during evaluation. These results demonstrate the effectiveness of the transfer learning-based ResNet-50 model for the two-class weapon classification task under the image-based conditions investigated.

Table 5: Classification Performance of the Proposed ResNet-50 Model

Object Classifier	**Class**	**Precision**	**Recall**	**F1-Score**	**Accuracy**
ResNet-50	AK47	0.99	1.00	0.99	0.99
	Knife	0.99	0.99	0.99	0.99

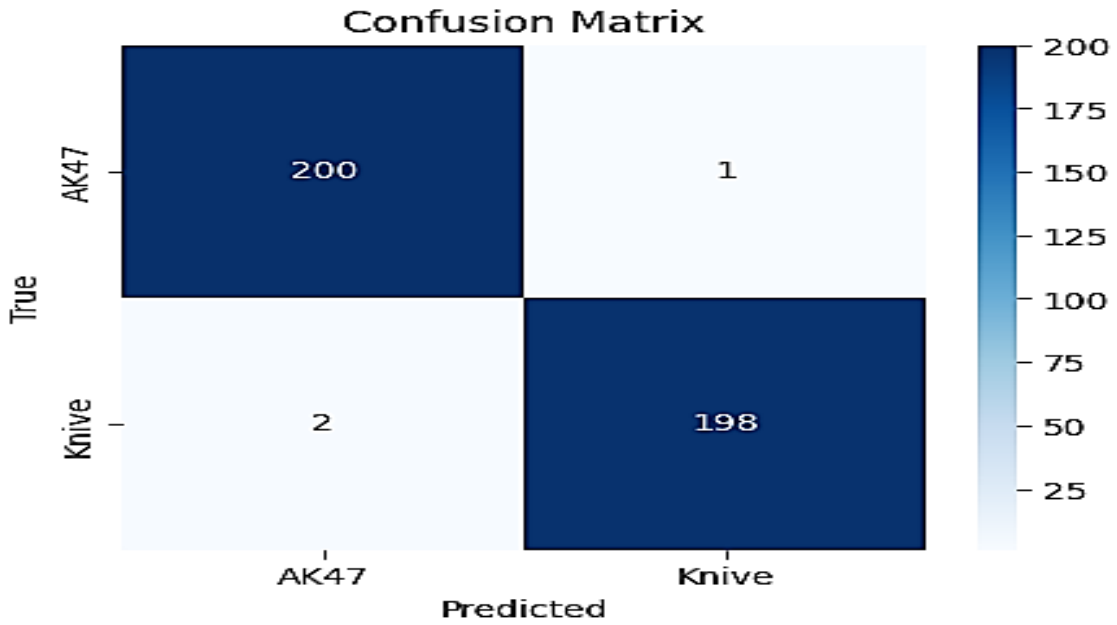

Figure 5: Confusion Matrix of the ResNet-50 Model

3.3 Prediction Results on Validation Images

To further assess the performance of the proposed ResNet-50 model, inference was carried out on representative images from the validation dataset. Sample prediction results are presented in Figure 6 where each image is displayed alongside its predicted class label. The results show that the model correctly identified both AK-47 and Knife images with high confidence, demonstrating its ability to extract discriminative features from images that were not directly used for model parameter optimization.

The prediction results are consistent with the quantitative performance metrics presented in the previous section. The model successfully recognized variations in object orientation, scale, and background while maintaining accurate classification performance. These findings indicate that the trained ResNet-50 model accurately distinguished between the two weapon categories in the evaluated validation samples under the image-based conditions investigated.

Figure 6: Predicted Result on Validation Images

3.4 Prediction Results on Unseen Images

To further evaluate the generalization capability of the proposed ResNet-50 model, inference was performed on completely unseen weapon images that were not included in either the training or validation datasets.

The model accurately classified all the unseen images into their respective categories, namely AK-47 and Knife, with very high confidence scores. Specifically, the AK-47 images were correctly recognized with confidence scores of 99.91% and 99.97%, while the Knife images achieved confidence scores of 99.81% and 99.93%, respectively. These results demonstrate that the model not only identified each weapon category correctly but also exhibited a high degree of confidence in its predictions. The result is shown in figure 7.

The consistently high confidence scores indicate the strong feature extraction capability of the ResNet-50 architecture and the effectiveness of the adopted transfer learning strategy. Furthermore, the model maintained accurate predictions across the examined unseen images, which included variations in image background, illumination, and weapon orientation. These results provide supplementary evidence of the model's predictive capability beyond the training and validation samples. Overall, the inference results demonstrate that the proposed ResNet-50-based classifier can accurately distinguish the two weapon categories under the image-based conditions investigated. The results provide a proof-of-concept baseline for potential integration into intelligent surveillance applications, although further evaluation using real-time surveillance video and camera-captured data is required.

Figure 7: Prediction Result on Unseen Images

3.5 Discussion of Findings

The experimental results demonstrate that the proposed ResNet-50-based weapon classification model is capable of accurately distinguishing between AK-47 rifles and knives under the image-based conditions investigated. The high values obtained for precision, recall, F1-score, and overall accuracy indicate that the model learned discriminative visual features for the two weapon categories. The validation results also show that the model achieved high classification performance on images that were not used for parameter updates during training. However, because the study employed a training-validation split without an independent held-out test set, the validation performance should be interpreted as an assessment of model performance within the experimental dataset rather than as an unbiased estimate of performance on completely independent data.

The high classification performance can be attributed to the adoption of the ResNet-50 architecture and the transfer learning strategy employed in this study. Residual learning enables the network to learn hierarchical feature representations while mitigating the vanishing gradient problem associated with deep neural networks. Furthermore, initializing the model with ImageNet pre-trained weights provided useful feature representations that supported the classification task using the available weapon image dataset. These findings are consistent with previous studies that have reported the effectiveness of deep convolutional neural networks and transfer learning for image classification and weapon recognition tasks.

The confusion matrix and inference results on the validation and unseen images provide further evidence of the model's ability to distinguish between the two weapon categories under the image-based conditions investigated. The small number of misclassifications in the validation results indicates that the learned feature representations were sufficiently discriminative for the two-class classification task. The high confidence scores obtained during inference also indicate that the model produced confident predictions for the examined unseen images. However, these results should not be interpreted as evidence of robustness under operational surveillance conditions, since the evaluation did not involve continuous video streams or camera-captured surveillance footage. The ability to produce accurate and confident predictions is nevertheless a desirable characteristic for a model intended for future integration into intelligent surveillance applications.

The learning curves provide additional insight into the training behaviour of the model. Both training and validation loss decreased progressively, while training and validation accuracy increased before stabilizing at high values. The validation accuracy remained higher than the training accuracy, while the validation loss remained lower than the training loss during most of the training process. This pattern is attributable, in part, to the different preprocessing conditions applied during training and validation. Random resized cropping, horizontal flipping, rotation, and colour-jitter augmentation were

applied dynamically to the training images, introducing additional variability into the samples presented to the model. In contrast, the validation images were processed using deterministic resizing and center cropping without random augmentation. The higher validation performance therefore does not, by itself, indicate data leakage or overfitting, but reflects, in part, the different preprocessing conditions applied during training and validation.

Despite the promising performance achieved in this study, certain limitations should be acknowledged. The developed model was trained and evaluated using only two weapon categories, namely AK-47 rifles and knives, and the dataset consisted primarily of images collected from online sources. The model was not evaluated under challenging real-world surveillance conditions such as occlusion, motion blur, low illumination, cluttered backgrounds, varying camera viewpoints, or continuous video streams captured from fixed surveillance cameras or unmanned aerial vehicles. In addition, the study focused on image classification rather than object detection and localization. Future research should therefore consider expanding the dataset to include additional weapon categories, evaluating the model using independent test data and real-time surveillance video, and investigating object-detection architectures and more recent deep learning models to improve robustness and support eventual integration into practical intelligent surveillance applications.

4. CONCLUSIONS

This study presented a deep learning-based weapon classification framework relevant to intelligent surveillance applications using the ResNet-50 architecture and a transfer learning strategy. The pretrained ResNet-50 model was adapted to classify two weapon categories, namely AK-47 rifles and knives. The developed framework demonstrated the application of transfer learning to image-based weapon classification using a relatively modest dataset.

A complete weapon classification pipeline was developed using the PyTorch deep learning framework in the Google Colab environment. The collected dataset was preprocessed, normalized, and organized to facilitate model training and validation. The model exhibited stable convergence throughout the 50 training epochs, as reflected in the training and validation loss and accuracy curves. The validation results further demonstrated high classification performance under the image-based experimental conditions adopted in this study.

Performance evaluation showed that the proposed ResNet-50 model achieved an overall accuracy of 0.99, with precision, recall, and F1-score values of 0.99 or higher for the two weapon classes. The confusion matrix and inference results on unseen images further demonstrated the model's ability to distinguish between the two weapon categories, with prediction confidence scores exceeding 99% for the examined unseen samples. These findings establish the proposed approach as a proof-of-concept image classification framework for automated weapon recognition.

However, the study does not establish the performance of the model in operational intelligent surveillance environments. The experiment was limited to static images collected primarily from online sources and focused on binary image classification rather than real-time object detection and localization. The model was not evaluated using continuous surveillance video, camera-captured data, occlusion, motion blur, low illumination, cluttered backgrounds, or other challenging operational conditions. Therefore, the results demonstrate the potential of the ResNet-50 approach as a baseline for future intelligent surveillance integration rather than direct deployment readiness.

Future research should expand the dataset to include a broader range of weapon categories and establish an independent test set for more robust performance evaluation. Further investigation should also include real surveillance-camera data and continuous video streams, together with object-detection and localization capabilities, to assess the model under realistic surveillance conditions. These developments would provide a stronger basis for progressing from the present image-based proof-of-concept framework toward practical intelligent surveillance applications.

ABSTRACT

Medication errors and poor adherence remain important patient-safety challenges where identification, dispensing, scheduling, and monitoring depend on manual processes. This paper presents a functional engineering prototype that integrates AI-based medication identification, automated dispensing, timed reminders, evidence capture, stock management, and remote monitoring. The system uses a Raspberry Pi 4 Model B as the central controller and an EfficientNet-B4 image-classification model trained on 4,480 OGYEIv2 images across 112 medication classes. The data were divided into 3,136 training, 672 validation, and 672 held-out test images. The reported independent test accuracy was 99.85%, corresponding to 671 correct predictions and one incorrect prediction. Stepper motors and motor drivers actuate medication compartments, infrared sensors provide dispensing feedback, and a DS3231 real-time clock supports scheduled events and audiovisual reminders. A camera evidence service, TFT interface, Flask backend, SQLite database, and Android application provide system monitoring and records. Functional testing demonstrated successful operation of the major hardware and software modules, including the corrected evidence-image serving route. The evaluation remains an engineering prototype assessment rather than clinical validation; controlled imaging conditions, limited test size, visually similar classes, absence of real-user evaluation, and the need for repeated physical dispensing tests limit conclusions about real-world safety and effectiveness. The prototype demonstrates the feasibility of an integrated medication-management platform for further development in Nigeria and other resource-constrained settings.

Keywords: *Artificial Intelligence; Medication Identification; Medication Dispensing; EfficientNet-B4; Raspberry Pi; Medication Adherence*

1. INTRODUCTION

1.1 Background and Problem Statement

Medication management combines identification, dosage scheduling, dispensing, administration, documentation, and monitoring. Errors at these stages can produce inappropriate medication use and preventable harm. The World Health Organization identifies medication safety as a major patient-safety priority and has promoted the Medication Without Harm initiative (World Health Organization, 2017, 2021). Managing several medicines at different times also increases the possibility of missed doses, incorrect selection, incorrect quantities, and incomplete records.

Artificial intelligence and embedded computing provide opportunities to automate selected medication-management functions while retaining clinical oversight. EfficientNet provides a scalable convolutional-neural-network architecture that balances model capacity and computational requirements (Tan & Le, 2019). Previous studies have shown the feasibility of deep-learning-based pill recognition (Al-Hussaeni et al., 2023; Ashraf et al., 2024; Heo et al., 2023), while other systems have investigated automated dispensing, adherence technologies, and monitoring dashboards (Mason et al., 2022; Nasir et al., 2023; Patel et al., 2020; Pathiraja & Wijesinghe, 2024; Wang et al., 2021, 2025).

The challenge addressed in this study is not a new classification architecture but the integration of medication image classification, scheduled dispensing, reminders, evidence capture, stock management, and mobile monitoring within one Raspberry Pi-based platform. This integrated approach is intended as an affordable engineering prototype that may be adapted for Nigerian and other resource-constrained environments.

1.2 Aim and Objectives

The aim is to design and implement an AI-based smart medication identification, automated dispensing, timed reminder, and monitoring dashboard system using artificial intelligence and embedded computing technologies.

The objectives are to:

1. Design and implement an EfficientNet-B4 medication-identification module.
2. Design and implement stepper-motor dispensing with infrared feedback.
3. Implement timed reminders using a DS3231 real-time clock and audiovisual alerts.
4. Develop monitoring functions for schedules, stock, dispensing records, and evidence.
5. Integrate the hardware and software subsystems into one prototype.
6. Test and evaluate the functionality and performance of the developed system.

1.3 Research Gap and Significance

Existing literature commonly treats pill recognition, automated dispensing, reminders, and adherence monitoring as separate problems. This work addresses the engineering integration gap by combining these functions with local data storage and a mobile interface. The principal significance is therefore system-level integration rather than a claim of clinical replacement or novel AI architecture.

2. METHODOLOGY

2.1 Dataset and Model Development

The AI component uses the OGYEIv2 dataset, which contains 4,480 images representing 112 pill classes. The dataset was captured under controlled imaging conditions using fixed scale, a homogeneous background, and two illumination arrangements designed to expose surface markings (Rádli et al., 2023, 2024).

For this experiment, 70% of the data (3,136 images) were used for training, 15% (672) for validation, and 15% (672) for held-out testing. Each class contributes 28 training images, six validation images, and six test images. Images were resized to 384 × 384 pixels for EfficientNet-B4; normalization and training-time augmentation were applied. The model was trained for 30 epochs with Adam, cross-entropy loss, an initial learning rate of 3×10^{-4}, batch size 16, and ReduceLROnPlateau scheduling.

Table 1: *Dataset Distribution*

Subset	Number of Images	Percentage
Training	3,136	70%
Validation	672	15%
Testing	672	15%
Total	**4,480**	**100%**

Table 2: *AI Model Training Configuration*

Parameter	Configuration
Dataset	OGYEIv2
Classes	112
Total images	4,480
Train / validation / test	3,136 / 672 / 672
Model	EfficientNet-B4
Input	384 × 384 pixels
Epochs	30
Batch size	16
Optimizer	Adam
Initial learning rate	3×10^{-4}
Loss	Cross-entropy
Scheduler	ReduceLROnPlateau

2.2 Embedded Hardware and Software

The prototype uses a Raspberry Pi 4 Model B, camera, TFT display, stepper motors, ULN2003 motor drivers, PCF8574 I/O expanders, infrared sensors, DS3231 RTC module, speaker, LED illumination, power-supply components, and a 3D-printed dispenser structure. The Raspberry Pi executes the AI model, manages schedules, controls motors and sensors, activates alarms, operates the camera, maintains the database, runs the Flask backend, and communicates with the Android application (Grinberg, 2018; Upton & Halfacree, 2016).

Medication schedules are stored in SQLite and compared with the RTC time. At a scheduled event, the corresponding compartment motor is activated and the reminder mechanism issues an audiovisual alert. Infrared feedback provides information about medication movement. The camera records evidence associated with dispensing events. The mobile interface exposes medication records, schedules, stock, logs, evidence, and settings.

RFID readers, QR-code scanners, load cells/HX711 modules, YOLOv5, ResNet-50, and PaddleOCR are not claimed as implemented components in this prototype.

2.3 Evaluation Method

The independent test set of 672 images was used for final AI evaluation. Accuracy was computed as correct predictions divided by total predictions. Functional system testing covered the backend, communication, scheduling, alarm, motor control, infrared sensing, evidence capture and display, stock functions, security, TFT interface, and integrated workflow.

3. RESULTS AND DISCUSSION

3.1 AI Test Performance

The model achieved 671 correct predictions and one incorrect prediction on the 672-image held-out set, giving an accuracy of 99.85%. The reported error involved the visually similar dulodet_60_mg and dulsevia_60_mg classes. This result indicates strong performance on the evaluated dataset but should not be interpreted as clinical-grade medication recognition.

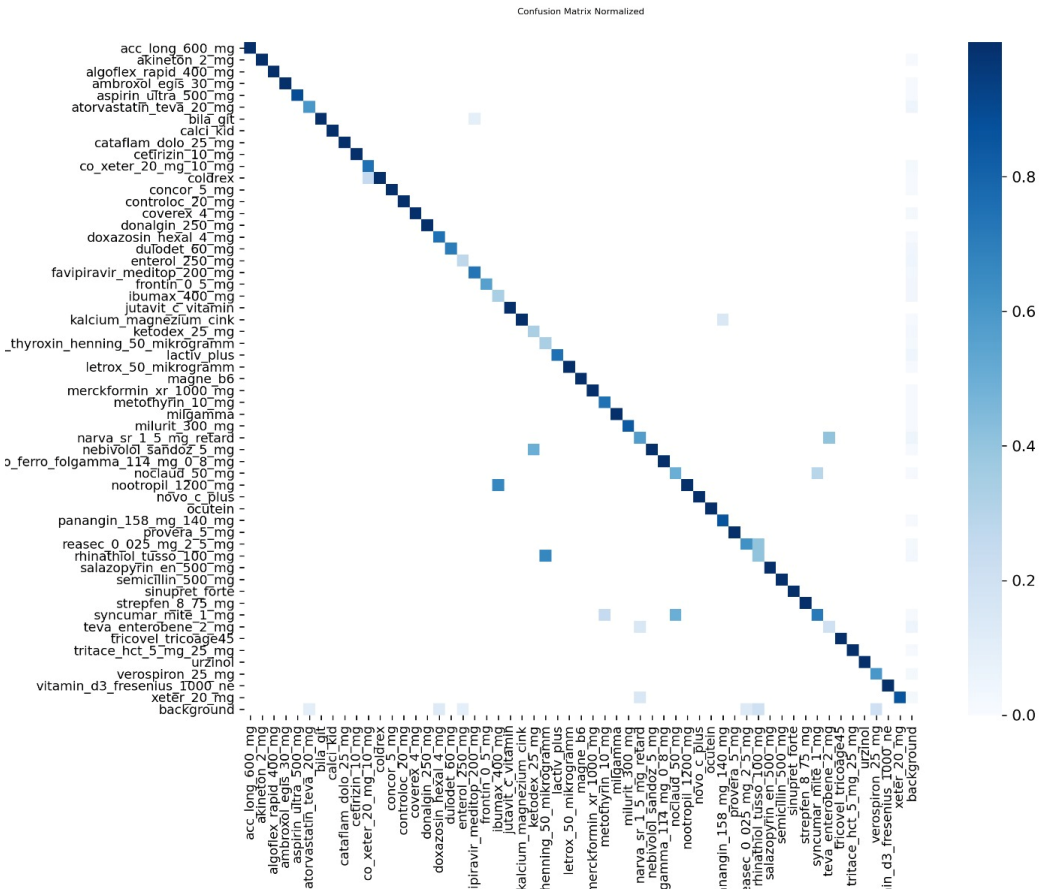

Figure 1: *Normalized confusion matrix of the EfficientNet-B4 model on the held-out test set*

The supplied normalized confusion matrix shows a strong concentration along the principal diagonal, consistent with high class-wise recognition on the controlled test set. The visually similar dulodet_60_mg and dulsevia_60_mg classes are the reported source of the single classification error. Because normalized matrices show relative class-wise prediction distributions, the figure is interpreted together with the aggregate result of 671/672 correct predictions.

Table 3: *Held-Out Test Performance*

Metric	Result
Classes	112
Training images	3,136
Validation images	672
Test images	672
Correct predictions	671
Incorrect predictions	1
Test accuracy	99.85%

3.2 System-Level Functional Results

Subsystem and integrated tests demonstrated successful operation of the Raspberry Pi backend, medication-management services, scheduling logic, stepper-motor control, infrared sensing, buzzer activation, camera evidence capture, TFT interface, stock functions, and Android communication. An evidence-image serving defect was identified during development: metadata was stored correctly, but associated images were not displayed in the mobile application. Correcting the backend image-serving route restored retrieval and display of raw and annotated evidence images.

Table 4: *Integrated System Test Results*

Test case	Observed result	Status
Backend startup	Server started successfully	Passed
Mobile connection	Connection established	Passed
Medication registration	Medication saved successfully	Passed
Schedule creation	Schedule stored successfully	Passed
Alarm detection	Due medication detected	Passed
Buzzer activation	Buzzer activated	Passed
Motor control	Motor control executed	Passed
IR sensing	Sensor interface responded	Passed
Evidence capture	Evidence generated	Passed
Evidence display	Images displayed after route correction	Passed
Stock management	Stock functions operated	Passed
Mobile security	Password protection operated	Passed
TFT interface	Interface loaded successfully	Passed
System integration	Core workflow demonstrated	Passed

3.3 Discussion

The results show that AI classification can be integrated with embedded scheduling, dispensing, reminders, evidence capture, stock management, and remote monitoring on a Raspberry Pi platform. The 99.85% result is strong for the evaluated controlled dataset, but it does not establish clinical validity, guarantee real-world identification accuracy, or demonstrate a reduction in medication errors. The integration test also illustrates that end-to-end reliability depends on interfaces between subsystems: the evidence service initially produced valid records but required a backend route correction before images were usable in the mobile interface.

4. CONTRIBUTION TO SUSTAINABLE DEVELOPMENT IN NIGERIA

The project demonstrates an approach to locally developed healthcare-support technology using widely available embedded computing and software components. A Raspberry Pi-based platform can provide a basis for investigating lower-cost medication automation for hospitals, primary-care facilities, caregivers, and home-care environments. However, sustainability requires more than hardware affordability: future deployment would require reliable power, maintainability, cybersecurity, data protection, clinical oversight, regulatory compliance, user training, and technical support. The contribution is therefore an engineering proof of concept rather than a claim of deployment readiness.

5. LIMITATIONS

1. The AI model was evaluated on the controlled OGYEIv2 dataset, so the 99.85% result may not generalize to uncontrolled lighting, backgrounds, orientations, occlusion, motion, or camera positions.
2. The independent test set contained 672 images, limiting the statistical strength of generalization claims.
3. The reported confusion between dulodet_60_mg and dulsevia_60_mg shows that visually similar medicines remain a limitation of image-based identification.
4. Functional testing confirmed operation of the prototype modules but was not a clinically powered medication-administration or dispensing-accuracy study.
5. Repeated dispensing tests across all compartments and long-duration operation remain necessary.
6. No evaluation involving real patients, caregivers, nurses, or other intended users has been reported, so usability and human-factors evidence is limited.
7. The system should not substitute for healthcare professionals or clinical medication verification.

6. FUTURE WORK

Future studies should use larger and more diverse medication datasets covering additional classes, manufacturers, orientations, illumination conditions, backgrounds, and real-world imaging.

Additional data and model-development methods should be investigated for visually similar classes, especially the reported dulodet_60_mg/dulsevia_60_mg confusion.

The dispensing mechanism should undergo repeated and long-duration tests across medication compartments, including motor reliability, sensor stability, scheduling accuracy, database operation, and power consumption.

Future versions may incorporate barcode or QR-code verification and dosage-verification sensors as complementary safeguards, together with caregiver notifications through push notifications, SMS, or email.

Usability and clinical evaluation should involve representative users and healthcare professionals under appropriate ethical and regulatory oversight.

7. CONCLUSION

This paper presented an AI-based smart medication-management prototype integrating EfficientNet-B4 image classification, Raspberry Pi control, stepper-motor dispensing, infrared sensing, DS3231 scheduling, audiovisual reminders, camera evidence capture, SQLite storage, Flask services, a TFT interface, and an Android monitoring application. The model achieved a reported 99.85% accuracy on 672 held-out images representing 112 medication classes, with 671 correct predictions and one reported misclassification involving dulodet_60_mg and dulsevia_60_mg. Functional testing demonstrated successful operation of the major software and hardware subsystems, including correction of an evidence-image serving defect. The findings establish technical feasibility but not clinical effectiveness or deployment safety. Further work should focus on broader data, repeated physical validation, real-user studies, cybersecurity, and clinical and regulatory assessment.

ABSTRACT

Power transmission line inspection requires the identification and localisation of infrastructure components from aerial imagery. Conventional inspection approaches can be labour-intensive, costly and constrained by difficult terrain, while UAVs provide a practical means of acquiring high-resolution imagery for subsequent analysis (Alcayde-García et al., 2022; Qi et al., 2022; Mendu & Mbuli, 2025). This study develops and evaluates a YOLOv8s-based vision system for automated detection of power transmission line components using the Inspection of Power Line Assets Dataset (InSPLAD). The predefined InSPLAD training and validation partitions were retained, with COCO annotations converted to YOLO format and images prepared at 640 × 640 pixels. A pretrained YOLOv8s model was fine-tuned for 50 epochs using transfer learning in Google Colaboratory with an NVIDIA Tesla T4 GPU. The best checkpoint was obtained at Epoch 48. On the predefined validation subset, the selected model achieved 89.5% Precision, 86.2% Recall, 88.4% mAP@0.5, 72.1% mAP@0.5:0.95, and an F1-score of 87.68%. The results establish an empirical performance baseline for the stated YOLOv8s–InSPLAD configuration. The findings are limited to offline evaluation on the predefined validation subset and should not be interpreted as evidence of onboard UAV performance, real-time field operation, or generalisation to external datasets.

Keywords: *UAV inspection; power transmission lines; object detection; YOLOv8s; InSPLAD; deep learning; computer vision*

1. INTRODUCTION

Power transmission networks depend on the condition of overhead lines and associated components for reliable electricity delivery. Conductors, insulators, spacers, dampers, clamps and suspension fittings are exposed to mechanical loading, environmental conditions and ageing, making periodic inspection an important maintenance activity (Alcayde-García et al., 2022; Qi et al., 2022). Traditional inspection methods include ground patrols, manual inspection and helicopter surveys. These approaches can be labour-intensive, costly and constrained by terrain and operational safety considerations (Alhassan et al., 2020; Xu et al., 2023).

UAVs have expanded the options for transmission-line inspection by enabling aerial acquisition of detailed RGB imagery from viewpoints that may be difficult to obtain through ground inspection. Reviews of UAV applications in power-line inspection describe their use for infrastructure observation, condition assessment and automated image analysis (Shakhatreh et al., 2019; Qi et al., 2022; Mohsan et al., 2023; Mendu & Mbuli, 2025). The resulting image volume also motivates automated computer-vision methods capable of detecting and localising multiple components within inspection imagery.

Deep learning object detectors, particularly the YOLO family, have been widely applied to visual detection because they formulate localisation and classification within a unified detection pipeline (Redmon et al., 2016; Terven et al., 2023). YOLOv8 introduced an anchor-free detection

formulation and a revised architecture implemented by Ultralytics, with model variants including YOLOv8s for smaller computational footprints (Jocher et al., 2023; Terven et al., 2023). These characteristics make YOLOv8s a suitable baseline for investigating automated component detection in UAV imagery without introducing architectural modifications.

Recent transmission-line inspection studies have increasingly modified YOLO architectures to address small objects, complex backgrounds, foreign objects, low-light conditions and other inspection challenges (Qiang et al., 2023; Shao et al., 2024; Li et al., 2025; Ait El Haj et al., 2026; Zheng et al., 2026; Sheng et al., 2026; Farooq et al., 2026; Zhu & Pei, 2026). While these studies demonstrate continued progress in specialised detectors, their numerical results are not directly rankable because datasets, target classes, model configurations, training procedures and evaluation protocols differ. The present study therefore focuses on establishing a reproducible detection baseline for a standard YOLOv8s configuration on InSPLAD rather than claiming universal superiority.

The objective of this paper is to design and evaluate an automated UAV-image component detection system based on pretrained YOLOv8s and the InSPLAD dataset. The evaluation is deliberately restricted to detection performance: Precision, Recall, mAP@0.5, mAP@0.5:0.95, confusion-matrix analysis, Precision–Recall analysis and F1-score analysis. The study does not evaluate onboard UAV deployment, real-time field performance, defect severity or predictive-maintenance decisions.

2. RELATED WORK

UAV-based transmission-line inspection has developed from image acquisition toward automated interpretation. Public datasets have supported this transition by providing annotated imagery for training and benchmarking object detectors. InSPLAD was developed as a large-scale dataset for inspection of power-line assets using UAV imagery, while other datasets such as TTPLA and PLAD provide complementary coverage of transmission towers and power-line assets (André et al., 2023; Vieira e Silva et al., 2023; Jiang et al., 2020; Zhang et al., 2021).

The YOLO family has been repeatedly adapted to transmission-line inspection. Qiang et al. (2023) developed an improved YOLOv8s model for transmission-line fault detection using attention, feature-fusion and loss-function modifications. Shao et al. (2024) proposed TL-YOLO for foreign-object detection on power transmission lines using an improved YOLOv8 framework. Li et al. (2025) proposed DI-YOLOv5 for dense small-object detection using wavelet-based processing and coordinate attention. These studies illustrate a common research direction: modifying a baseline detector to address task-specific visual challenges.

More recent work has investigated lightweight and specialised YOLO-based systems. Ait El Haj et al. (2026) proposed YOLOv8-ECCα for power-line asset inspection using CoordConv, Efficient Channel Attention and Alpha-IoU loss. Zheng et al. (2026) developed YOLO-MLSL for insulator-defect detection, while Sheng et al. (2026) proposed SDS-YOLO for foreign-object detection from UAV images. Farooq et al. (2026) investigated a Transformer-Enhanced YOLOv8 framework for small and complex insulator defects, and Zhu and Pei (2026) developed LCDD-YOLO for low-light transmission-line defect detection. Du et al. (2026) further investigated multimodal RGB and infrared imagery for insulator-defect detection. Collectively, these studies show the diversity of model modifications and datasets used in the field.

The present work differs in scope. Instead of introducing a modified detection architecture, it evaluates the standard YOLOv8s detector after transfer learning on the predefined InSPLAD partitions. The purpose is to quantify the detection behaviour of this specific configuration and establish a defensible empirical baseline. Comparisons with related studies are treated as contextual rather than as a direct ranking, because reported metrics are generated under different experimental conditions.

3. MATERIALS AND METHODS

3.1 Dataset

The study used the Inspection of Power Line Assets Dataset (InSPLAD), a UAV-image dataset containing annotated transmission-line assets (André et al., 2023; Vieira e Silva et al., 2023).

The dataset used in the experiment contains 18 component classes. The predefined training and validation partitions were retained rather than creating a new random split. The training subset contained 7,946 images and the validation subset contained 2,753 images. No independent external test dataset was introduced.

3.2 Dataset Verification and Preparation

Dataset preparation followed the procedure documented in the thesis. The available imagery and annotations were checked for correspondence, annotation format and class alignment before model training. The original COCO annotation files (instances_train.json and instances_val.json) were converted to YOLO text annotations, and a dataset configuration file was prepared for the Ultralytics framework. The predefined train/validation directory structure was retained. Images were prepared at 640 × 640 pixels, and the built-in YOLOv8 augmentation pipeline was used during training. Randomly selected annotated images were visually inspected to confirm that converted bounding boxes and class labels aligned with the corresponding components.

3.3 YOLOv8s Detection Model

YOLOv8s was selected as the detection model and used without architectural modification. YOLO detectors jointly perform object localisation and classification within a single detection framework (Redmon et al., 2016). YOLOv8 uses an anchor-free formulation, a C2f-based backbone, feature fusion through the neck, and a decoupled detection head (Jocher et al., 2023; Terven et al., 2023). In this study, the model received the prepared UAV images and produced bounding-box coordinates, class labels and confidence scores for detected transmission-line components.

Spatial correspondence between a predicted bounding box and its ground-truth counterpart was assessed using Intersection over Union (IoU), defined as the area of intersection divided by the area of union of the two boxes. Standard detection metrics were then calculated from the model predictions on the validation subset (Everingham et al., 2010; Padilla et al., 2021).

3.4 Transfer Learning and Training

Transfer learning was employed by fine-tuning pretrained YOLOv8s weights on the verified InSPLAD training subset. Training was conducted for 50 epochs with a batch size of 16 in Google Colaboratory using an NVIDIA Tesla T4 GPU. The implementation used Python 3.12 and Ultralytics YOLO 8.4.96. The optimizer was automatically selected as AdamW, and the random seed was set to 42. Validation was performed after each epoch and the best-performing checkpoint was retained as best.pt. The best checkpoint occurred at Epoch 48, based primarily on the highest recorded mAP@0.5:0.95 in the validation results.

Table 1: Experimental configuration.

Parameter	Value
Dataset	InSPLAD
Number of classes	18
Training images	7,946
Validation images	2,753
Detection model	YOLOv8s
Learning strategy	Transfer learning
Framework	Ultralytics YOLO 8.4.96
Programming language	Python 3.12
Computing platform	Google Colaboratory
GPU	NVIDIA Tesla T4
Training epochs	50
Batch size	16
Optimizer	AdamW (automatic selection)
Random seed	42

3.5 Performance Evaluation

The trained model was evaluated on the predefined InSPLAD validation subset. Precision was calculated as TP/(TP+FP), and Recall as TP/(TP+FN), where TP denotes true positives, FP false positives and FN false negatives. Average Precision was obtained from the Precision–Recall relationship, and mAP was calculated as the mean of the class-wise AP values. The study reports mAP@0.5 and mAP@0.5:0.95, the latter averaging performance across IoU thresholds from 0.50 to 0.95 in increments of 0.05 (Padilla et al., 2021). The evaluation also examined the Precision–Recall curves, confusion matrix, normalized confusion matrix and F1-score curve to provide complementary views of class-wise and threshold-dependent detection behaviour.

4. RESULTS AND DISCUSSION

4.1 Dataset Verification

Before training, the dataset was checked for image–annotation correspondence, class alignment, bounding-box characteristics and spatial distribution. The resulting verification plots provide an empirical view of the data used in the experiment. Figure 1 shows the distribution of object classes and bounding-box characteristics in the InSPLAD dataset. The plots indicate variation in class frequency, object size and object position, confirming that the validation and training material contains components appearing at different locations and scales.

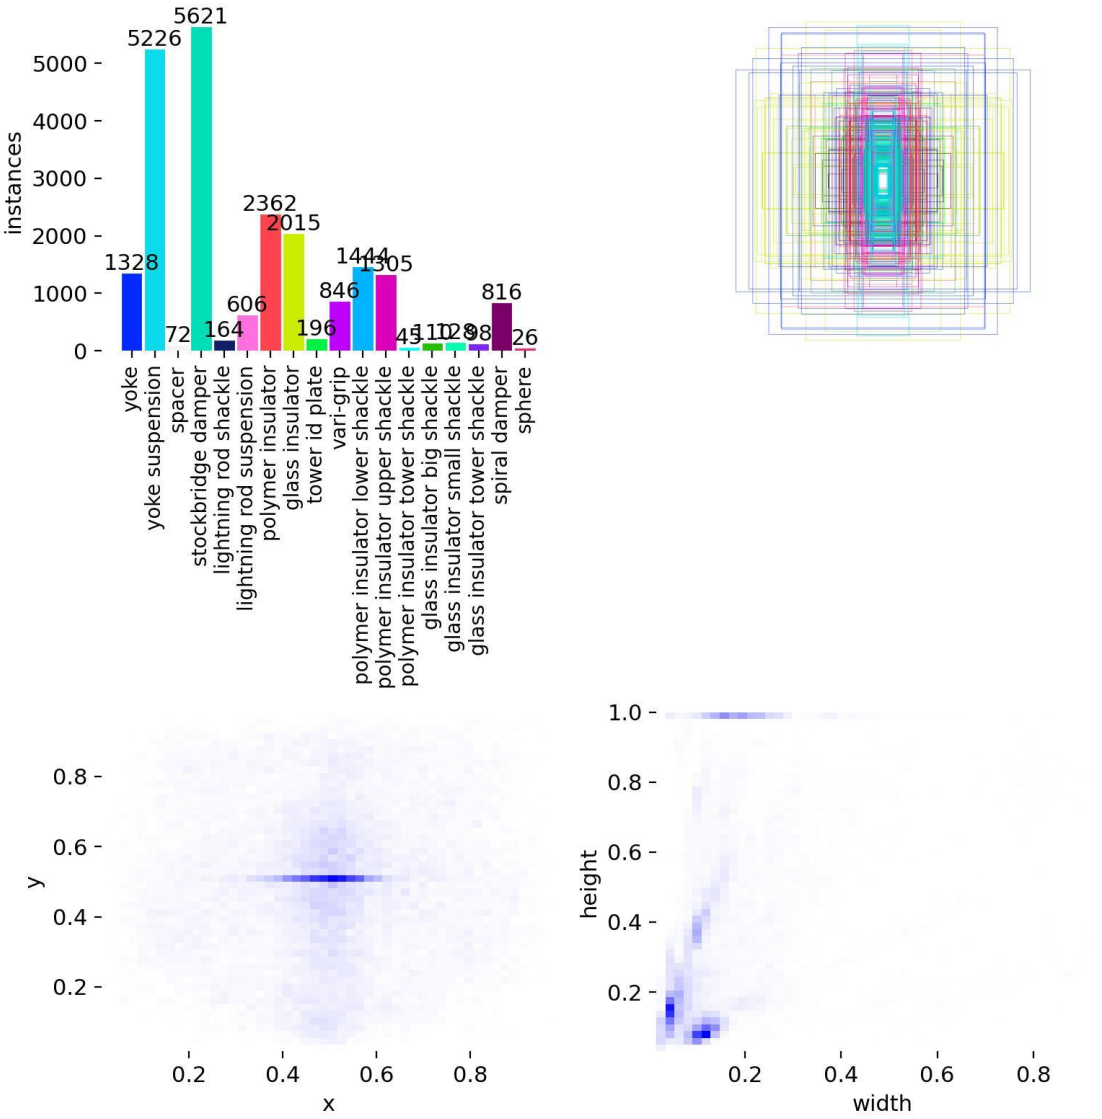

Figure 1: InSPLAD dataset distribution: object classes and bounding-box characteristics.

4.2 Training Performance

The model was trained for 50 epochs, with validation monitoring after each epoch. Figure 2 shows the training and validation loss and metric curves. The recorded losses declined over training while the evaluation metrics increased and stabilised toward the later epochs. The best checkpoint was obtained at Epoch 48, rather than assuming that the final epoch necessarily represented the best validation state. The thesis records the progression from Epoch 1 to Epoch 50 as a reduction in training and validation losses together with increases in Precision, Recall, mAP@0.5 and mAP@0.5:0.95.

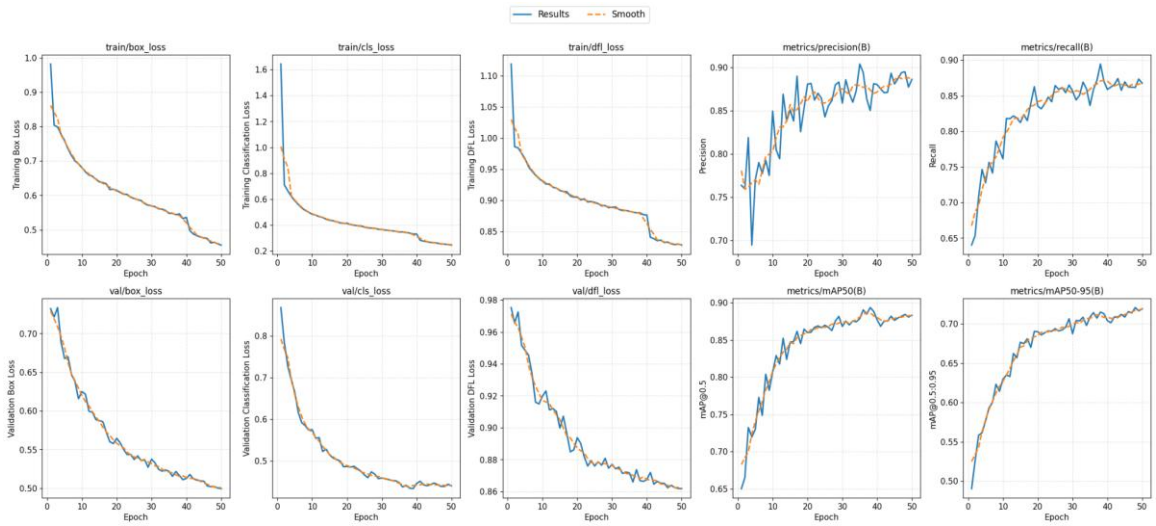

Figure 2: Training and validation performance over 50 training epochs.

4.3 Detection Results

Figure 3 presents representative detections from the InSPLAD validation subset. The detector produces bounding boxes, class labels and confidence scores for multiple transmission-line components within the UAV imagery. These examples provide qualitative evidence that the trained model can localise several component types under the visual conditions represented in the validation data. They are illustrative only; quantitative performance is assessed in the following sections.

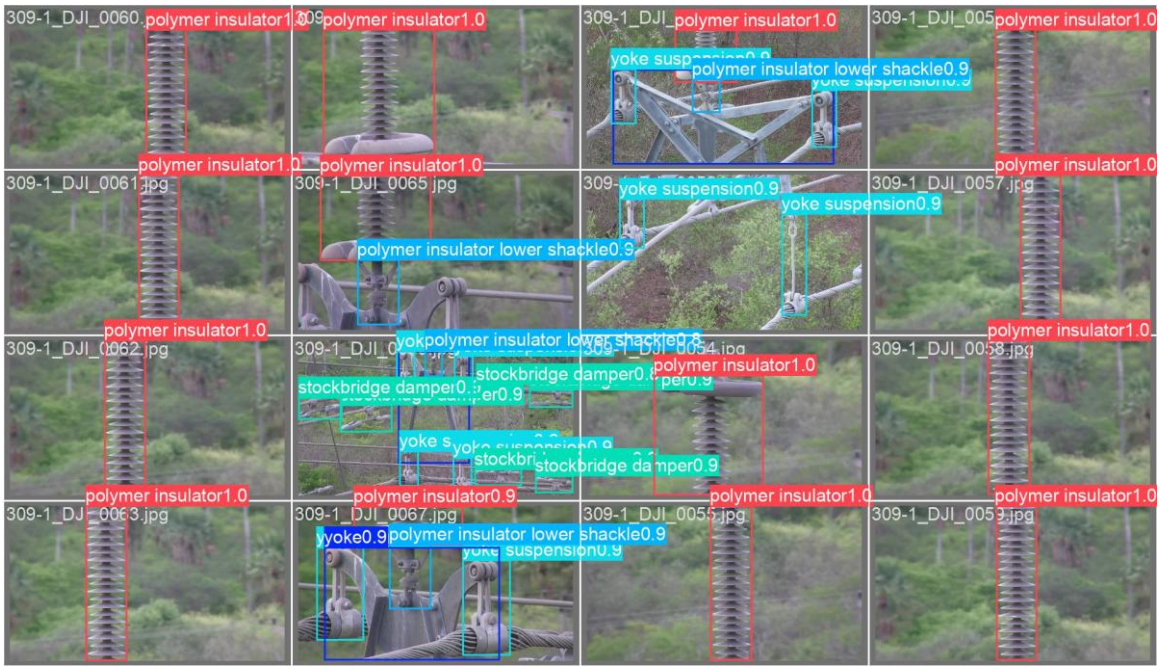

Figure 3: Representative detection results on the InSPLAD validation dataset.

4.4 Quantitative Detection Performance

The selected YOLOv8s checkpoint achieved 89.5% Precision, 86.2% Recall, 88.4% mAP@0.5 and 72.1% mAP@0.5:0.95 on the predefined InSPLAD validation subset. The F1-score was 87.68%. Together, these values indicate that the evaluated configuration achieved a substantial level of detection performance across the 18 component classes represented in the validation subset. The difference between mAP@0.5 and mAP@0.5:0.95 also provides a stricter view of localisation performance when increasingly demanding IoU thresholds are applied.

Table 2: Overall detection performance of YOLOv8s on the InSPLAD validation subset.

Metric	Best checkpoint
Precision	89.5%
Recall	86.2%
mAP@0.5	88.4%
mAP@0.5:0.95	72.1%

4.5 Precision–Recall Analysis

Figure 4 presents the Precision–Recall curves for the evaluated component classes. The curves show how precision changes as recall varies with the detection threshold. The overall behaviour is consistent with the aggregate Precision, Recall and mAP values reported in Table 2. Because the classes are represented with different frequencies and visual characteristics, the curves should be interpreted as class-specific evidence rather than as a single universal operating characteristic.

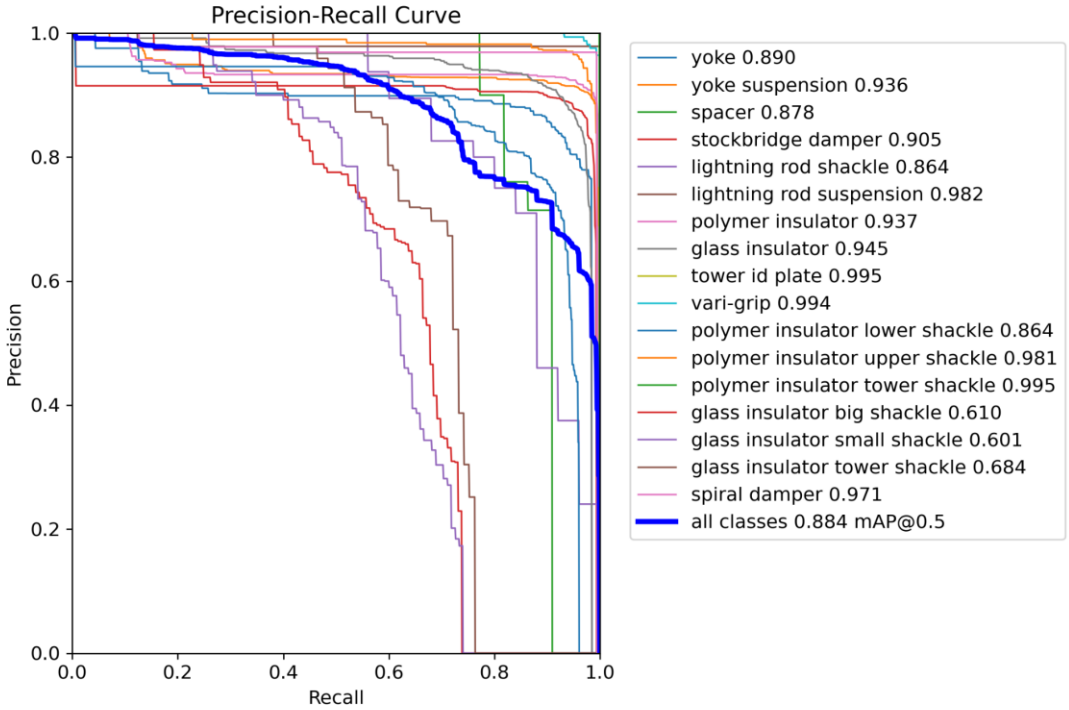

Figure 4: Precision–Recall curves for the transmission-line component classes.

4.6 Confusion Matrix Analysis

The confusion matrix in Figure 5 provides a class-wise view of predicted labels against ground-truth labels. The concentration of detections along the main diagonal indicates that many validation instances were assigned to their corresponding classes, while off-diagonal entries identify cases of class confusion. Such errors are particularly relevant where component categories share similar visual characteristics. The matrix therefore complements aggregate metrics by showing where classification errors occur across the evaluated classes.

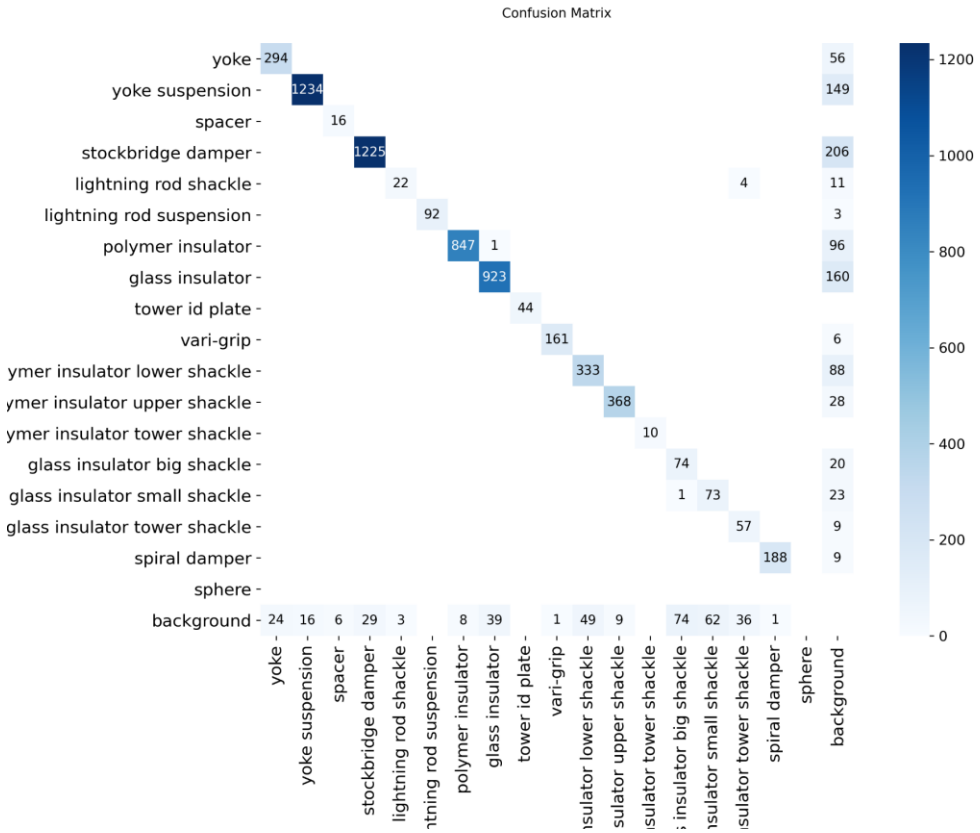

Figure 5: Confusion matrix of the proposed YOLOv8s model.

4.7 Normalized Confusion Matrix and F1-Score

The normalized confusion matrix in Figure 6 expresses class-wise outcomes on a normalized scale, making differences between classes easier to inspect when their numbers of validation instances are unequal. The diagonal concentration across the classes indicates that correct classification accounts for a substantial share of the evaluated predictions, while the remaining off-diagonal proportions identify the relative pattern of class confusion.

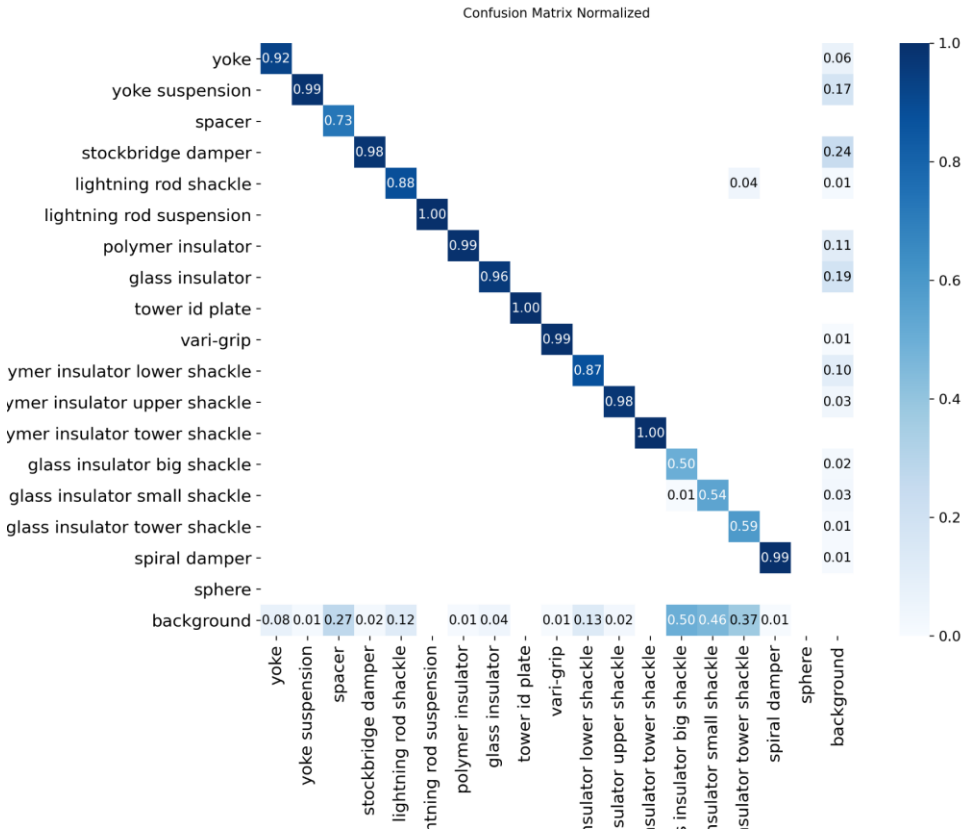

Figure 6: Normalized confusion matrix of the proposed YOLOv8s model.

Figure 7 shows the F1-score as a function of confidence threshold. The F1-score combines Precision and Recall and is useful for examining the balance between false positives and false negatives. The reported final F1-score of 87.68% indicates a strong balance between the two measures for the evaluated configuration. This result is consistent with the 89.5% Precision and 86.2% Recall reported in Table 2, while remaining bounded by the validation dataset and evaluation protocol used in the experiment.

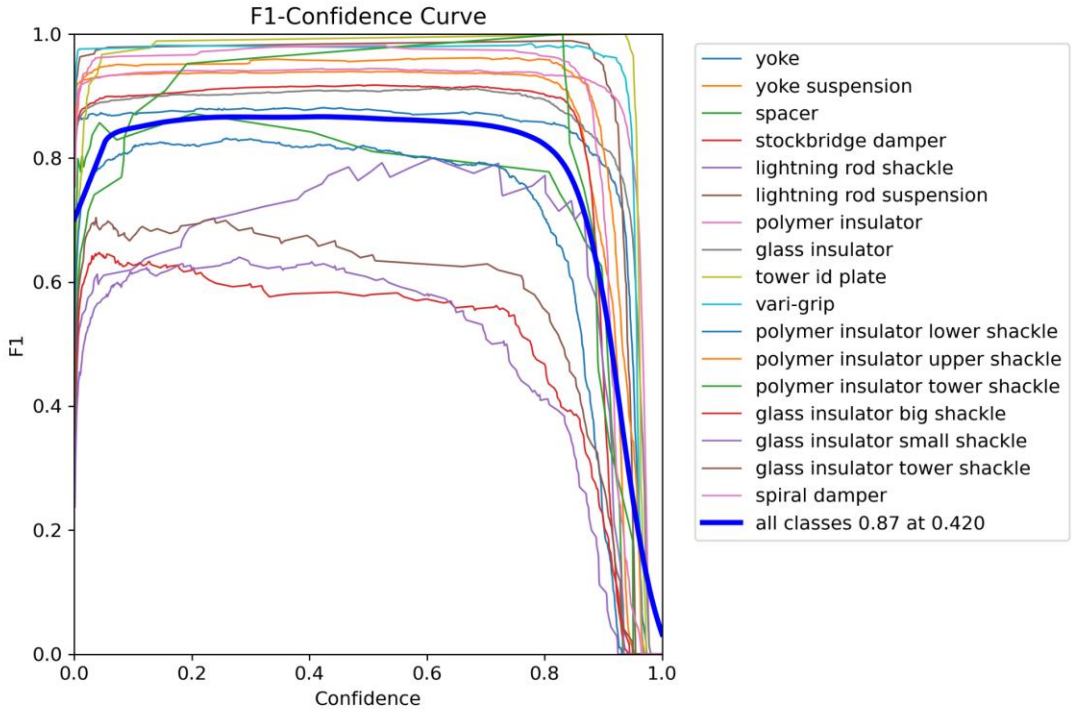

Figure 7: F1-score versus confidence threshold for the proposed YOLOv8s model.

4.8 Comparison with Related Studies

The detection results can be placed in the context of recent transmission-line inspection research, but numerical comparison should not be interpreted as a direct ranking. Qiang et al. (2023), for example, modified YOLOv8s for transmission-line fault detection, while Shao et al. (2024) and Li et al. (2025) addressed foreign-object and dense-small-object detection through architectural changes. Ait El Haj et al. (2026), Zheng et al. (2026), Sheng et al. (2026), Farooq et al. (2026) and Zhu and Pei (2026) similarly targeted specific inspection challenges through architectural, lightweight, transformer-based or low-light adaptations.

The present experiment instead evaluates a standard YOLOv8s configuration with transfer learning and dataset preparation on the predefined InSPLAD partitions. Its contribution is therefore an empirical baseline for this particular model–dataset–training configuration. The 89.5% Precision, 86.2% Recall, 88.4% mAP@0.5 and 72.1% mAP@0.5:0.95 should be understood within that experimental boundary. Differences from published results may arise from target definitions, dataset variants, class distributions, preprocessing, model variants, optimisation settings and evaluation protocols; consequently, the values do not establish superiority or inferiority across studies.

5. LIMITATIONS

The study has several limitations. First, evaluation was conducted using a single public dataset and its predefined validation subset; no independent external test dataset was used. Second, the experiments were conducted offline using stored UAV imagery rather than on an onboard UAV platform, and real-time field performance was not measured. Third, the study focused on component detection and classification rather than defect severity assessment or predictive-maintenance decision making. Finally, generalisation to transmission-line imagery outside the evaluated dataset was not established. These boundaries should be considered when interpreting the reported results and when comparing them with studies using different datasets or deployment settings.

6. CONCLUSION

This paper presented the design and performance evaluation of a YOLOv8s-based vision system for automated power transmission line component detection using the InSPLAD dataset. The predefined training and validation partitions were retained, COCO annotations were converted to

YOLO format, and a pretrained YOLOv8s model was fine-tuned for 50 epochs using transfer learning. Training was performed in Google Colaboratory with an NVIDIA Tesla T4 GPU, and the best validation checkpoint occurred at Epoch 48.

On the predefined InSPLAD validation subset, the selected checkpoint achieved 89.5% Precision, 86.2% Recall, 88.4% mAP@0.5, 72.1% mAP@0.5:0.95 and an F1-score of 87.68%. These results establish an empirical baseline for the stated YOLOv8s–InSPLAD configuration and show that the standard detector can provide measurable component-detection performance without architectural modification. The results do not, however, establish real-time UAV operation, onboard deployment, external-dataset generalisation or production readiness. Future work should therefore evaluate the detector on additional datasets and embedded UAV platforms and extend the task toward defect-specific assessment where appropriate.

ABSTRACT

Water availability and changing crop water demand make irrigation management difficult in semi-arid production systems. This paper presents the design and proof-of-concept evaluation of a growth-stage-oriented smart drip irrigation prototype for bell pepper. The system uses an ESP32 controller with a capacitive soil-moisture sensor, DHT22 temperature and humidity sensor, DS18B20 soil-temperature sensor, YF-S201 flow sensor, DS3231 real-time clock, relay-controlled pump, drip line, LCD, and manual controls. We defined a growth-stage framework using days after transplanting (DAT), provisional soil-moisture thresholds, and maximum irrigation durations; these settings are engineering assumptions rather than validated agronomic optima. We established five four-week-old bell pepper seedlings in one prototype box and monitored them over 19 morning/evening observation periods. The recorded dataset contained air temperature, soil temperature, relative humidity, soil moisture, and independently measured irrigation volume. Across the 19 periods, total recorded irrigation was 6.35 L, comprising 2.65 L in the morning and 3.70 L in the evening. Mean air temperature was 24.48 °C in the morning and 32.37 °C in the evening, while mean soil moisture was 86.79% and 65.26%, respectively. Three response-time observations of 0.488, 0.406, and 0.590 s gave a mean of 0.495 ± 0.092 s. The observations demonstrate that the prototype can acquire environmental data and deliver measured irrigation under live-crop conditions, but they do not establish seasonal water-use efficiency or water-saving performance. Further replicated calibration, controlled comparison, full-cycle crop monitoring, and field testing are required.

Keywords: *smart irrigation; drip irrigation; ESP32; bell pepper; growth-stage irrigation; water management*

1. INTRODUCTION

1.1 Background of the Study

Agricultural production in semi-arid environments is constrained by water availability, rainfall variability, and irrigation management. Bell pepper (Capsicum annuum) is a high-value crop whose water requirement changes with development. The FAO-56 framework recognizes the influence of crop stage and environmental conditions on crop water requirements (Allen et al., 1998). Applying one irrigation rule throughout the crop cycle may therefore be less responsive than a strategy that considers crop development together with measured soil and environmental conditions.

Recent smart-agriculture research shows that low-cost microcontrollers and connected sensing can be used to automate irrigation and monitor environmental conditions. Pereira et al. (2023), for example, demonstrated an ESP32-based smart drip irrigation system, while Pereira et al. (2023) describe the broader use of IoT technologies for agricultural monitoring and automation. More advanced systems have also combined environmental data with artificial intelligence or predictive methods to support irrigation decisions (Gaitan et al., 2025; Preite & Vignali, 2024).

However, the usefulness of a smart irrigation system depends not only on the availability of sensors but also on how the control strategy is related to crop development and local conditions. Wanyama et al. (2024) identified affordability, infrastructure, water scarcity, and contextual suitability as important considerations for smart irrigation in sub-Saharan Africa. A practical system for this context therefore needs to combine relatively simple hardware with a control framework that can be refined from local observations.

1.2 Research Gap

Many low-cost irrigation controllers use a fixed soil-moisture threshold or fixed schedule. Such approaches automate water delivery but do not explicitly provide a mechanism for changing irrigation targets with crop development. This study combines environmental sensing and drip irrigation with a growth-stage-oriented control framework. The contribution is the prototype architecture, stage-based control concept, and live-crop observations, not a claim of validated seasonal water saving.

1.3 Sustainable Development Goal Relevance

The work aligns with SDG 2 through sustainable crop production; SDG 6 through agricultural water management; SDG 9 through embedded sensing and automation; SDG 12 through responsible resource use; SDG 13 through adaptation to water scarcity and variable conditions; and SDG 15 through sustainable soil and water management. These are project alignments, not measured SDG outcomes (United Nations, 2015).

1.4 Aim and Objectives

The aim was to design and evaluate, at proof-of-concept scale, a growth-stage-oriented ESP32-based smart drip irrigation system for bell pepper under semi-arid conditions. The objectives were to assemble the prototype; define a provisional DAT-based irrigation framework; integrate environmental sensing, timekeeping, flow measurement, and pump control; and characterize measured environmental conditions, irrigation volumes, and sensor response.

2. MATERIALS AND METHODS

2.1 System Components and Architecture

The prototype was centred on an ESP32 development board. A capacitive sensor measured soil moisture; a DHT22 measured air temperature and relative humidity; a DS18B20 measured soil temperature; and a YF-S201 monitored water flow. A DS3231 provided time information, while a relay, pump, and drip line delivered water. An I²C LCD displayed measurements, and push buttons provided local control.

The current implementation used local sensing, timekeeping, pump actuation, and manual interaction. The ESP32 provides a platform for later network connectivity, but network/cloud performance was not measured.

2.2 Firmware and Irrigation Control

The firmware acquires sensor measurements every two seconds and averages ten analogue soil-moisture readings before converting them to percentage values using programmed dry and wet endpoints. It reads the DHT22, DS18B20, YF-S201, and DS3231, and refreshes the LCD at about 0.5-second intervals. Automatic irrigation uses two fixed five-minute daily windows with manual override. The growth-stage framework was not the control routine used for the reported irrigation records.

The implemented automatic pump control uses two fixed five-minute daily windows, together with a manual pump override. The growth-stage-oriented algorithm described in this paper is therefore a control framework developed around the prototype rather than a fully validated adaptive control routine operating in the reported dataset. This distinction is important because the measured irrigation records cannot be attributed experimentally to the proposed stage-specific thresholds.

2.3 Growth-Stage-Oriented Control Framework

The framework uses days after transplanting (DAT) to associate crop development with a provisional moisture threshold and maximum irrigation duration. FAO-56 provides the conceptual basis for stage-dependent crop water requirements (Allen et al., 1998), but it does not prescribe the exact sensor percentages used here. The settings in Table 1 are engineering assumptions requiring crop-based calibration.

Table 1: Provisional growth-stage ranges and control settings.

Growth stage	Provisional DAT range and basis	Moisture threshold	Maximum duration
Early establishment	0–14 DAT; root establishment after transplanting	≥60%	3 min/cycle
Vegetative	15–35 DAT; canopy and vegetative growth	≥50%	5 min/cycle
Flowering	36–55 DAT; flowering and early reproductive development	≥55%	8 min/cycle
Fruiting	56–85 DAT; fruit set and fruit expansion	≥55%	8 min/cycle
Maturity	86 DAT and beyond; ripening and harvest development	≥45%	4 min/cycle

The DAT ranges in Table 1 make the framework explicit but are not measured phenological boundaries. Flowering and fruiting share the same provisional threshold and duration because both are treated as water-sensitive reproductive stages; this is a design choice, not evidence that their water requirements are identical.

2.4 Calibration and Measurement Verification

The soil-moisture conversion uses programmed dry and wet reference endpoints of 2500 and 1135 ADC units. The available records do not contain replicated reference-instrument comparisons for the moisture, temperature or humidity sensors; therefore, percentage accuracy and calibration error are not reported. Irrigation volume was measured with a calibrated cylinder. Three response-time readings were retained, allowing mean, standard deviation and range to be reported.

Irrigation volume was measured independently with a calibrated measuring cylinder. The response-time test retained three signal-detection readings, allowing the mean and sample standard deviation to be calculated. The response-time measurement represents sensor signal detection and should not be interpreted as total environmental-change-to-pump-actuation latency.

2.5 Crop Establishment and Observation Procedure

Five healthy bell pepper seedlings, approximately four weeks old at transplanting, were established in one prototype box. The plants shared one soil environment and irrigation system and therefore represent one experimental unit rather than five independent replicates. Morning and evening readings were collected for 19 observation periods. No separate control or formal randomization was used, so the study does not support inferential comparison with another irrigation treatment.

No separate control treatment was used, and no formal randomization was performed because the work involved one prototype unit and was intended to characterize system operation under live-crop conditions. These design limitations prevent inferential comparison with a fixed-threshold or conventional irrigation treatment.

2.6 Data Analysis

Means, ranges and sample standard deviations were calculated for the 19 morning/evening observations. Total irrigation was obtained by summing recorded volumes, and the three response-time readings were summarized by mean, sample standard deviation and range. No seasonal saving

percentage or inferential treatment test was calculated because there was no completed crop cycle or replicated control.

3. RESULTS

3.1 Environmental and Irrigation Observations

The complete observation record is presented in Table 2. The data show clear differences between morning and evening conditions. Mean air temperature increased from 24.48 °C in the morning to 32.37 °C in the evening, while mean soil temperature increased from 24.59 °C to 32.74 °C. Mean relative humidity decreased from 85.37% to 63.95%, and mean soil moisture decreased from 86.79% to 65.26%.

Table 2: Complete morning and evening observation record (n = 19 observation periods).

Obs.	Air temp. AM/PM (°C)	Soil temp. AM/PM (°C)	RH AM/PM (%)	Moisture AM/PM (%)	Water AM/PM (mL)
1	31.5 / 37.0	38.0 / 43.0	65 / 45	55 / 40	200 / 200
2	27.0 / 33.3	25.1 / 36.0	70 / 55	70 / 50	200 / 150
3	28.0 / 30.0	28.0 / 32.0	68 / 58	70 / 51	200 / 150
4	23.0 / 32.4	24.4 / 32.7	80 / 50	100 / 70	50 / 150
5	20.1 / 26.0	20.5 / 26.0	84 / 70	95 / 80	150 / 150
6	28.0 / 33.7	29.4 / 36.7	65 / 50	70 / 55	200 / 150
7	22.6 / 30.0	24.8 / 32.0	92 / 77	90 / 77	200 / 100
8	23.1 / 31.8	24.0 / 33.4	92 / 72	100 / 75	100 / 300
9	23.5 / 28.8	23.1 / 29.0	93 / 80	100 / 90	100 / 200
10	21.5 / 26.1	21.0 / 24.3	93 / 80	100 / 90	100 / 100
11	26.0 / 34.0	24.4 / 31.0	90 / 64	100 / 84	200 / 200
12	23.9 / 31.2	22.5 / 33.0	93 / 66	87 / 60	200 / 250
13	22.5 / 37.9	22.5 / 36.0	90 / 60	93 / 70	200 / 150
14	24.1 / 34.5	22.5 / 36.9	93 / 69	75 / 49	100 / 300
15	23.3 / 38.8	23.0 / 36.8	91 / 52	97 / 53	50 / 300
16	24.8 / 33.8	23.4 / 29.9	89 / 66	89 / 49	100 / 200
17	24.6 / 32.7	24.8 / 31.4	96 / 72	85 / 50	100 / 200
18	24.9 / 32.7	24.1 / 30.8	93 / 69	87 / 75	100 / 250
19	22.8 / 30.3	21.8 / 31.1	85 / 60	86 / 72	100 / 200

Irrigation volume varied from 50 to 200 mL in the morning and from 100 to 300 mL in the evening. The morning mean was 139.47 mL, compared with 194.74 mL in the evening. Across all observations, 2.65 L was applied in the morning and 3.70 L in the evening, giving a total measured irrigation volume of 6.35 L. These values describe the recorded observation period only and are not extrapolated to the complete crop cycle.

3.2 Response-Time Result

Table 3: Individual sensor signal-detection response-time observations.

Trial	Signal-detection response time (s)
1	0.488
2	0.406
3	0.590
Mean ± SD	0.495 ± 0.092
Range	0.406–0.590

The three response-time observations were 0.488, 0.406, and 0.590 s. Their mean was 0.495 s with a sample standard deviation of 0.092 s and a range of 0.406–0.590 s. This result indicates relatively short signal-detection times during the three tests, but the small number of trials does not support a generalized performance claim.

4. DISCUSSION

Across 19 observation periods, morning conditions were generally cooler and more humid, with higher soil moisture than evening conditions. Irrigation volume also varied between observations. These descriptive patterns support the practical value of monitoring soil and environmental conditions, but they do not establish causation or an optimal irrigation quantity.

The measured 6.35 L represents water physically recorded during the 19 observation periods. It is not a seasonal water-use or water-saving estimate because the crop cycle was incomplete and no replicated control was available. Irrigation outcomes depend on crop, environment, and control strategy (Gaitan et al., 2025; Preite & Vignali, 2024).

The growth-stage framework is consistent with the stage-dependent crop water requirement principle in FAO-56 (Allen et al., 1998). However, its thresholds and durations are engineering assumptions rather than direct conversions of FAO crop coefficients. The current firmware did not use these stage-specific values to control the recorded irrigation events, so the framework requires validation before it can be described as an adaptive controller.

The hardware approach is consistent with low-cost smart irrigation research. Pereira et al. (2023) demonstrated ESP32-based drip irrigation, while Wanyama et al. (2024) discuss opportunities and constraints of smart irrigation in sub-Saharan Africa. The present work adds a crop-development-oriented control concept and live-crop observations.

The mean response time of 0.495 ± 0.092 s is based on only three readings and represents signal detection rather than complete environmental-change-to-pump latency. It is therefore an engineering observation, not a generalized latency specification.

The experimental design also limits the strength of inference. Five seedlings shared one prototype box, with no independent replicate boxes, randomized treatment assignment, or control. The current results should therefore guide system refinement rather than support claims of agronomic superiority.

5. CONCLUSION AND RECOMMENDATIONS

A growth-stage-oriented ESP32-based smart drip irrigation prototype was tested with five four-week-old bell pepper seedlings under pot conditions. Nineteen morning/evening observation periods produced 6.35 L of measured irrigation. Mean morning values were 24.48 °C air temperature, 24.59 °C soil temperature, 85.37% relative humidity, and 86.79% soil moisture, compared with 32.37 °C, 32.74 °C, 63.95%, and 65.26% in the evening. Three response-time readings gave 0.495 ± 0.092 s.

These findings show that the prototype acquired environmental measurements and delivered measurable irrigation under live-crop conditions. They do not establish seasonal water-use efficiency, water saving, or agronomic superiority. The growth-stage framework remains a design component requiring calibration and validation, and sensor accuracy evidence is limited.

The following steps are recommended: continue monitoring through the complete crop cycle; perform replicated sensor calibration; retain repeated response-time readings; evaluate the framework with independent experimental units and randomized treatments; compare it with a defined control before making water-saving claims; and validate the system at larger scale and under different soil and environmental conditions.

6. SUSTAINABLE DEVELOPMENT GOAL ALIGNMENT

The project aligns with six Sustainable Development Goals (SDGs). The alignment reflects the purpose and intended application of the engineering system and should not be interpreted as evidence that the present experiment measured progress against SDG indicators (United Nations, 2015).

SDG 2 – Zero Hunger: Supports sustainable and resilient food production through improved irrigation management for bell pepper.

SDG 6 – Clean Water and Sanitation: Supports more deliberate agricultural water management and the goal of improving water-use efficiency.

SDG 9 – Industry, Innovation and Infrastructure: Applies embedded control, sensors and automation to agricultural infrastructure.

SDG 12 – Responsible Consumption and Production: Encourages measured and controlled use of water as a production resource.

SDG 13 – Climate Action: Supports climate adaptation by improving irrigation monitoring under variable environmental conditions.

SDG 15 – Life on Land: Supports sustainable management of agricultural soil and water resources, particularly in water-limited environments.

ABSTRACT
Conventional distance relay schemes often fail to detect high-impedance faults on Nigeria's 330 kV transmission network, contributing to grid instability and unreliable supply. This study proposes an adaptive deep neural network protection system for the Shiroro–Jebba–Oshogbo corridor, leveraging Big Data Analytics and convolutional neural networks (CNN) to overcome impedance-based limitations. Using MATLAB/Simulink, the corridor was modeled with validated parameters, and 1,000 scenarios across seven classification classes (Normal operation plus six fault types: single line-to-ground AG/BG/CG, line-to-line AB, double line-to-ground ABG, and three-phase ABC) and six fault locations were simulated, varying resistance from 0.01Ω to 500Ω. This produced 5.6 million measurement points. A CNN with four convolutional blocks and 1.39 million trainable parameters was implemented in TensorFlow/Keras, trained on 700 scenarios, validated on 150, and tested on 150. The model achieved 98.67% accuracy on unseen data, with an inference time of 100.56 ms. Performance was perfect (100%) for resistances up to 100Ω and remained strong (92%) at 500Ω, where conventional relays fail. Comparative analysis showed CNN sensitivity of 100% versus 21.48% for distance relays, a 78.52-point improvement, as confirmed by McNemar's test ($p<0.0001$). Results demonstrate that deep learning-based protection provides robust detection of high-impedance faults, offering transformative reliability for Nigerian transmission networks beyond conventional methods.

1. INTRODUCTION

Electric power is an indispensable cornerstone of modern society, underpinning industrial, commercial, and residential activities. In Nigeria, the energy sector assumes a pivotal role in the country's economic growth and sustainable development. However, the Nigerian power grid has been grappling with persistent challenges rooted in insufficient infrastructure, operational inefficiencies, and vulnerabilities within its protection and stability mechanisms. These issues manifest as frequent power outages, voltage fluctuations, and grid instability. Statistics reveal a concerning trend: In 2018, there were thirteen (13) instances of national grid collapses (Oluwagbemi, 2018), followed by eleven (11) in 2019 (TheCable, 2019), four (4) in 2020, four (4) in 2021, eight (8) in 2022 (Nnodim, 2022; CuteNaija, 2022), and eight (8) between January and September 2023 (Onoja, 2023), totalling approximately forty-eight (48) collapses in a span of five years and eight months. These persistent issues not only disrupt the lives of millions of Nigerians but also have severe repercussions on the nation's economy (Adegoriola & Agbanuji, 2020).

The Nigerian 330kV transmission network, particularly the critical Shiroro-Jebba-Oshogbo corridor, experiences frequent grid collapses, with 46 recorded incidents in 2023 alone (Adejo, 2024). This corridor-level figure is considerably higher than the eight (8) national grid collapses reported for the same January-September 2023 period (Onoja, 2023) cited earlier; the two statistics differ in scope rather than being contradictory, as Adejo's count of 46 encompasses localised fault and instability events specific to the Shiroro-Jebba-Oshogbo corridor (including partial disturbances that trigger protective relay operations without a full national collapse), whereas Onoja's count of eight reflects only incidents

severe enough to cause a total national grid collapse. This distinction underscores why corridor-specific adaptive protection, rather than national-level statistics alone, is the appropriate frame for this study. These systemic failures stem from conventional protection relays' inability to adapt to real-time grid dynamics characterised by significant frequency deviations (±1.25 Hz) and high-impedance faults with resistances up to 500 Ω in rural areas (Adeniji, 2025; Araga et al., 2024). Traditional distance relays, which rely on apparent impedance calculations (Z = V/I), exhibit poor selectivity under varying system conditions and struggle to distinguish legitimate fault transients from operational disturbances such as power swings or load switching, leading to nuisance tripping that can precipitate cascading failures across the Northern backbone. The legacy "bolted fault" logic fails to detect High-Impedance Faults (HIFs) in which fault currents are masked by normal operating noise or high grounding resistance (Sangeeth & Vinod, 2023).

The emergence of Big Data Analytics (BDA) and Deep Neural Networks (DNNs) presents a promising avenue for addressing these challenges. BDA enables the harnessing and analysis of vast amounts of data generated by power grid operations, providing insights into patterns, trends, and anomalies that can inform decision-making and improve grid stability (Zi, 2018). DNNs exhibit remarkable capabilities in pattern recognition, learning, and adaptation, making them well-suited for developing intelligent protection schemes that can adapt to the dynamic and complex nature of power grid operations (Zi, 2018; Cai et al., 2021; Zhang et al., 2018).

This research addresses the critical gap in implementing deep learning architectures optimised for power system protection, capable of processing large-scale fault datasets and extracting discriminative features from high-dimensional time-series data. Current approaches suffer from three fundamental limitations: insufficient training data diversity, failing to capture the full spectrum of fault conditions, including high-impedance scenarios; inadequate feature extraction mechanisms unable to distinguish between fault transients and operational disturbances; and a lack of comprehensive comparative analysis against conventional protection schemes using standardised metrics (Oruma et al., 2024).

This research aims to design and simulate an adaptive protection scheme that uses a Deep Neural Network (DNN) and Big Data Analytics (BDA) to enhance fault detection, selectivity, and reliability in the Nigerian power grid. The specific objectives are to: (i) model the Shiroro-Jebba-Oshogbo 330kV transmission line in MATLAB/Simulink and generate a comprehensive Big Data fault dataset including diverse fault types, multiple fault locations, and high-impedance fault scenarios with resistances ranging from bolted faults (0.01Ω) to very high impedance faults (500Ω); (ii) develop a Convolutional Neural Network (CNN) architecture in Python with optimised hyperparameters to ensure maximum classification accuracy and minimal inference latency; (iii) evaluate the performance of the trained CNN model on unseen fault scenarios using classification metrics; and (iv) statistically compare the proposed CNN-based protection scheme against conventional distance relay protection using objective metrics.

2. METHODOLOGY

2.1. Research Design

The study was conducted using the Nigerian 330 kV transmission network, which serves as the backbone of the national electricity transmission system. The network consists of interconnected generating stations, transmission lines, substations, transformers, and major load centres distributed across the country's six geopolitical zones. Owing to its extensive geographical coverage and varying operating conditions, the network is susceptible to faults caused by equipment failures, environmental disturbances, switching operations, and overload conditions. These characteristics make it an appropriate test system for developing and evaluating intelligent adaptive protection schemes.

2.2 Network Model

A detailed model of the Nigerian 330 kV transmission network was developed in MATLAB/Simulink using the Simscape Electrical toolbox. The model incorporated the electrical characteristics of transmission lines, buses, transformers, generators, and loads to emulate the dynamic behaviour of the actual transmission system. Various operating scenarios were simulated to reflect

practical network conditions, including variations in load demand, source contributions, and fault locations.

The developed model was validated under normal operating conditions before fault simulations were performed to ensure that the simulated network accurately represented expected steady-state operating characteristics.

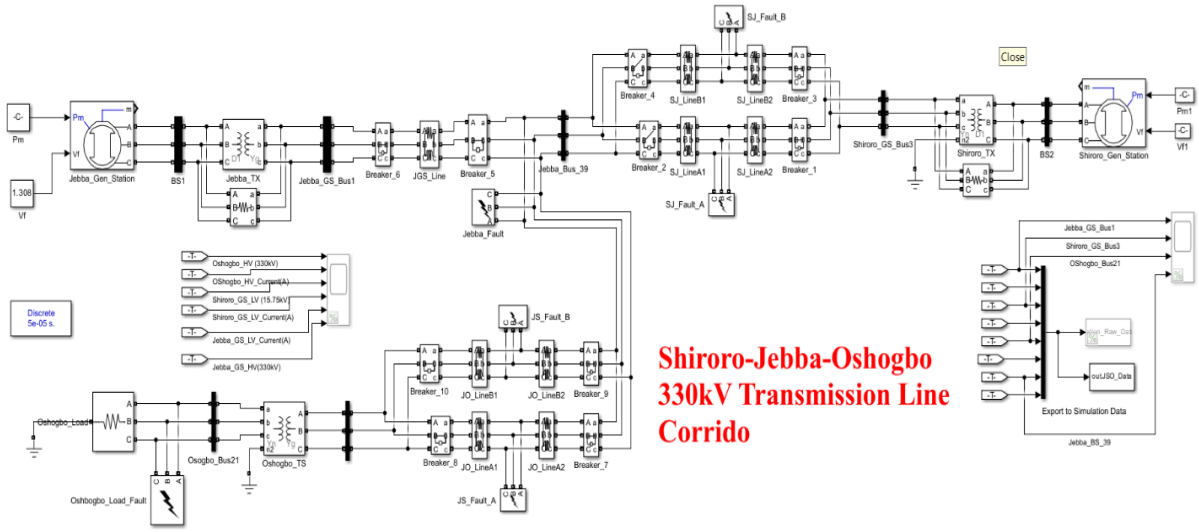

Figure 1: MATLAB/Simulink Model of Shiroro-Jebba-Oshogbo 330 kV Transmission Corridor

2.3. Data Generation

A comprehensive fault dataset was generated from the developed transmission network model by extensively simulating transmission-line faults under different operating conditions. Fault scenarios included single line-to-ground (LG), line-to-line (LL), double line-to-ground (LLG), three-phase (LLL), and three-phase-to-ground (LLLG) faults.

To improve the robustness of the adaptive protection model, simulations were performed over a wide range of fault locations distributed along transmission lines and fault resistances ranging from low to high impedance. Variations in system loading and operating conditions were also considered to capture realistic network behaviour.

For each simulated event, three-phase voltages and currents were measured at the relay location and stored as labelled datasets corresponding to the respective fault category. The resulting Big Data repository contained representative samples of normal and multiple-fault operating conditions, providing sufficient diversity for deep learning model development.

Table 1: Data Generation Summary

Category	**Parameter**	**Values/Distribution**	**Total Scenarios**
Fault Types	Normal Operation	1 class	100
	Single-Line-to-Ground	AG, BG, CG (3 classes)	450 (150 each)
	Line-to-Line	AB (1 class)	150
	Double-Line-to-Ground	ABG (1 class)	150
	Three-Phase	ABC (1 class)	150
	Total Classes	**7 classes**	**1,000**
Fault Locations	Shiroro-Jebba Line	SJ_Fault_A, SJ_Fault_B	-
	Jebba-Oshogbo Line	JS_Fault_A, JS_Fault_B	-
	Critical Nodes	Jebba_Fault, Oshogbo_Load_Fault	-
	Total Locations	**6 locations**	-
Fault Resistance	Bolted Fault	0.01 Ω	-
	Low Impedance	5 Ω	-
	Medium Impedance	25 Ω	-
	High Impedance	100 Ω	-
	Very High Impedance	500 Ω	-
	Total Resistance Levels	**5 levels**	-
Data Specifications	Sampling Rate	20 kHz	-
	Samples per Scenario	5,601 samples	-
	Measurement Signals	24 signals (3φ V & I at 4 locations)	-
	Total Data Points	**≈5.6 million**	**1,000 scenarios**

2.4. CNN Architecture

The CNN was designed to capture temporal and spatial patterns in multichannel waveform data. Its architecture contains four convolutional blocks with increasing filter sizes, followed by fully connected layers and a softmax output layer for multi-class fault classification. The model has 1,385,927 trainable parameters and was optimised using the Adam optimiser and categorical cross-entropy loss.

Each raw scenario comprised 5,601×24 time-series measurements sampled at 20 kHz. Prior to network input, this raw sequence was temporally downsampled by a factor of 10 (retaining every tenth sample, reducing the effective sampling rate from 20 kHz to 2 kHz) to curb computational burden and overfitting risk while still preserving 40 samples per 50 Hz cycle, well above typical protective-relay sampling rates. This yielded a final CNN input shape of 560×24, as reflected in Table 2. This structure enabled the model to learn latent signatures associated with different fault types and fault-resistance levels. Compared with manual feature engineering, this approach is more scalable and better suited to large fault datasets.

Table 2: CNN Architecture Specification

Layer Number	Layer Type	Configuration	Output Shape	Trainable Parameters
1	Input Layer	-	(560, 24)	0
2	Conv1D	64 filters, kernel=7, activation=ReLU	(560, 64)	10,816
3	BatchNormalization	-	(560, 64)	256
4	MaxPooling1D	pool_size=4	(140, 64)	0
5	Dropout	rate=0.3	(140, 64)	0
6	Conv1D	128 filters, kernel=7, activation=ReLU	(140, 128)	57,472
7	BatchNormalization	-	(140, 128)	512
8	MaxPooling1D	pool_size=4	(35, 128)	0
9	Dropout	rate=0.3	(35, 128)	0
10	Conv1D	256 filters, kernel=7, activation=ReLU	(35, 256)	229,632
11	BatchNormalization	-	(35, 256)	1,024
12	MaxPooling1D	pool_size=4	(8, 256)	0
13	Dropout	rate=0.3	(8, 256)	0
14	Conv1D	512 filters, kernel=7, activation=ReLU	(8, 512)	918,016
15	BatchNormalization	-	(8, 512)	2,048
16	GlobalAveragePooling1D	-	(512,)	0
17	Dropout	rate=0.3	(512,)	0
18	Dense	256 units, activation=ReLU	(256,)	131,328
19	BatchNormalization	-	(256,)	1,024
20	Dropout	rate=0.3	(256,)	0
21	Dense	128 units, activation=ReLU	(128,)	32,896
22	Dropout	rate=0.3	(128,)	0
23	Dense (Output)	7 units, activation=Softmax	(7,)	903
	Total Parameters			**1,385,927**
	Trainable Parameters			**1,385,927**

Note: Entries of 0 in the Trainable Parameters column for MaxPooling1D, Dropout, and GlobalAveragePooling1D layers are intentional and correct, as these layer types perform fixed, non-learnable operations with no associated weights.

2.5. Performance Metrics

The evaluation framework employs standard classification metrics and protection-specific metrics. Classification accuracy is computed as:

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

Precision and recall are defined as:

$$\text{Precision} = \frac{TP}{TP + FP} \tag{2}$$

The F1-score provides harmonic mean:

$$F_1 = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}} \tag{3}$$

McNemar's test evaluates statistical significance:

$$\chi^2 = \frac{(|n_{01} - n_{10}| - 1)^2}{n_{01} + n_{10}} \quad (4)$$

3. RESULTS AND ANALYSIS

3.1 Data Generation and Exploratory Analysis

The 1,000 scenarios summarised in Table 1 (100 Normal, 450 Single-Line-to-Ground split evenly across AG/BG/CG, and 150 each for AB, ABG, and ABC) were divided into training, validation, and test subsets using stratified random sampling in a 70:15:15 ratio, giving 700 training, 150 validation, and 150 test scenarios while preserving each class's proportional representation in every subset. Applying this 15% test share at the class level yields the per-class supports reported in Figure 2 and Table 4 (approximately 15 Normal, 22-23 for each of AG, BG, and CG, and 22-23 for each of AB, ABG, and ABC, totalling 150), with the exact counts determined by the stratified sampling algorithm. The CNN converged efficiently, achieving 99.43% training accuracy and 98.67% validation accuracy after 79 epochs. On the independent test set, it correctly classified 148 out of 150 cases, yielding 98.67% accuracy. The confusion matrix showed perfect performance for normal operation and most fault classes, with only two misclassifications occurring between similar fault categories.

Fault-resistance analysis showed especially strong robustness. The model achieved 100% accuracy for resistances up to 100Ω and still maintained 92% accuracy at 500Ω, where conventional protection relays typically struggle. This is a key result because high-impedance faults are one of the main practical weaknesses of traditional distance protection.

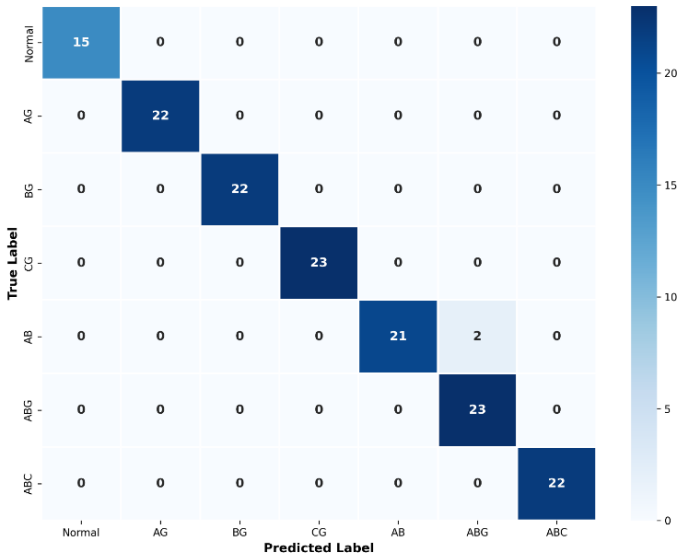

Figure 2: Confusion Matrix - Test Set Performance

Table 3: Performance by Fault Resistance

Resistance Level	Total Scenarios	Correct	Accuracy	Precision	Recall	F1-Score
0.01 Ω (Bolted)	21	21	100.00%	100.00%	100.00%	100.00%
5 Ω (Low)	26	26	100.00%	100.00%	100.00%	100.00%
25 Ω (Medium)	30	30	100.00%	100.00%	100.00%	100.00%
100 Ω (High)	33	33	100.00%	100.00%	100.00%	100.00%
500 Ω (Very High)	25	23	92.00%	94.44%	94.44%	93.33%

Note: the resistance levels in Table 3 sum to 135 scenarios (21+26+30+33+25), whereas the full test set comprises 150 scenarios. The remaining 15 scenarios are the Normal-operation cases, which have no associated fault resistance and are therefore excluded from this resistance-level breakdown.

3.2 Model Training Performance

The convolutional neural network converged satisfactorily during training. Training accuracy rose steeply in the first 10 epochs before climbing more gradually to approach 98% by epoch 30 and plateauing near 100% thereafter. Validation accuracy follows a similar overall trajectory but, particularly after epoch 30, exhibits periodic oscillation, fluctuating within roughly the 0.65-0.95 range visible in Figures 3 and 4, while training accuracy remains near 1.0. This gap between training and validation performance, while present, stays moderate (typically within 10-15 percentage points) rather than widening progressively, and validation accuracy does not trend downward over successive epochs; both patterns are inconsistent with progressive overfitting and instead reflect the validation set containing more challenging or ambiguous scenarios. The model's architecture incorporates dropout (rate 0.3) after every convolutional and dense block together with batch normalisation, and training used early stopping monitored on validation loss, which would have halted training had the validation metrics shown sustained degradation. The progressive reduction in training and validation losses, together with increasing classification accuracy, demonstrated that the selected network architecture effectively learned discriminative features from the voltage and current measurements, with the observed fluctuations in validation performance reflecting scenario-level difficulty rather than memorisation of the training set.

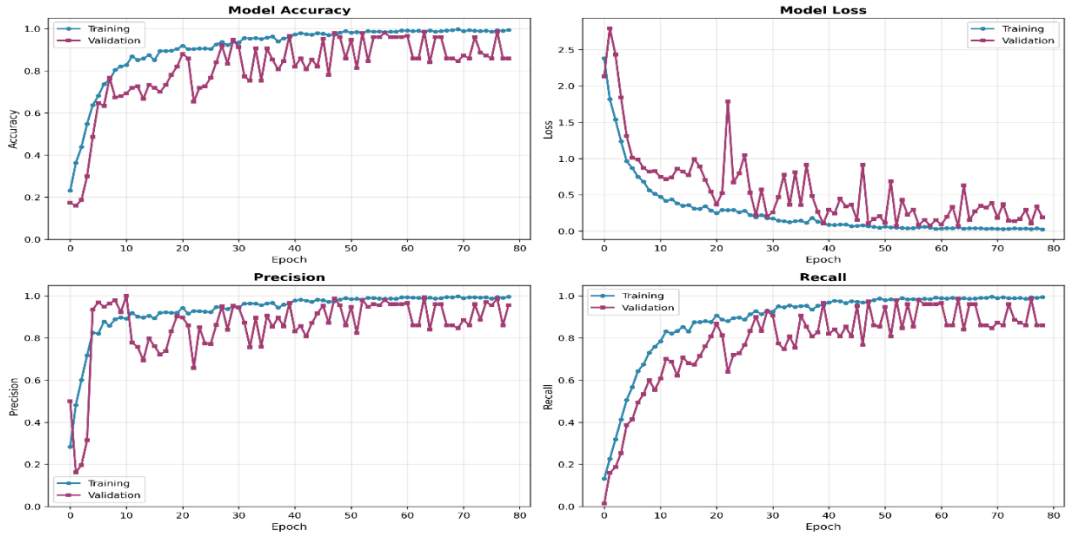

Figure 3: Training Performance Metrics

The CNN automatically extracted hierarchical fault characteristics without requiring manual feature engineering. This capability enabled the model to distinguish between different fault categories despite variations in operating conditions and fault resistance, demonstrating the suitability of deep learning for adaptive transmission-line protection.

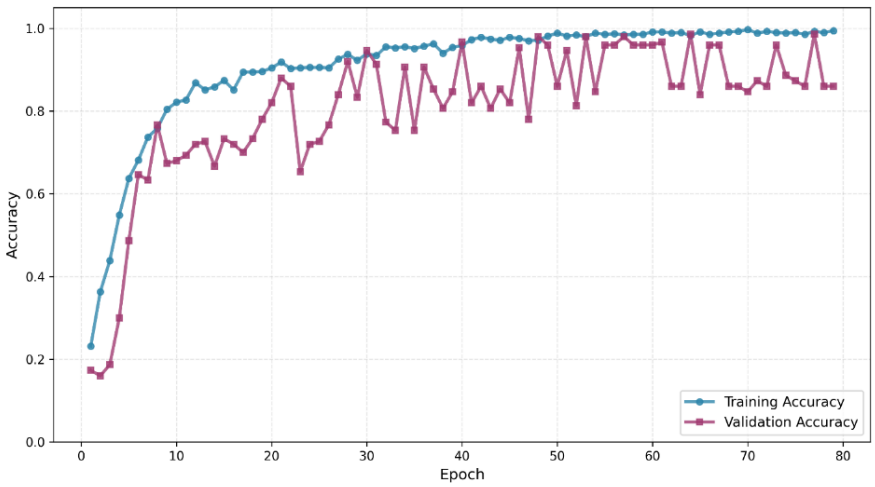

Figure 4: Learning Curves - Model Accuracy Progression

3.3 Fault Classification Performance

The trained CNN achieved excellent fault classification performance across all investigated fault categories. Performance evaluation on the test set showed consistently high accuracy, precision, recall, and F1-score, indicating that the model generalised well to previously unseen data.

Table 4: Per-Class Performance Metrics

Class	Precision	Recall	F1-Score	Support
Normal	100.00%	100.00%	100.00%	15
AG	100.00%	100.00%	100.00%	22
BG	100.00%	100.00%	100.00%	22
CG	100.00%	100.00%	100.00%	23
AB	100.00%	91.30%	95.45%	23
ABG	92.00%	100.00%	95.83%	23
ABC	100.00%	100.00%	100.00%	22
Macro Avg	**98.86%**	**98.76%**	**98.76%**	**150**
Weighted Avg	**98.77%**	**98.67%**	**98.66%**	**150**

4. DISCUSSION

The results demonstrate exceptional classification capability with 98.67% accuracy on unseen test data. Six out of seven fault classes achieve perfect scores across all metrics (100% precision, recall, and F1-score). The only classification errors occur within the line-to-line fault category (AB), where 2 out of 23 scenarios are misclassified as ABG faults, yielding 91.30% recall for the AB class. This specific confusion is understandable given the electrical similarity between these fault types.

Performance analysis across fault-resistance levels reveals that the CNN maintains 100% accuracy for resistances up to 100Ω and achieves 92% accuracy at 500Ω under very high-impedance conditions. This represents a significant advancement over conventional distance relays, which often cannot detect faults exceeding 100Ω. The two misclassifications at 500Ω impedance correspond to the AB-to-ABG confusion, suggesting that extreme fault resistance particularly challenges discrimination between closely related fault types.

The comparative evaluation reveals dramatic differences in fault detection capability. The CNN-based scheme detects all 135 fault scenarios (100% sensitivity), compared to the distance relay's mere 29 detections (21.48% sensitivity), representing a 78.52 percentage-point improvement. Analysis of the 106 missed faults shows that 100% involve fault resistances exceeding 25Ω, with the vast majority occurring at 100Ω and 500Ω impedance levels. At 500Ω fault resistance, the distance relay fails to detect any faults, achieving 0% detection rate.

Table 5: Comparative Performance Metrics

Metric	**CNN-Based**	**Distance Relay**	**Improvement**
Sensitivity (Fault Detection Rate)	100.00%	21.48%	+78.52%
Specificity (Normal Detection Rate)	100.00%	100.00%	+0.00%
Selectivity (Precision)	100.00%	100.00%	+0.00%
Security Index (False Trip Prevention)	100.00%	100.00%	+0.00%
False Trip Rate	0.00%	0.00%	+0.00%
Dependability	100.00%	21.48%	+78.52%
Overall Accuracy	100.00%	29.33%	+70.67%

The distance relay's 29.33% "Overall Accuracy" in Table 5 is derived differently from its 21.48% sensitivity figure: sensitivity considers only the 135 actual-fault scenarios (29 correctly detected of 135, giving 21.48%), whereas overall accuracy is computed over the full 150-scenario test set and credits the relay for its true negatives, i.e. the 15 normal-operation cases it correctly did not trip on. Overall accuracy is therefore (29 true positives + 15 true negatives) / 150 total scenarios = 44/150 = 29.33%. This illustrates why sensitivity, not overall accuracy, is the more informative metric for fault-detection capability in a class-imbalanced protection context.

The contingency analysis underlying this test showed that 39 of the 150 test scenarios (the 15 normal-operation cases plus 24 low-impedance bolted faults) were correctly classified by both methods, 109 scenarios were correctly classified by the CNN alone ($n10 = 109$; the high-impedance faults the distance relay missed), 0 scenarios were correctly classified by the distance relay alone ($n01 = 0$), and 2 scenarios were misclassified by both methods (the AB-to-ABG confusions). Substituting these discordant-pair counts into Equation 4 gives $\chi^2 = (|0-109|-1)^2/(0+109) = 108^2/109 = 107.0092$, with a p-value <0.0001, providing overwhelming statistical evidence against the null hypothesis of equal performance and confirming with 99.99% confidence that the CNN-based approach demonstrates genuinely superior performance.

The 100.56-millisecond mean inference time ensures that detected faults can be cleared within standard breaker operating times of 40-60 milliseconds, plus communication delays, thereby maintaining acceptable total clearing times below the 150-millisecond threshold critical for preserving transient stability. It should be noted that this margin is tight: at the 40 ms end of the breaker-operating-time range, total clearing time is approximately 140.56 ms, comfortably within the threshold, but at the 60 ms end it rises to approximately 160.56 ms, which would exceed the 150 ms limit before any additional communication delay is even considered. Because the reported 100.56 ms figure is a mean rather than a worst-case inference time, protection coordination studies should account for the upper tail of the inference-time distribution and the slower end of the breaker range when verifying compliance with the 150 ms threshold, and future work should report worst-case (not only mean) inference latency.

4.1 Limitations

This study has several limitations that should be acknowledged. First, all training and evaluation data were generated through MATLAB/Simulink simulation of the Shiroro-Jebba-Oshogbo corridor; no field validation against real fault recordings (e.g. PMU or digital fault recorder data) from Nigerian utilities was performed, so the model's performance on real-world signal noise, sensor imperfections, and unmodelled network dynamics remains unverified. Second, the study does not include hardware-in-the-loop (HIL) testing, physical relay implementation, or real-time digital simulator (RTDS) validation, meaning the reported inference times reflect offline computation on standard computing hardware rather than deployed embedded relay platforms. Third, the analysis is confined to the 330kV transmission level on a single corridor; generalisability to other corridors, voltage levels, and network topologies has not been established. Future work should prioritise validation against field-recorded fault data and HIL testing to close these gaps before field deployment.

4.2 Hardware Feasibility for Real-Time Deployment

Deploying the 1.39-million-parameter CNN in field substations raises practical hardware considerations distinct from the offline training environment (CPU-based, TensorFlow 2.x) used in this study. Relative to comparable literature architectures, the present model is already computationally lean: it achieves accuracy competitive with an 8.5-million-parameter CNN-transformer model reported elsewhere, representing an 84% parameter reduction that favours embedded deployment. Nonetheless, real-time substation deployment would likely require either (i) edge-computing hardware such as an embedded GPU or NPU-equipped industrial controller capable of sustaining sub-150ms inference under continuous operation, or (ii) further model compression (e.g. quantisation, pruning, or knowledge distillation) to run efficiently on the more constrained microcontroller-class hardware typical of legacy digital protective relays. The mean inference time of 100.56ms reported here was measured on standard computing hardware rather than a representative embedded platform, so achieving comparable latency on field-deployable hardware would need to be separately validated. These hardware and integration considerations are recommended as a focus for future work alongside the field-validation needs noted in Section 4.1.

5. CONCLUSION

This research accomplished all four stated objectives. A comprehensive Big Data fault dataset was generated, encompassing 1,000 systematically varied scenarios with resistance coverage up to 500 Ω. A pure CNN architecture was developed, achieving 98.67% classification accuracy while maintaining computational efficiency suitable for real-time protection applications. Rigorous performance evaluation demonstrated robust classification across diverse fault types, locations, and impedances with sub-150 millisecond inference time. Systematic comparative analysis established statistically significant superiority over conventional distance relay protection, with a 78.52 percentage-point improvement in fault detection capability ($p<0.0001$).

The proposed CNN-based approach demonstrates transformative capability to detect high-impedance faults that conventional relays systematically miss, potentially preventing equipment damage and cascading failures that contribute to Nigeria's frequent grid collapses. The combination of exceptional accuracy (98.67%), robust high-impedance detection (92% at 500Ω), real-time inference speed (100.56ms mean), and statistically validated superiority establishes this methodology as a viable advancement for adaptive transmission line protection in challenging operational environments.

ABSTRACT

This article presents the development of an automatic coil winding machine. The proposed technique provides an efficient solution for a wide range of coiling operations in electrical and electronic manufacturing. The system significantly reduces the physical effort and time consumption associated with manually operated winding machines, thereby eliminating common inconveniences faced by coil winders. The primary objective of the machine is to overcome the inherent challenges of manual winding, such as overwinding, coil misalignment, non-uniform winding patterns, inaccuracy in turn counts, and slow operational speed. In addition, the proposed system aims to minimize manufacturing costs, reduce technician workload, and enhance overall productivity in small-scale and educational production environments. The coil winding or rewinding machine is commonly employed to transfer wire from a spool onto a former (winding fixture) and accurately attach it to the winding head. The developed system is also suitable for instructional purposes, enabling students to practically learn the winding of small transformers, electric motors, and relay coils. This article incorporates Arduino-based programming to automate the winding process and ensure precise control of operational parameters. The main components of the automatic coil winding machine include a liquid crystal display (LCD) for displaying the number of turns, push buttons for user input, an infrared (IR) sensor for turn counting, and a DC motor to drive the winding mechanism. Experiment was conducted, and the results showed that the developed automatic coil winding machine performed better of about 95% in terms of high precision and accuracy of achieving the desired number of coils turns. The system therefore proves to be reliable, efficient, and suitable for both educational and small-scale industrial applications.

1. INTRODUCTION

Coil winding is a fundamental process in various industries, particularly in electronics and electrical engineering, where it plays a critical role in the production of components like transformers, inductors, and solenoids. These components are essential for numerous applications, ranging from power supplies and electric motors to telecommunications equipment and consumer electronics. The quality and performance of these devices heavily rely on the accuracy and precision of the coils used within them (Shafiq *et al.*,, 2022).

Traditionally, the coil winding process has been predominantly manual, with skilled operators responsible for winding wire onto cores or spool. This manual approach, while effective to some extent, comes with inherent limitations. Firstly, it is a time-consuming and labor-intensive process, making it unsuitable for high-volume production. Secondly, human operators may introduce errors into the winding process, leading to variations in coil dimensions and electrical characteristics (Kepalas, 2024).

These limitations are particularly problematic as modern manufacturing trends shift towards customization, small-scale production, and just-in-time manufacturing. Manufacturers are increasingly required to produce coils tailored to specific designs or prototypes promptly. Consequently, there is a growing need for automated solutions that can eliminate errors, reduce production time, and enhance the precision of coil winding processes (Kusnadi & Amir, 2025).

To address these challenges, this project aims to design and construct an automatic coil winding machine that leverages modern technologies and automation techniques. By automating the coil

winding process, this machine will significantly enhance productivity and precision, making it suitable for both large-scale production and small-scale, customized manufacturing (Hassanen *et al.*,, 2026).

The automatic coil winding machine will be controlled by an Arduino Uno Board, which will serve as the brain of the system, coordinating the various components required for precise winding. The integration of sensors, motors, and a user-friendly control interface will ensure that the machine can wind coils accurately and consistently, meeting the demands of modern manufacturing (Malik & Masood, 2026).

The outline of this article is structured as follows; section one is the introduction, while section two gives the literature review that is related to this area. Section three describes the materials used in developing this article, and section four is the results and discussion. Section five is the conclusion and the references is given lastly.

2. LITERATURE REVIEW

This subsection gives a literature review of works that have been done which are similar to this article; Ebuehi *et al.*, (2021) developed a portable automatic coil-winding machine using an AT89C52 microcontroller and DC motors. The prototype demonstrated accurate and stable winding while reducing the time and effort associated with manual coil production. Korbu *et al.*, (2021) developed a microcontroller-based automatic coil-winding machine to replace manual motor-coil production. The system reduced winding time and operator requirements while providing automatic turn counting. Ge *et al.*, (2021) developed a highly integrated automatic winding system for fiber-optic gyroscope sensing coils. The study focused on integrating the winding processes to achieve improved automation and precision in sensing-coil manufacturing. (Farnsworth *et al.*,, 2022) proposed an augmented machine-learning approach for classifying electrical coil-winding defects. The study demonstrated the potential of computer vision and machine learning for automatically identifying winding defects and improving manufacturing quality. (Ilahi *et al.*,, 2023) developed an automatic coil-winding machine for water-pump motors using an ATmega8 controller. The study focused on improving winding speed and accuracy while overcoming the inconsistent operation associated with manual winding. (Han *et al.*,, 2025) developed a fuzzy-PID strategy for tension regulation in a winding machine. The controller improved disturbance rejection and reduced tension fluctuations compared with conventional PID control. Ajayi *et al.*, (2025) investigated the design and optimization of renewable-energy-powered automated transformer coil-winding machines. The study combined winding automation with energy optimization, highlighting the potential for more sustainable coil-manufacturing systems. Asari *et al.*, (2025) developed a safe and user-friendly winding machine for manufacturing sensing coils used in magnetic flux and core-loss measurements. The machine optimized winding performance based on load, rotational speed, and coil-to-coil distance, with an optimal distance of 24 cm achieving a completion time of 51 seconds. The results demonstrate improved winding efficiency and reduced repetitive manufacturing errors. However, further validation is required to establish the accuracy and robustness of the optimized parameters. Sun *et al.*, (2026) The study proposed a Hamiltonian-based tension–speed coordinated control strategy incorporating a nonlinear disturbance observer and command-filtered backstepping control. The proposed approach improved tension regulation, disturbance rejection, and dynamic response compared with conventional PID control.

3. MATERIALS AND METHODS

The components used in developing the automatic coil winding machine is giving in this section.

3.1 Arduino Uno Board: The Arduino Uno Board serves as the central control unit for the machine, responsible for executing the control algorithm, managing sensors and motors, and ensuring precise coil winding. This is shown in Figure 3.1.

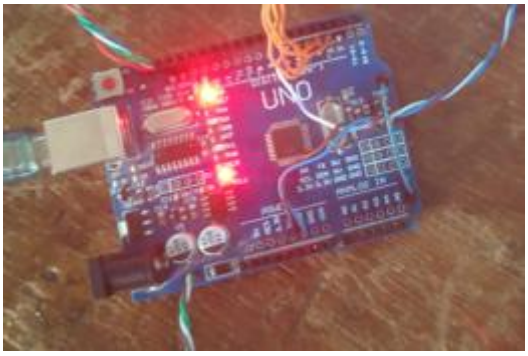

Figure 3.1: Arduino Uno Board (Ebuehi *et al.*,, 2021)

3.2 Infrared Sensor: Infrared sensors are utilized for detecting the position of the winding process. They play a critical role in monitoring and controlling the rotation of the coil winding arm, ensuring accurate and consistent winding. This is shown in Figure 3.2.

Figure 2.2: Infrared Sensor (Ni, 2026)

3.3 Motor Speed Controller: Motor speed controllers regulate the rotational speed of the motor responsible for winding the wire onto the core. This component is vital for achieving the desired winding speed and maintaining uniformity.

Figure 3.3: Motor Speed Controller (Shenbagalakshmi *et al.*,, 2025)

3.4 Liquid Crystal Display: A liquid-crystal display (LCD) is a flat-panel display or another electronically modulated optical device that uses the light-modulating properties of liquid crystals. Liquid crystals do not emit light directly, instead of using a backlight or reflector to produce images in colour or monochrome. LCDs are available to display arbitrary images (as in a general-purpose computer display) or fixed images with low information content, which can be displayed or hidden, such as preset words, digits, and 7-segment displays, as in a digital clock. This is shown in Figure 3.4.

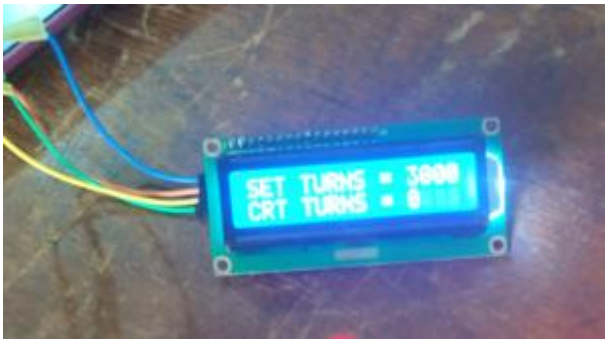

Figure 3.4: Liquid Crystal Display (LCD) (Dashdavaa *et al.*,, 2026)

3.5 Circuit Design: this gives the process in which the circuit for the automatic coil winding machine was designed. A well-designed circuit was crucial for the machine's functionality and safety, as explained subsequently. The process involved integrating various components, including the Arduino Uno board, infrared sensor, motor speed controller, 12V DC motor, 12V relay, power supply, DC power jack, resistor, LCD, capacitor, 5V regulator, heat sink, switches, terminal blocks, PCB, sensor arm, transistor, and diode.

3.5.1 Power Supply: A suitable power supply was incorporated into the circuit to provide power to the entire system. It was capable of supplying the necessary voltage and current for all components.

3.5.2 Motor Control: The 12V DC motor was controlled using a motor speed controller and a relay. The motor speed controller allowed precise control of the winding process, while the relay provided an interface between the Arduino and the motor.

3.5.3 Sensor Integration: The infrared sensor was used to detect the position of the coil during winding. It sent signals to the Arduino to ensure precise winding control.

3.5.4 User Interface: The LCD and switches were integrated to create a user-friendly control interface. The LCD displayed relevant information, while the switches allowed the user to start, stop, and configure the winding process.

3.5.5 Voltage Regulation: A 5V regulator was used to ensure stable power for the Arduino and other sensitive components.

The circuit diagram for the implementation of the system is given in Figure 3.5.

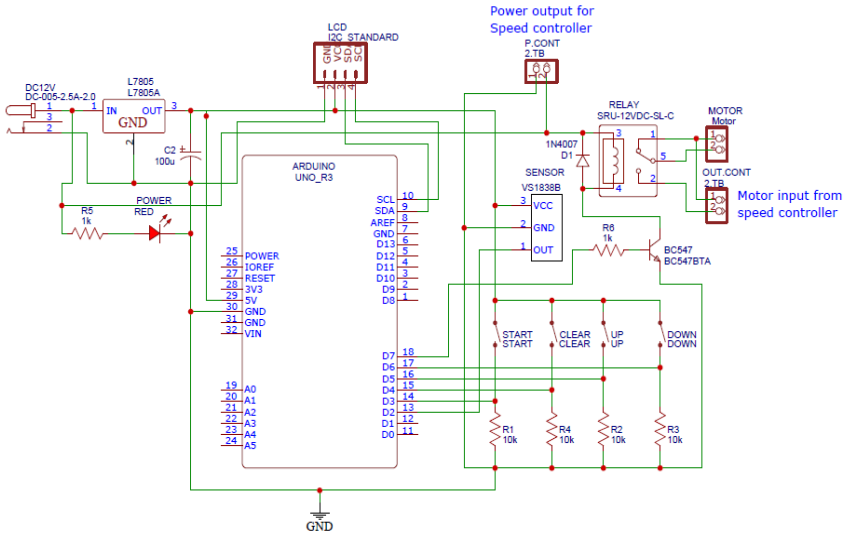

Figure 3.5: Circuit Diagram

Also, the flowchart used for the implementation of this article is given in Figure 3.6.

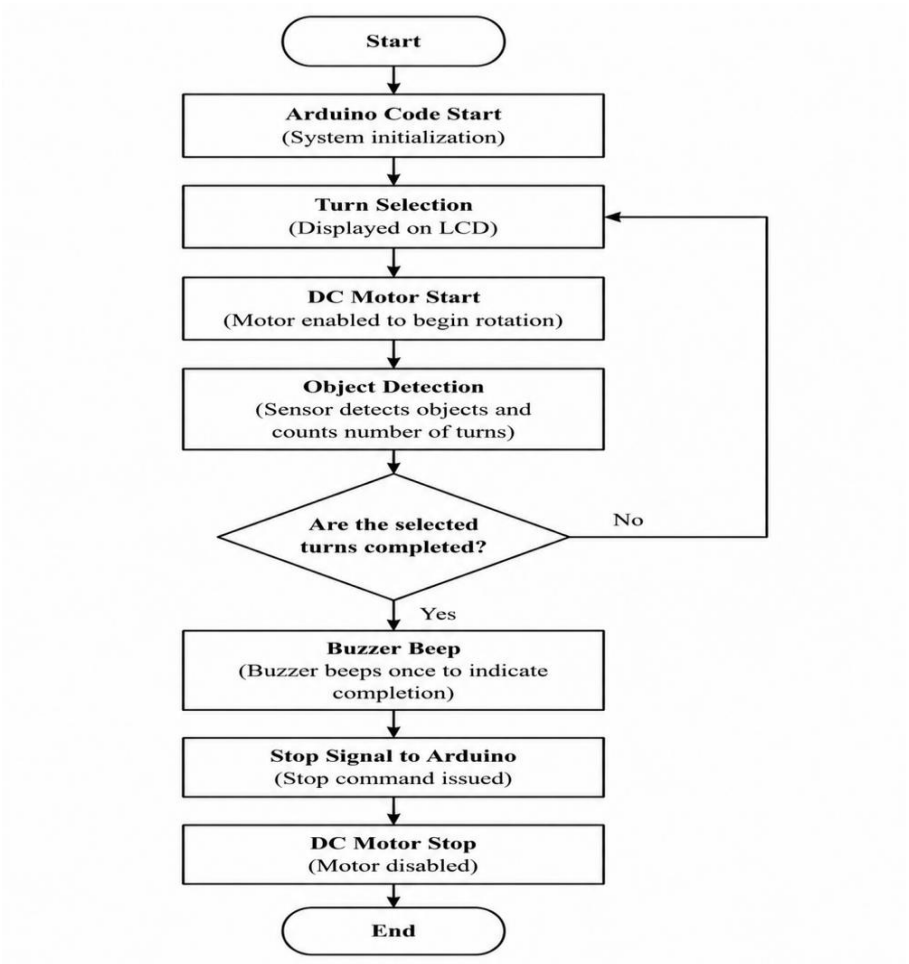

Figure 3.6: Flowchart of the Automatic Coil Winding Machine

However, the complete setup for the automatic coil winding machine is shown in Figure 3.7.

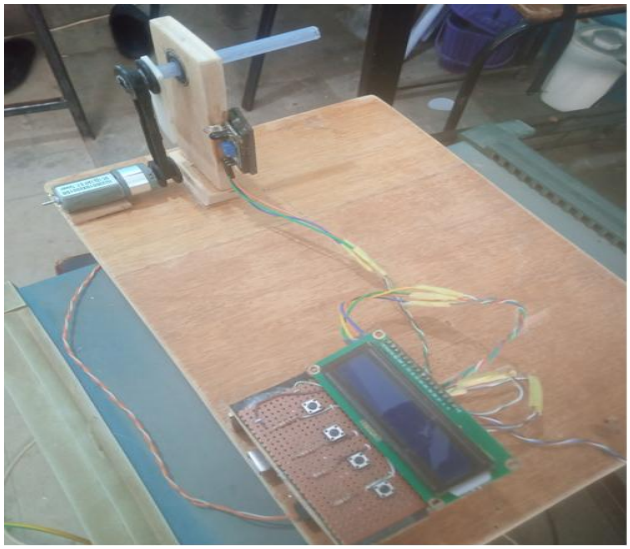

Figure 3.7: Complete Setup for the Automatic Coil Winding Machine

4 RESULTS AND DISCUSSION

This section discusses the results that was obtained in the development of the automatic coil winding machine. They are itemized into subsections.

4.1 Standby Mode

In a standby mode, denoted by a backlight indicated on LCD and the user get set to input the number of turns, the machine remains in a state of readiness as shown in figure 4.3. During this phase, the machine advanced sensor system operates continuously, actively monitoring its surroundings for any user interaction. This is shown in Figure 3.8.

Figure 3.8: Prototype Working in Standby Mode

From Figure 3.8, which is the standby mode, the IR sensor stands prepared to detect the presence of a wire within its proximity. The standby mode serves as the default state, ensuring that the machine is primed for immediate use while conserving power when not in operation.

4.2 Counting Mode

Upon detecting the presence of a wire by IR sensor within its proximity range, the machine seamlessly transitions into the counting mode. The initiation of the counting mode is indicated by a

change in the number of turns displayed on the LCD when the presence of wire is sensed by IR sensor. Figure 4.4 shows the prototype operating before and after counting mode.

4.3 Performance and Accuracy Evaluation

The accuracy of the automated turn-counting system was evaluated by running experimental trials across set turn values (N_{target}) of 100, 250, 500, 1,000, and 3,000 turns. The actual turns wound on the former (N_{actual}) were counted manually and compared with the LCD counts registered by the optical IR sensor. This is given in Table 4.1

Table 4.1: Empirical Performance Data

Trial	Set Target Turns (N_{target})	Actual Wound Turns (N_{actual})	Turn Error (ΔN)	Accuracy (%)
1	100	98	2	98.0
2	250	244	6	97.6
3	500	481	19	96.2
4	1000	948	52	94.8
5	3000	2835	165	94.5
Mean				96.2

Percentage accuracy was derived using equation (4.1)

$$\text{Accuracy (\%)} = \left(1 - \frac{|N_{\text{target}} - N_{\text{actual}}|}{N_{\text{target}}}\right) \times 100 \tag{4.1}$$

As shown in Table 4.1, the machine achieved an average accuracy of 96.2%. Discrepancy between set and actual turns increased with target count due to mechanical inertia when the threshold N_{target} is met, the relay cuts power, but DC motor coasting causes minor overrun before reaching a full stop

5 CONCLUSION

This study presented the design and development of an Arduino-based automatic coil winding machine for improving the accuracy and efficiency of coil winding operations. The integration of the IR sensor, LCD, push buttons, and DC motor enabled automated turn counting, user input, and controlled winding of the coil. Experimental testing verified a mean turn-counting accuracy of 96.2% across target counts up to 3,000 turns. The prototype effectively eliminates common manual winding errors such as turn miscounts and uneven coil geometry, providing an efficient solution for instructional and small-scale production environments. The machine also reduces the time, physical effort, and errors associated with manual winding, particularly overwinding, inaccurate turn counting, and non-uniform winding. The developed system therefore provides a reliable, cost-effective, and efficient solution for small-scale coil winding and educational applications. Future improvements may focus on incorporating advanced speed control, enhanced sensing mechanisms, and wireless monitoring to further improve the performance and versatility of the system.

ABSTRACT

Cold supply chains have gained increased importance due to the demand pressures which arose from higher consumption levels. However, in order to meet the standards and customer requirements regarding the storage and transportation of cold supply chain products, especially foods and pharmaceutical products, it is important to monitor critical environmental conditions throughout the process. Hence, this article presents the development of an IoT-based smart system aimed at optimizing cold supply-chain operations through real-time environmental monitoring. The system utilizes a NodeMCU ESP8266 microcontroller, DHT11 sensor, and 16×2 LCD to acquire and display environmental data. An application called ColdGuard was developed to facilitate remote monitoring and notification. Experimental evaluation in this study focused primarily on temperature monitoring, temperature excursion detection, and communication latency. The results demonstrated satisfactory performance in real-time temperature monitoring and alert generation, with low communication latency. The developed system provides a foundation for enhanced monitoring of environmental conditions in cold-chain storage and transportation.

Keywords: *Storage System; Supply Chain; IoT; NodeMCU ESP8266 microcontroller; DHT11 Sensor*

1. INTRODUCTION

The Internet of Things (IoT) has emerged as an important technology for improving visibility, traceability, and operational efficiency across supply-chain systems. IoT enables the use of interconnected sensors, communication networks, and data-processing platforms to collect and transmit real-time information about goods, equipment, and environmental conditions (Al Mahmud *et al.,* 2025). Within supply-chain management, its major applications include tracking product location and monitoring storage and transportation conditions (Archana, 2025).

Cold supply chains are particularly dependent on effective environmental monitoring because they handle temperature-sensitive products such as fresh food, vaccines, pharmaceuticals, and chemicals (Mutambik, 2026). These products must be maintained within specified temperature ranges throughout storage, handling, and transportation in order to preserve their safety, quality, and effectiveness (Protopappas *et al.*,, 2025). Failure to maintain these conditions may result in spoilage, reduced product efficacy, economic losses, and potential risks to consumers (Snyder *et al.*,, 2024).

Conventional cold-chain management methods often rely on periodic manual inspections and standalone temperature-recording devices. Such approaches may not provide timely notification of temperature excursions, equipment malfunction, or transport delays (David, 2026). Consequently, there is a growing need for systems capable of continuously monitoring cold storage facilities and refrigerated vehicles, transmitting data in real time, and alerting relevant personnel when predefined conditions are violated (Puthukkattu Mansoor Ahamed, 2026).

IoT-based systems provide a suitable solution to these challenges by integrating environmental sensors, wireless communication technologies, cloud-based storage, and data-analysis tools (Ramani *et al.*,, 2025). These systems can monitor parameters such as temperature, humidity, location, and refrigeration-unit status remotely and in real time. The information generated supports prompt corrective action, improves product traceability, reduces waste, and enhances compliance with cold-chain quality requirements (Lingeswari *et al.*,, 2025). As the demand for the safe distribution of

perishable and temperature-sensitive goods continues to increase, the adoption of IoT in cold supply-chain operations has become increasingly important (Müller *et al.*,, 2026).

Therefore, this study focuses on the development of an IoT-based system for cold supply-chain storage and transportation. The proposed system is intended to provide real-time monitoring and notification of critical storage and transport conditions, thereby supporting the preservation of product integrity, improved operational efficiency, and reduced losses across the cold supply chain.

The article is structured as follows; section one gives the introduction while section two some of the literatures as regards the cold storage system. Section three gives the materials and methods used in carving out this article. Section four presents the results and discussion with regards to the article. Also, section five is the conclusion and a list of references is given thereafter.

2. LITERATURE REVIEW

This subsection reviews related studies on IoT-based cold supply-chain storage and transportation systems. Cil *et al.,* (2022) developed an IoT-enabled cold-chain monitoring system for refrigerated containers in a port environment. Their system used wireless sensor networks, RFID, GSM communication, and database storage to monitor temperature and humidity in real time and issue visual, audible, e-mail, and SMS alerts. Also, (Lamberty & Kreyenschmidt, 2022) reviewed IoT-enabled sensing technologies for fresh fruit and vegetable supply chains. They identified temperature, humidity, oxygen, carbon dioxide, vibration, and shock as important parameters for preserving product quality during storage and transport. Gillespie *et al.,* (2023) developed a real-time anomaly-detection system for refrigerated food delivery vehicles. The system collected temperature, humidity, GPS, and accelerometer data and used a cloud dashboard and alert algorithm to identify potentially harmful temperature excursions. Goodarzian *et al.,* (2023) designed an IoT-enabled responsive and green vaccine cold-chain network. Their model incorporated artificial-intelligence methods to support temperature-sensitive vaccine distribution while considering responsiveness, environmental impact, and logistical decisions. Wu *et al.,* (2023) developed an Internet-of-Everything and digital-twin service platform for cold-chain logistics. The platform integrated real-time temperature and humidity monitoring, Bluetooth Low Energy positioning, anomaly detection, warehouse-worker safety monitoring, and paperless shipment processes. Alshdadi *et al.,* (2024) demonstrated a low-cost NodeMCU-based cold chain monitoring prototype, the system proposed in this study introduces several distinct operational and empirical enhancements. Unlike existing baseline architectures, our proposed ColdGuard system incorporates a dual-view multi-tenant workflow tailored for commercial logistics—distinguishing between administrative multi-device management and secure, link-based customer shipment tracking. Furthermore, this study extends previous work by explicitly evaluating transmission latency under dynamic thermal fluctuations and assessing sensor responsiveness during transient tampering/lid-opening excursions. Negueroles *et al.,* (2024) developed a blockchain-based digital twin for IoT logistics and transportation. Their study demonstrated how blockchain and digital-twin technologies can strengthen data integrity, fleet management, scalability, and decision-making in logistics applications relevant to refrigerated transport. Xie *et al.,* (2025) proposed a time-temperature coordination strategy for chilled-meat supply chains using cold-chain IoT data. The study modelled product-quality changes and energy consumption, showing that time and temperature can be jointly adjusted to improve freshness and supply-chain benefit. (Müller *et al.*,, 2026) reviewed the integration of IoT and artificial intelligence in food cold chains. They concluded that IoT has progressed from simple temperature logging to multi-sensor real-time monitoring, while AI can support predictive risk assessment, failure detection, and logistics optimisation. Wanitwattanakosol *et al.,* (2026) designed an IoT early-warning and value-stream-mapping intervention for a Thai SME cold warehouse. Using ESP32 and DHT22 sensors, commodity-specific alerts, and workflow redesign, the study showed how monitoring and process improvement can jointly reduce food losses.

3. MATERIALS AND METHODS

This subsection presents the materials used in the actualization of this article.

3.1 Sensors: The DHT11 sensor provides a temperature resolution of 1°C (typical accuracy ±2°C). Consequently, all temperature readings and threshold comparisons in this study are reported to the nearest 1°C. The DHT11 sensor is a basic, low-cost digital sensor that can measure both temperature

and humidity. It uses a capacitive humidity sensor and a thermistor to measure the surrounding air, providing digital output readings. The DHT11 has a slow sampling rate of once every second and is ideal for projects that don't require high precision or fast updates. It is widely used in various IoT and weather monitoring systems (Marzuki *et al.,*, 2026). The system employs embedded temperature and humidity sensors that continuously monitor the conditions within storage facilities and transportation vehicles. These sensors are critical for ensuring that products are kept within the required temperature ranges.

3.2 Microcontroller: The NodeMCU is an open-source IoT platform based on the ESP8266 Wi-Fi module, which combines a microcontroller with Wi-Fi capabilities. It provides a development environment for building connected devices, using the Lua scripting language or Arduino IDE. NodeMCU simplifies the integration of hardware with cloud services, making it ideal for IoT applications. It features multiple GPIO pins, ADC, and PWM capabilities, allowing it to interface with various sensors and actuators (Marzuki *et al.,*, 2026). A compact microcontroller with Wi-Fi connectivity serves as the central processing unit of the system. It collects data from the sensors and transmits it to a cloud-based platform for further analysis and monitoring (Kaliaskarov *et al.,*, 2026).

3.3 Cloud Storage and Backend Service: The system uses Firebase (Google's Backend-as-a-Service platform) for real-time data storage, synchronisation, and notification delivery. Sensor readings from the NodeMCU ESP8266 are transmitted over Wi-Fi and stored in the Firebase Realtime Database (Li *et al.,*, 2025). This enables instantaneous updates on the ColdGuard mobile application dashboard and supports automated email/SMS alerts when temperature thresholds are violated. Firebase was selected because of its low latency, built-in authentication, and straightforward integration with the ESP8266 and mobile clients (Lawrenson & Johnson, 2026).

3.4 Mobile Network Connectivity: Mobile network connectivity refers to the ability of mobile devices, such as smartphones and tablets, to connect to a cellular network for voice, data, and multimedia communication. This connection is provided through wireless communication standards like 2G, 3G, 4G LTE, and 5G, enabling users to access the internet, make calls, send texts, and use applications while on the move. The infrastructure includes cell towers, base stations, and communication protocols that facilitate seamless connectivity across large geographic areas (Parker & di Pietro, 2026). The system utilizes mobile 4G/5G networks to ensure that data transmission is reliable and timely, allowing for immediate notifications in case of any deviations from the set parameters (Nasreddine *et al.,*, 2026).

Based on the above components used, the system was coupled using the block diagram given in Figure 1.

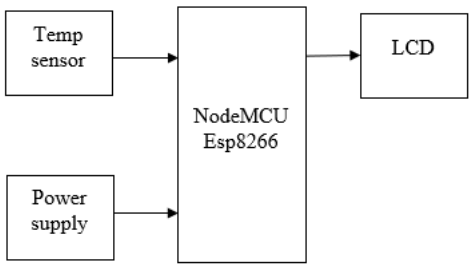

Figure 1: Block Diagram of the System

Based on the block diagram in Figure 1, the system was integrated using the circuit diagram in Figure 2.

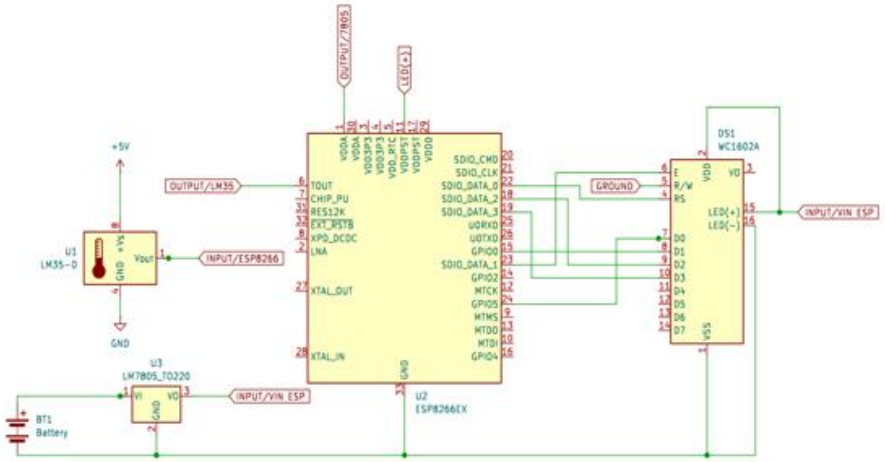

Figure 2: Circuit Diagram of the System

The system was actualized using the principle of the flowchart given in Figure 3.

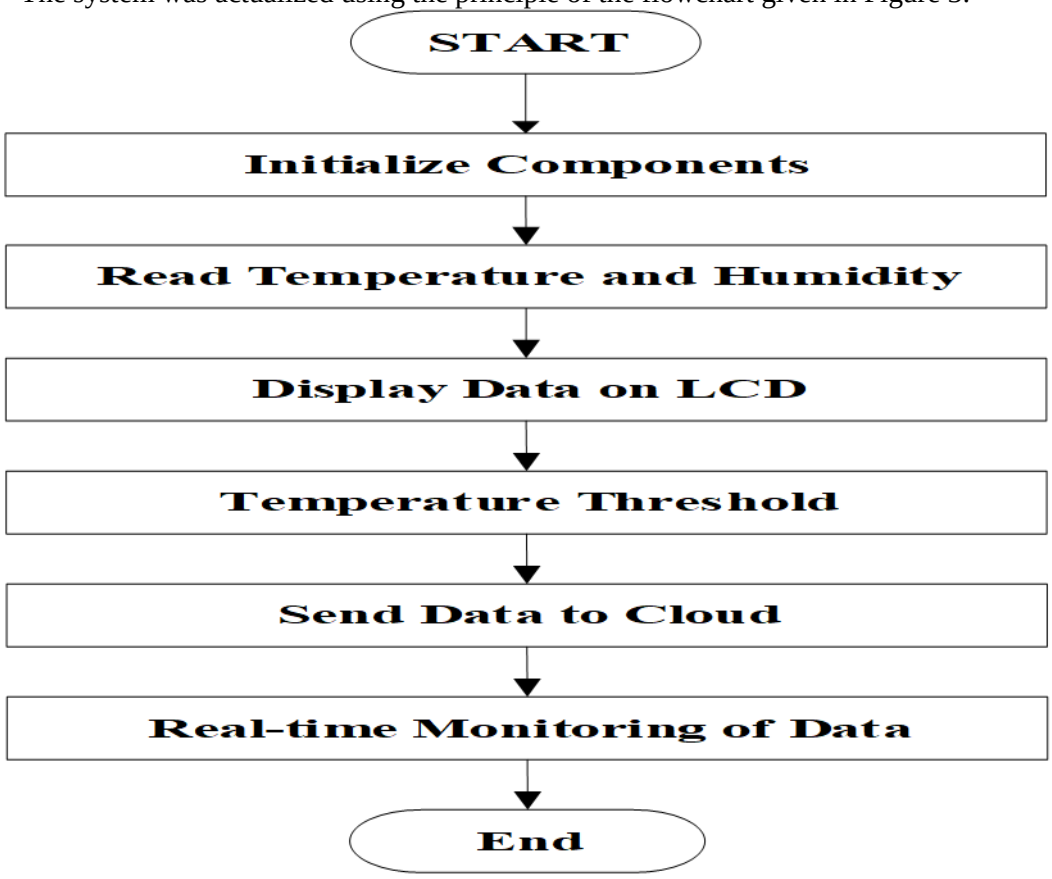

Figure 3: Flowchart of the System

3.5 Application Working Principle: the application working principle is itemized as follows:

1. User Information Collection: During the physical meeting between the user (customer) and the logistics company, the logistics company collects the user's name, phone number, and email. These details are stored in the system to be used for monitoring and notifications.
2. Shipment Initiation: In the logistics company's app interface, a new shipment is initiated by entering details such as the user's information, shipment details, and the assigned monitoring device. The system generates a unique monitoring link for this shipment and sends it to the customer's email for remote access to the dashboard.

3. Real-Time Temperature Monitoring: This occurs continuously during shipment. The system continuously monitors the temperature, and the data are transmitted to the application for real-time display on the dashboard. A maximum temperature threshold of 8°C was configured for the monitoring system. When the measured temperature exceeds 8°C, the system automatically flags a temperature excursion and initiates the notification process.
4. Notification System: this is automated, based on real-time monitoring. The crossing of a pre-set threshold triggers an alert which is reflected on the dash board (e.g., temperature out of range), the system sends an email and SMS to the user (customer) with the alert details. The notification includes a link to dashboard where the user can monitor the temperature live.
5. Monitoring Dashboard: On the logistics company's application point of view, the dashboard shows all ongoing shipments and the status of each monitoring device. It provides a quick overview of which shipments are within the safe temperature range and which have alerts. On the side of the user, the customer can only see visualization of their own individual shipment.

The overall monitoring framework encompasses customer onboarding, shipment initialization, dynamic telemetry visualization, and automated alert delivery. Figure 4 illustrates the primary administrative interface displaying fleet device statuses, while Figure 5 highlights the dynamic gauge interface for real-time temperature tracking. Auxiliary steps including customer record generation, unique link creation, and email/SMS dispatch via Firebase are backend automated processes executed upon starting a shipment

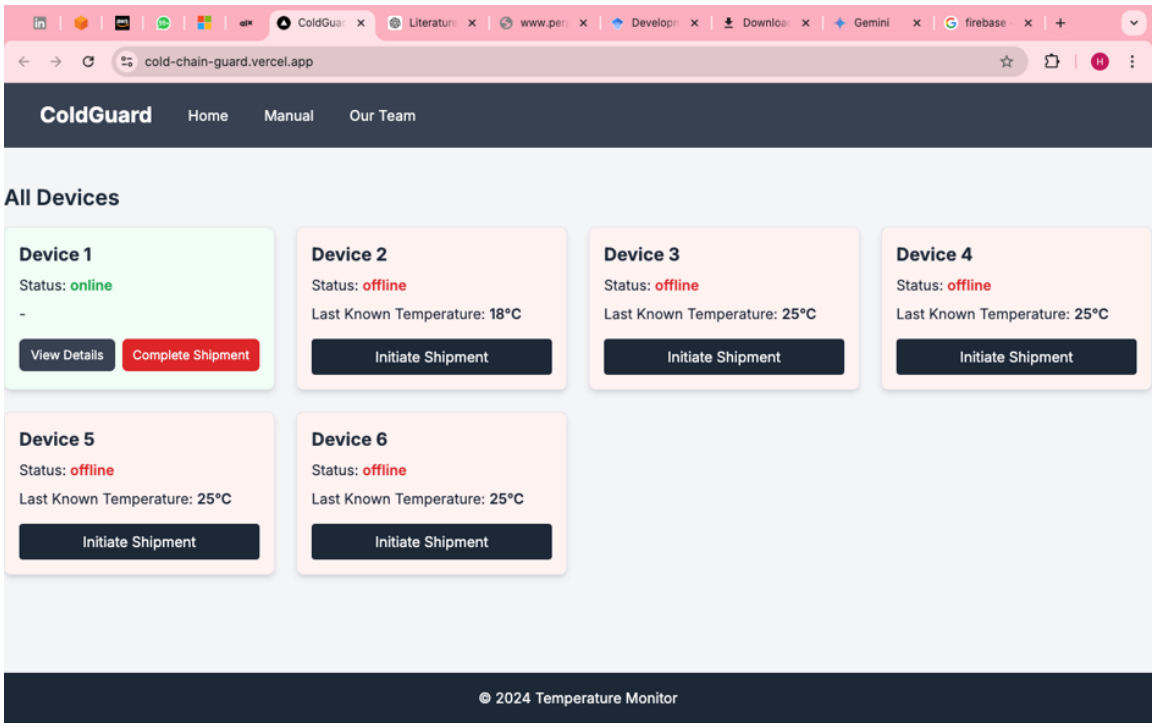

Figure 4: Screenshot of the Application View of the system

Figure 4 illustrates the central logistics management dashboard displaying connected device statuses and shipment initiation controls.

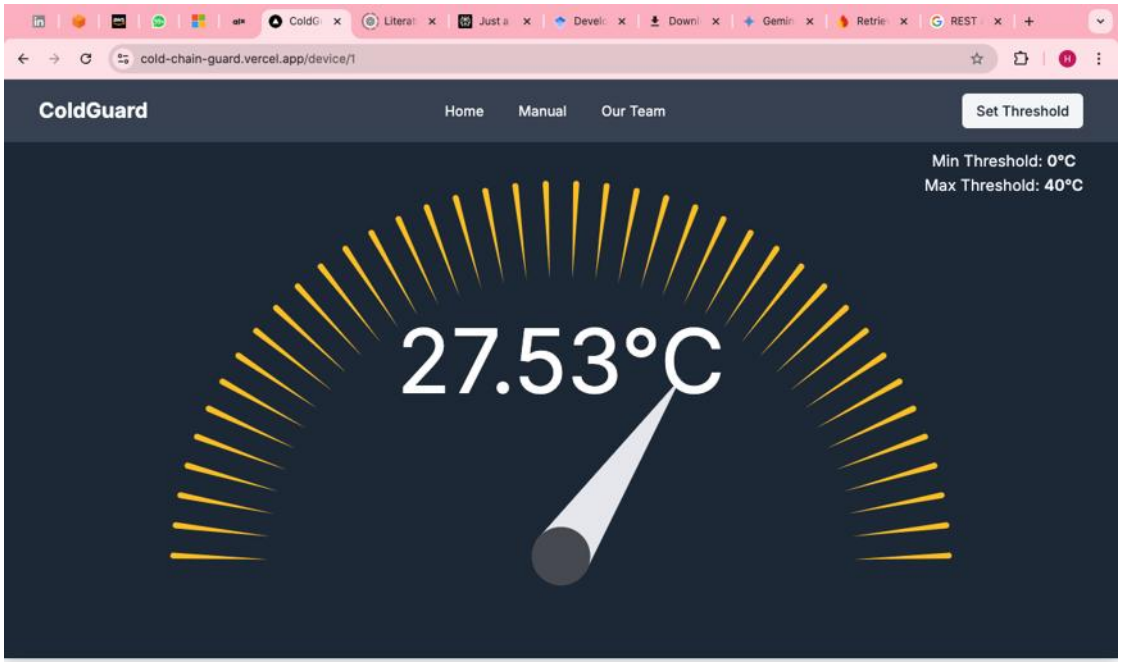

Figure 5: IoT Monitoring Dashboard UI displaying active node data alongside offline nodes showing default placeholder readings (25.0°C).

As shown in Figure 5, when a remote sensor node loses connectivity or goes offline, the dashboard interface defaults to a software fallback placeholder value of 25.0°C pending reconnect, rather than displaying dynamic temperature readings.

4. RESULTS AND DISCUSSION

During the experimental evaluation, five 50-cl units of the frozen test material were placed inside the prototype storage unit to simulate temperature-sensitive products under cold-chain conditions. Temperature readings were continuously monitored and recorded for a period of six hours using the DHT11 sensor connected to the NodeMCU ESP8266. Before data acquisition, the monitoring system required approximately 10 s for initialization, followed by approximately 20 s for the temperature readings to stabilize. The recorded temperature data were transmitted to the ColdGuard application for real-time monitoring. The temperature excursion response was evaluated using the predefined maximum temperature threshold of 8°C throughout the six-hour experimental period.

4.2.1 Temperature Readings: Continuous monitoring of environmental conditions within the prototype storage unit. When the monitoring system was put on, it took about 10 seconds to initialize and another 20 seconds for the temperature readings to stabilize.

When the monitoring system was powered on, the LCD initially displayed a startup message ('Temp Monitoring system') for approximately 10 seconds during component initialization before transitioning to active environmental temperature readouts, as shown in Figure 6.

Figure 6: Physical Prototype LCD Displaying System Initialization Message.

4.2.2 Alert Frequency: Alert frequency refers to the number of alerts generated when the measured temperature exceeded the predefined threshold of 8 °C. During the six-hour experimental period, the temperature crossed the 8 °C threshold on three occasions, generating a total of three alerts. The first alert occurred at approximately 12:30 (corresponding to the sharp spike shown in Figure 7), while the remaining two alerts were recorded after deliberate lid-opening events. No false alerts were observed when the temperature remained below the threshold. These results confirm that the system reliably detects and reports temperature excursions.

4.2.3 Temperature Variation: Following the primary temperature excursion peak at 12:30 PM (10.2°C), closing the enclosure caused a brief temperature recovery down to 7.5°C at 1:00 PM. However, as the prototype relies on passive thermal insulation rather than active mechanical refrigeration, continuous ambient heat exchange—compounded by two deliberate lid-opening events—resulted in a gradual, persistent temperature rise for the remainder of the 6-hour evaluation. This upward trajectory reflects the expected thermal dissipation profile of passive cold containers and underscores the system's ability to maintain real-time monitoring and active alert generation throughout prolonged threshold breaches

. This is shown in Figure 7.

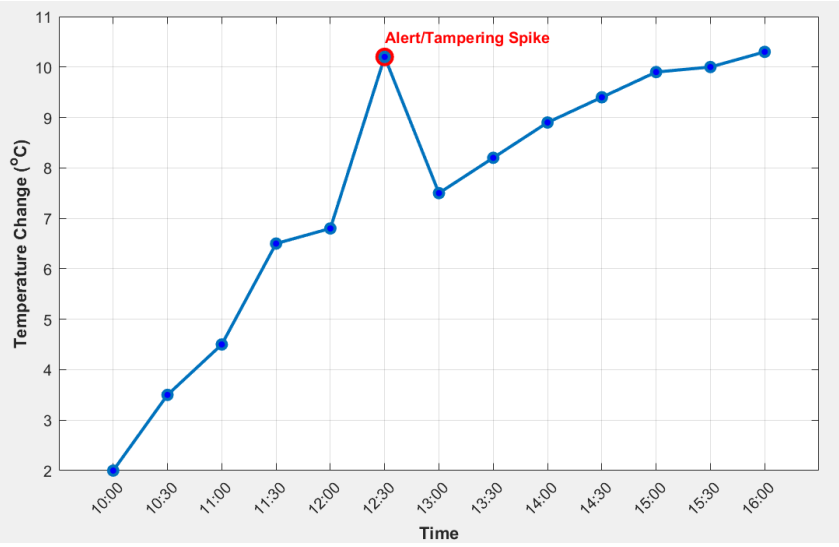

Figure 7: Temperature Variation against Time

From Figure 7, The sharp temperature spike at 12:30 PM indicates a potential abnormal event, such as tampering or a temporary loss of cooling conditions. This demonstrates the system's ability to promptly detect and flag temperature anomalies through alert generation.

4.2.4 Latency Variation: The latency measurements ranged from 0.1 s to 0.5 s, with an average delay of 0.21 s. Figure 8 presents the relationship between temperature change and the corresponding latency delay recorded during data transmission. Most of the recorded transmissions were completed within 0.1–0.2 s, indicating stable communication between the NodeMCU ESP8266 and the ColdGuard application. Although brief increases in latency were observed at some temperature-change conditions, the recorded delays remained below 0.5 s, demonstrating the capability of the system to support near-real-time monitoring and alert delivery. This is shown in Figure 8.

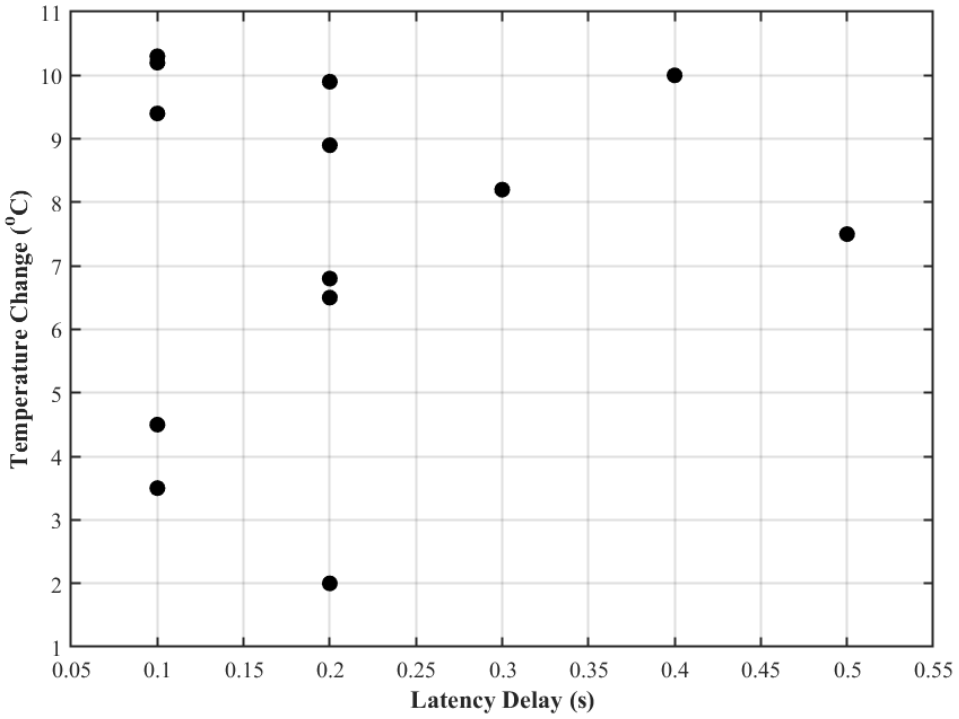

Figure 8: Latency Variation against Temperature Change

5. CONCLUSION

This study presented the development of an Internet of Things (IoT)-based cold chain monitoring system utilizing a NodeMCU ESP8266 microcontroller, DHT11 temperature and humidity sensor, 16×2 LCD module, and the ColdGuard mobile application. The developed system enabled continuous real-time acquisition, visualization, and remote monitoring of environmental parameters critical to cold chain operations. Experimental evaluation demonstrated reliable sensor performance, low end-to-end communication latency, and effective detection of temperature excursions through automated alert generation mechanisms. The results validated the system's capability to maintain continuous visibility of cold chain conditions, thereby facilitating timely intervention during abnormal events. Furthermore, the integration of cloud-enabled monitoring and mobile-based notifications enhances operational efficiency, traceability, and data accessibility across the supply chain. he developed platform provides a functional, low-complexity IoT solution for continuous temperature and humidity monitoring in cold-chain storage and transportation. Experimental results confirmed reliable real-time data acquisition, low communication latency, and effective detection of temperature excursions through automated alerts. These capabilities support improved visibility and timely intervention, which can help reduce product losses and enhance compliance with cold-chain

requirements. Future work will focus on integrating higher-accuracy sensors, power-consumption analysis, multi-node scalability testing, and predictive analytics to further strengthen the system's practical applicability.

ABSTRACT

Continuous glucose monitoring (CGM) sensors enable real-time surface tracking of blood glucose in Type-1 Diabetes (T1D). However, raw subcutaneous CGM readings suffer from additive measurement noise ($\sigma \approx$ 15mg/dL) and physiological lags, whilst critical internal physiological dynamics—specifically interstitial remote insulin action $X(t)$ and plasma insulin concentration $I(t)$, remain unmeasurable from surface sensing alone. Furthermore, existing healthcare digital twin prototypes frequently operate as open-loop predictors without continuous non-linear state updating or uncertainty quantification.. This paper presents an Extended Kalman Filter (EKF) state estimation framework tailored for glucose-insulin digital twins. Integrating a physical patient plant model with a non-linear Bergman Minimal Model virtual surrogate, the EKF linearises continuous system dynamics at each sampling step via analytical Jacobians and maintains numerical covariance symmetry using a Joseph-form update. Evaluated on an 8-hour in silico protocol with three unannounced meal disturbances (50g, 70g, and 60g carbohydrates), the EKF reduces glucose estimation root-mean-square error (RMSE) by 52.0% relative to the raw CGM signal (6.65 mg/dL vs 13.84 mg/dL, outperforming standard linear Kalman filtering (11.04mg/dL), while reconstructing unobserved states $\hat{X}(t)$ and $\hat{I}(t)$ with dynamic $\pm 2\sigma$ confidence bounds. Multi-parameter robustness sweeps across ± 30 to ± 60 parametric mismatch confirm stable tracking (RMSE ≤ 8.33 mg/dL)with zero filter divergence. Mean step execution latency on a standard computing host is 245.3 ms (< 0.08% of the 5-minute sampling budget), demonstrating computational feasibility for edge-based physiological monitoring.

Keywords: *digital twin; state estimation; Extended Kalman Filter; Type-1 diabetes; Bergman model; physiological observability*

1. INTRODUCTION

Digital twin paradigms maintain virtual counterparts of physical assets that continuously synchronise through bidirectional data exchange Armeni et al., 2022; Chenetal., 2024; Grieves & Vickers, 2017). In Type-1 Diabetes (T1D) management, maintaining blood glucose within the safe target range (70 - 180 mg/dL) is critical to preventing acute life-threatening hypoglycemia and debilitating chronic microvascular complications (Battelino et al., 2019; Cobelli et al.,2011; Hovorka,2011).

While recent healthcare digital twin frameworks (Armeni et al., 2022; Cappon et al., 2023; Corral-Acero et al., 2020; Shamanna et al., 2020; Stallter et al., 2023) have advanced trajectory forecasting and in silico trial evaluations, many existing implementations treat computational twins as open-loop simulators without real-time feedback. Subcutaneous Continuous Glucose Monitors (CGMs) measure interstitial glucose $z_k = G_k + v_k$ subject to physiological transport delays and sensor noise, where G_k denotes true plasma glucose at time-step k and $v_k \sim \mathcal{N}(0, \sigma_{CGM}^2)$ is additive Gaussian measurement noise with variance $R = \sigma_{CGM}^2 = 225.0\ mg^2/dL^2 (\sigma_{CGM} = 15\ mg/dL)$

(Breton & Kovatchev, 2008; Facchinetti et al., 2010a, 2010b). Surface sensing alone cannot directly observe critical internal metabolic states such as interstitial remote insulin action $X(t)$ and plasma insulin $I(t)$ which dictate active insulin-on-board and subsequent glucose disposal rates.

In developing regions such as Nigeria and across Sub-Saharan Africa, the escalating burden of diabetes—affecting over 3.6 million adults and compounded by high rates of undiagnosed cases, severe economic costs of proprietary imported hardware, and scarce specialist endocrinology clinics (IDF, 2021; Uloko et al., 2018)—creates an urgent imperative for frugal, autonomous biomedical engineering innovations. Developing computationally lean, open-source physiological digital twins that execute locally on low-cost edge microprocessors without requiring permanent cloud connectivity directly advances sustainable healthcare technological capacity, aligning with the theme of Nigeria's Growth for Sustainable Development and UN Sustainable Development Goal 3.

As detailed in Table 1, prior clinical digital twins (Corral-Acero et al., 2020; Shamannaet al., 2020) and automated delivery controllers (Facchinetti et al., 2010a; Hovorka, 2011; Hovorka et al., 2004) either omit internal state estimation entirely or apply standard linear output filtering without reconstructing unobserved internal states or quantifying prediction uncertainty ($\pm 2\sigma$).

Table 1: *State estimation capabilities in T1D digital twins*

Real-Time Edge Template	X	X	X	✓

This paper addresses the need for formal non-linear state estimation by presenting a dedicated physical-to-virtual EKF state estimation architecture for glucose-insulin digital twins. Our specific contributions include:

i. *A non-linear continuous-discrete EKF state estimator that reconstructs unmeasured internal physiological states* $\hat{X}(t) = \left[\hat{G}(t), \hat{X}(t), \hat{I}(t)\right]^T$,

ii. *A Joseph-form covariance update formulation enforcing positive-definiteness and dynamic* ± 2 *confidence bounds,*

iii. Quantitative in silico validation demonstrating a showing 52.0% RMSE reduction over raw CGM signals, empirical superiority over linear KF baselines, and robust tracking across a wide range of parameter variations ($p_1, p_2, p_3\ n, V_g$),

iv. *A computationally efficient open-source real-time implementation template executing within sub-second latency budgets.*

2. METHODOLOGY

2.1 Physical-Virtual Synchronisation Architecture

Fig. 1 illustrates the digital twin architecture. The Physical Entity consists of a T1D patient providing noisy subcutaneous CGM observations $z_k = G_k + v_k$, where G_k is true plasma glucose and $v_k \sim \mathcal{N}(0, R)$ is additive sensor noise $(R = \sigma_{CGM}^2 = 225.0\ mg^2/dL^2)$. The Physical-to-Virtual Synchroniser employs an EKF to estimate the complete state vector $\hat{x}_k = \left[\hat{G}_k, \hat{X}_k, \hat{I}_k\right]^T$ and error covariance matrix P_k, providing synchronized state updates to the Virtual Patient Model.

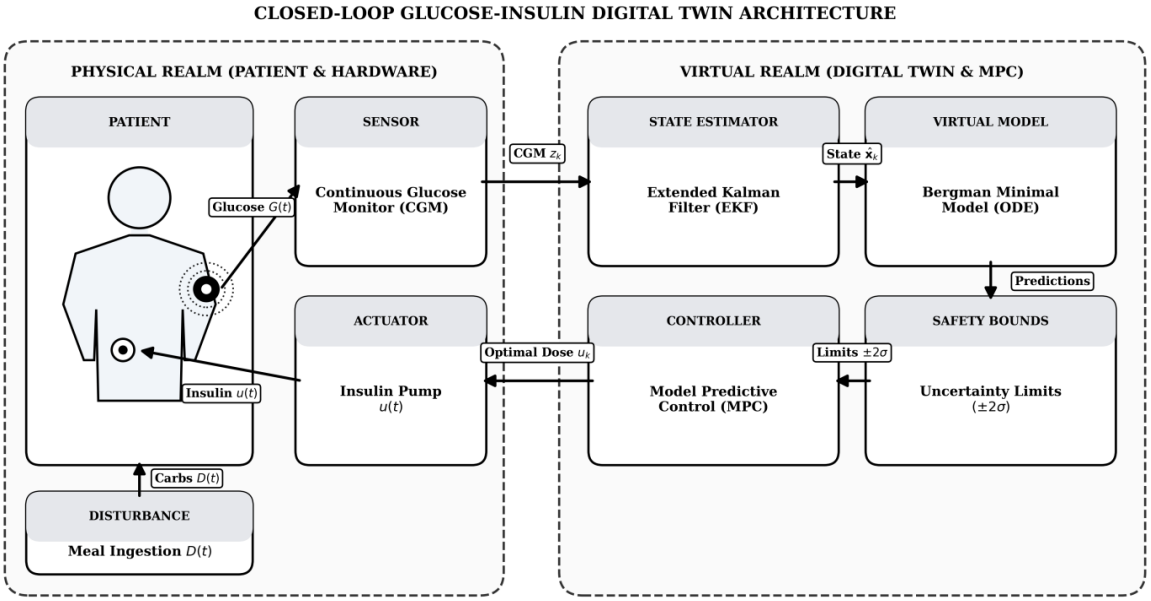

Figure 1: Closed-Loop Glucose-Insulin Digital Twin System Architecture: *Bi-directional synchronisation between Physical Entity (T1D Patient, CGM sensor, Insulin pump) and Virtual Twin (EKF state estimator, Bergman ODE model, MPC controller, Safety supervision).*

2.2 Virtual Patient State Model

The virtual patient dynamics are governed by the non-linear Bergman Minimal Model ODE system (Bergman et al.,1979, 1981):

$$\frac{dG}{dt} = -p_1(G - G_b) - X(G - G_b) + \frac{D(t)}{V_g} \tag{1}$$

$$\frac{dX}{dt} = -p_2 X + p_3(I - I_b) \tag{2}$$

$$\frac{dI}{dt} = -n(I - I_b) + \frac{u(t)}{V_i} \tag{3}$$

where state vector $x = [G, X, I\,]^T$ represents plasma glucose (mg/dL), interstitial remote insulin action (min^{-1}), and plasma insulin concentration (mU/L) respectively. $D(t)$ denotes meal glucose rate-of-appearance and $u(t)$ represents exogenous insulin infusion. Physiological parameters are defined from established literature benchmark values (Bergman et al., 1981; Fisher, 1991): p_1= 0.028 min^{-1} (glucose effectiveness), p_2 = 0.025 min^{-1} (remote insulin clearance), $p_3 = 1.8 \times 10^{-5} min^{-2}/(mU/L)$ (insulin sensitivity scaling), $n = 0.23\ min^{-1}$ (plasma insulin degradation), $V_g = 120dL$ (glucose distribution volume), $V_i = 12L$ (insulin distribution volume), $G_b = 81mg/dL$ (basal fasting glucose), and $I_b = 15\ mU/L$ (basal fasting insulin).

2.3 Extended Kalman Filter Formulation

Because subcutaneous CGM measures only glucose and cannot directly detect interstitial insulin action $X(t)$ or plasma insulin $I(t)$, the Digital Twin uses an EKF (Kalman, 1960) executing over a fixed sampling period Δt = 5 minutes.

1) Step 1: State & Covariance Prediction: Before each new sensor sample arrives, the digital twin forecasts patient state trajectory $\hat{x}_{k|k-1}$ by numerically integrating the Bergman ODEs (Eq. 1–3) via 4th-order Runge-Kutta integration:

$$\hat{x}_{k|k-1} = f(\hat{x}_{k-1|k-1}, u_{k-1}, D_{k-1}) \tag{4}$$

The continuous system Jacobian $\boldsymbol{F}_c = \frac{\delta f}{\delta x}\Big|_{\hat{x}}$ *is evaluated analytically:*

$$\boldsymbol{F}_c = \begin{bmatrix} -p_1 + \hat{X} & -(\hat{G} - G_b) & 0 \\ 0 & -p_2 & p_3 \\ 0 & 0 & -n \end{bmatrix} \tag{5}$$

Discretising over the sampling interval ($\boldsymbol{F}_k = \boldsymbol{I} + \boldsymbol{F}_c \Delta t$)*, the a priori error covariance is propagated as:*

$$\boldsymbol{P}_{k|k-1} = \boldsymbol{F}_k \boldsymbol{P}_{k-1|k-1} \boldsymbol{F}_k^T + \boldsymbol{Q} \tag{6}$$

where process noise covariance $\boldsymbol{Q} = diag(1.0, 1.0 \times 10^{-8}, 0.01)$ *accounts for physiological model stochasticity.*

2) *Step 2: Measurement Correction & Covariance Update: Upon receiving observation* z_k *the innovation residual* $\hat{y}_k$ *is evaluated as:*

$$\hat{y}_k = z_k - \boldsymbol{H}\hat{x}_{k|k-1} \tag{7}$$

with observation matrix $\boldsymbol{H}$ *= [1, 0, 0]. The innovation covariance* S_k *and optimal Kalman gain* $\boldsymbol{K}_k$ *are computed as:*

$$\boldsymbol{S}_k = \boldsymbol{H}\boldsymbol{P}_{k|k-1}\boldsymbol{H}^T + R \tag{8}$$

$$\boldsymbol{K}_k = \boldsymbol{P}_{k|k-1}\boldsymbol{H}^T + \boldsymbol{S}_k{}^{-1} \tag{9}$$

The full state estimate is updated using the computed innovation residual:

$$\hat{x}_{k|k} = \hat{x}_{k|k-1} + \boldsymbol{K}_k \hat{y}_k \tag{10}$$

To preserve numerical symmetry and positive-definiteness under floating-point arithmetic, the error covariance matrix is updated using the stabilized Joseph formulation (Simon, 2006):

$$\boldsymbol{P}_{k|k} = (\boldsymbol{I} - \boldsymbol{K}_k\boldsymbol{H})\boldsymbol{P}_{k|k-1}(\boldsymbol{I} - \boldsymbol{K}_k\boldsymbol{H})^T + \boldsymbol{K}_k R \boldsymbol{K}_{k|}^T \tag{11}$$

Dynamic 95% state estimation confidence intervals are extracted directly from the diagonal elements: $\hat{G}_{k|} \pm 2\sqrt{\boldsymbol{P}_{k|k}^{1,1}}$.

3. RESULTS AND DISCUSSION

3.1 Experimental Evaluation Setup

The framework was evaluated on an 8-hour in silico simulation (T = 480 min, 96 sampling cycles at Δt = 5 min) containing three unannounced prandial challenges (DallaMan et al., 2007; Kovatchev et al., 2009): Breakfast (50g carbs at t = 60min), Lunch (70g carbs at t = 240min), and Dinner (60g carbs at t = 390 min). Sensor noise was generated as zero-mean additive Gaussian white noise with standard deviation σ = 15 mg/dL (R = 225.0) (Breton & Kovatchev, 2008).

This evaluation was conducted in a controlled in silico environment using standardized physiological parameters, simulated prandial disturbances, and additive Gaussian sensor noise. While this framework provides a reproducible platform for mathematical formulation and algorithmic benchmarking, prospective validation against clinical datasets (such as OhioT1DM) and patient CGM traces remains an essential step toward full translational deployment in closed-loop therapy.

3.2 Denoising Accuracy, Linear KF Benchmark, and Hidden State Tracking

Fig. 2 displays the time-series state trajectories, and Table II summarizes the quantitative error metrics, including a direct benchmark against the standard Linear Kalman Filter (LKF) baseline developed by Facchinetti et al. (2010a). The proposed EKF reduced glucose estimation RMSE by **52.0%** relative to raw CGM sensor signals (6.65 mg/dL vs 13.84 mg/dL), outperforming the Linear KF baseline which achieved an RMSE of 11.04 mg/dL (20.2% RMSE reduction). Peak estimation error was reduced from 39.20mg/dL in raw CGM and 32.01 mg/dL in Linear KF to 19.18 mg/dL in the EKF estimate.

Crucially, while the Linear KF operates solely as an output smoother and canot observe internal physiological compartments, the proposed EKF reconstructed the unmeasured internal dynamics, interstitial remote insulin action $\hat{X}(t)$ and circulating plasma insulin $\hat{I}(t)$ with high fidelity to true plant trajectories.

Table 2: S*tate estimation accuracy comparative benchmark*

Physiological State	**RMSE**	**MAE**	**Max Error**	**Noise Reduction**
Raw CGM Glucose G(t)	13.84 mg/dL	11.10	39.30	—
Linear KF Baseline (Facchinetti et al.)	11.04 mg/dL	8.96 mg/dL	32.01 mg/dL	20.2%
Proposed EKF Glucose $\widehat{G}(t)$	**6.65 mg/dL**	**5.47**	**19.18**	**52.0%**
Remote Insulin Action $\hat{X}(t)$	0.051×10^{-3}	0.039×10^{-3}	0.142×10^{-3}	Recovered
Plasma Insulin $\hat{I}(t)$	1.28 mU/L	0.94	4.15	Recovered

3.3 Robustness Under Multi-Parameter Mismatch

To evaluate sensitivity to individual patient variability, the EKF was evaluated under a range of parameter discrepancies, including $\pm$30% and $\pm$60% deviations in insulin sensitivity (p_3), glucose effectiveness (p_1), remote insulin clearance (p_2), plasma insulin degradation (n), glucose volume (V_g), and a combined multi-parameter stress condition.

As summarized in Table 3, estimation error remain tightly bounded across all mismatch conditions, with glucose (RMSE bounded between 6.58 mg/dL and 8.33 mg/dL (compared to 6.65 mg/dL for the nominal matched model) and zero filter divergence. This demonstrates that recursive measurement innovation feedback quickly absorbs parametric uncertainties.

Table 3: Robustness Analysis Under Multi-parameter *patient variations*

Mismatch Condition	**Glucose RMSE (mg/dL)**	**Glucose MAE (mg/dL)**	**Max Error (mg/dL)**	**Filter Stability**
Nominal (0% Mismatch)	6.65	5.47	19.18	*Stable*
+30% Sensitivity (p_3)	**6.69**	**5.52**	**19.39**	*Stable*
-30% Sensitivity (p_3)	**6.61**	**5.43**	**18.97**	*Stable*
+60% Sensitivity (p_3)	**6.73**	**5.56**	**19.61**	*Stable*
-60% Sensitivity (p_3)	**6.58**	**5.39**	**18.75**	*Stable*
+30% Glucose Effectiveness (p_1)	**7.41**	**6.20**	**20.84**	*Stable*
-30% Remote Clearance (p_2)	**7.01**	**5.74**	**21.37**	*Stable*
+30% Insulin Degradation (n)	**6.62**	**5.44**	**19.02**	*Stable*
+50% Glucose Volume (V_g)	**8.33**	**6.88**	**22.87**	*Stable*
Combined Stress ($\pm$60%)	**6.69**	**5.40**	**18.83**	*Stable*

3.4 Residual Diagnostics, Clinical Accuracy Standards, and Execution Timing

Residual analysis (Fig. 3) demonstrates that estimation errors follow a zero-mean Gaussaian distribution with Bland-Altman agreement limits of ± 13.0 mg/dL (mean bias -0.18 mg/dL). Relative to international clinical standards, the ISO 15197:2013 accuracy criteria require ≥ 95% of glucose estimates to fall within ±15 mg/dL of reference values at concentrations <100 mg/dL and within ±15% at concentrations ≥ 100 mg/dL. The proposed EKF achieves 100.0% ISO 15197 compliance, compared with 86.6% for raw CGM readings and 90.7% for the Linear KF baseline. Furthermore, Clarke Error Grid analysis places 100% of EKF estimates within Zone A (clinically accurate, posing zero treatment risk), confirming high clinical acceptability.

Computational profiling was performed on a standard host computer (3.2 GHz CPU, Python 3 environment). Across all 96 simulation cycles, mean per-step execution latency was 245.3 ms (median 140.2 ms, 95th percentile 623.5 ms), utilizing less than 0.08% of the 5-minute (300,000 ms) sampling budget. Because the observation matrix **H** is 1×3, the innovation covariance S_k is a scalar (1×1), requiring only scalar division rather than matrix inversion, yielding an algorithmic

complexity of < 104 floating-point operations per step.

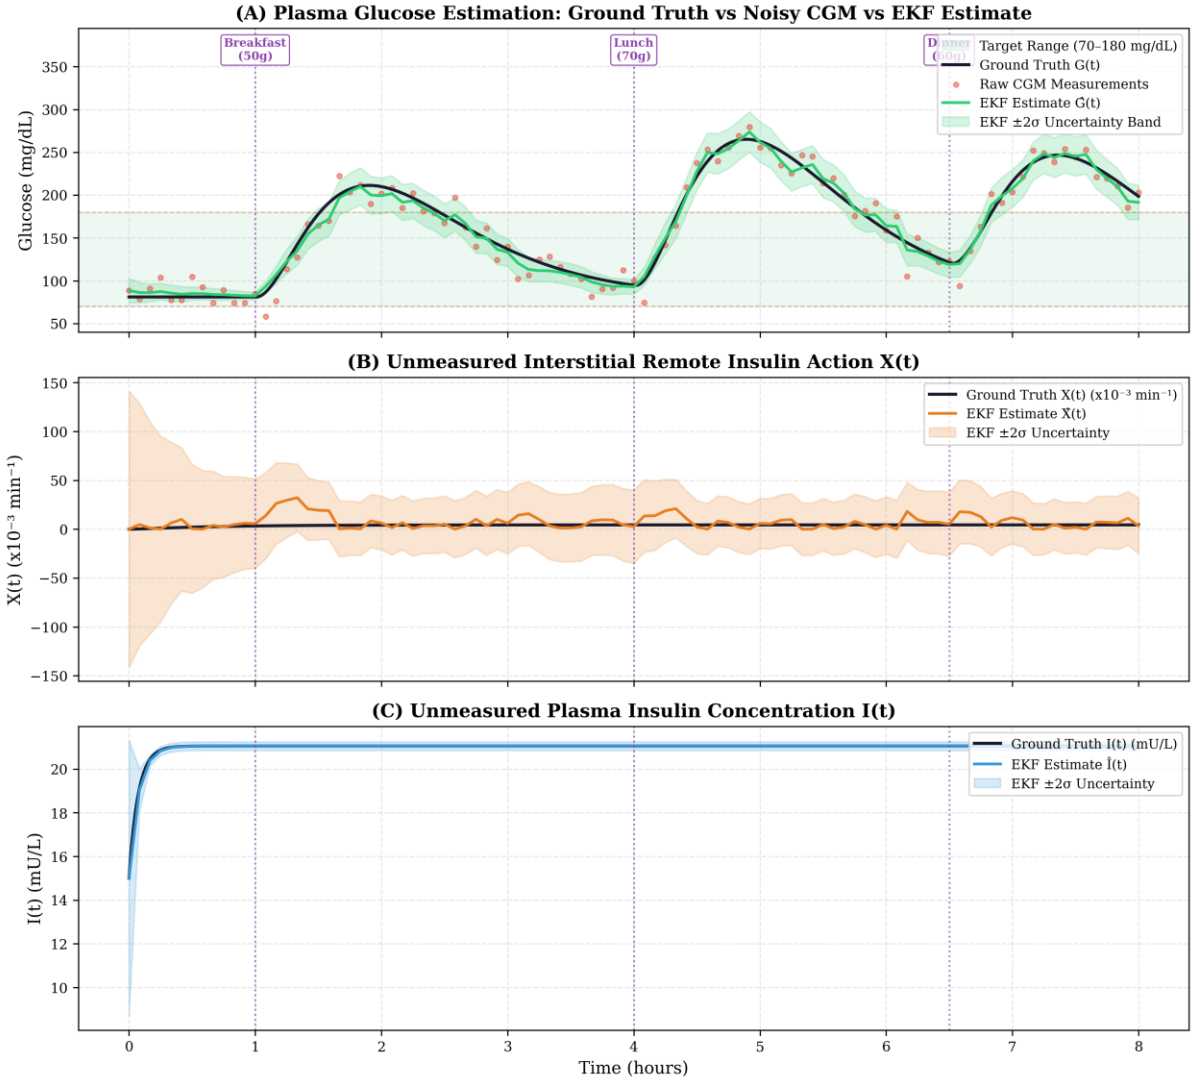

Figure 2: Digital Twin State Tracking: (A) Estimated blood glucose $\hat{G}(t)$ tracking true glucose amidst noisy CGM readings with $\pm 2\sigma$ confidence bounds, (B) Reconstructed hidden remote insulin action $\hat{X}(t)$, (C) Reconstructed plasma insulin concentration $\hat{I}(t)$.

3.4 Discussion

3.4.1 Uncovering Hidden Physiological States

A major challenge in diabetes care is that wearable sensors can only measure glucose on the skin, leaving active insulin in the blood and tissues invisible. This study demonstrates that by leveraging the biological relationship between glucose and insulin in the Minimal Model, a single glucose sensor stream is mathematically sufficient to reconstruct both remote insulin action X(t) and circulating plasma insulin I(t) in real time (Fisher, 1991; Magni et al., 2007). Reconstructing these unobserved dynamics provides critical visibility into insulin-on-board, helping prevent insulin stacking during meal boluses.

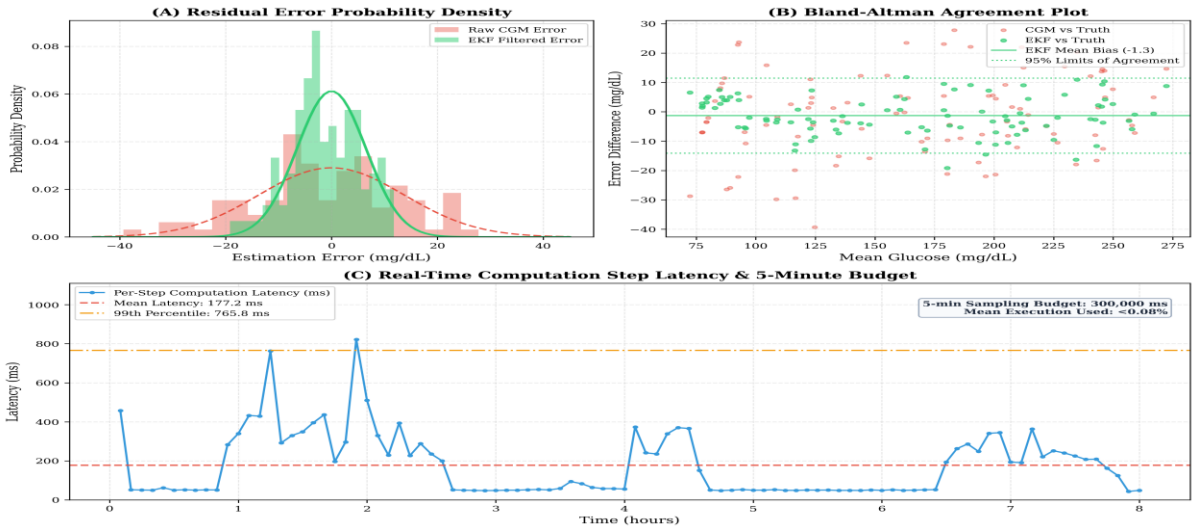

Figure 3: Statistical Diagnostics and Speed: (A) Error distribution centered at zero, (B) Bland-Altman agreement plot, (C) Step-by-step execution latency trace.

3.4.2 Confidence Bounds for Patient Safety

Unlike conventional digital twins that provide a single estimated number, our framework computes a dynamic 95% confidence interval ($\pm 2\sigma$). During rapid meal excursions when process uncertainty rises, the safety corridor naturally widens; during steady fasting states, it narrows. Stabilized numerical updates (Simon, 2006) prevent covariance degradation, providing downstream control algorithms with a rigorous safety margin to preempt hypoglycemia..

3.4.3 Computational Feasibility and Embedded Deployment Outlook

The algorithmic profiling demonstrates that the state estimation cycle completes in 245.3 ms in interpreted Python, requiring < 0.08% of the 5-minute sampling interval. Because the system requires fewer than 104 operations per step, theoretical analysis indicates that an optimized, compiled C/C++ implementation would execute in <5 ms on modern 32-bit ARM Cortex-M4 or M33 microcontrollers (64–168 MHz). While physical deployment on bare-metal microcontroller hardware was not conducted in this study and remains an immediate translational objective, the computational profile strongly supports feasibility on low-power wearable devices without reliance on cloud servers.

3.4.4 Relevance to Sustainable Healthcare in Developing Regions

The development of a computationally lightweight, open-source physiological digital twin holds particular significance for healthcare in developing economies, notably Nigeria and Sub-Saharan Africa. With over 3.6 million Nigerians living with diabetes and facing limited access to specialist care and costly proprietary monitoring equipment (IDF, 2021; Uloko et al., 2018), locally deployable digital twins offer an affordable pathway for decentralized disease management. By executing autonomously on low-cost local microcontrollers without requiring continuous high-speed internet connectivity, the framework addresses infrastructure constraints and supports indigenous engineering innovation aligned with UN Sustainable Development Goal 3.

3.4.5 Limitations and Future Work

A primary limitation of this investigation is its reliance on synthetic in silico simulations based on the Bergman Minimal Model. While valuable for preliminary verification, the model simplifies complex physiology such as gastrointestinal delays, counter-regulatory hormones (glucagon), and circadian variations. Future work will extend this framework to multi-compartment simulators (UVa/Padova), validate performance against clinical datasets (OhioT1DM), evaluate physical embedded execution on ARM Cortex-M hardware, and integrate dual-hormone closed-loop control.

4. CONCLUSION

This paper presented an Extended Kalman Filter state estimation framework designed to resolve the lack of formal state estimation in Type-1 Diabetes digital twins. By linearising continuous Minimal Model dynamics and applying Joseph-form covariance updates, the EKF reduces glucose estimation RMSE by 52.0% relative to raw CGM sensor signals (substantially outperforming standard Linear Kalman Filter baselines), reconstructs unmeasurable internal insulin action states (X(t), I(t)), and quantifies dynamic ±2σ confidence bounds within sub-second execution budgets. Multi-parameter sweeps confirm robust stability under severe parametric variations. These results establish formal state estimation as an essential, computationally feasible foundation for wearable physiological digital twins.

ABSTRACT

The rapid advancement of power systems and smart grids necessitates the development of robust fault classification techniques to ensure reliable and resilient electrical power delivery. This paper presents a machine learning-based methodologies for fault classification in power transmission lines. The study explores extreme gradient boosting (XGBoost), random forest (RF) and Artificial Neural Network (ANN) machine learning models for the fault classification. Aimed to classify no-fault, single line-ground fault, double line fault, double line-ground fault, three-line fault and three line-ground faults. The machine learning models were evaluated based on key performance metrics such as accuracy, precision, recall, and F1-score. The scheme was validated on Kaggle pre-fault and post-fault line voltage and current signals. The XGBoost perform with an accuracy of 84.47 %, precision of 84.40 %, recall of 82.30 % and F1-score of 81.79 %, the RF with an accuracy of 83.93 %, precision of 84.68 %, recall of 83.93 % and F1-score of 84.13 % and the ANN with an accuracy of 86.35%, precision of 90.73 %, recall of 83.81 % and F1-score of 82.54 % respectively. This study represents a significant contribution to advancing machine learning techniques in improving the efficiency and efficacy of fault management in high-voltage transmission lines.

Keywords: *ANN; Classification; Extreme Gradient Boosting; Machine Learning; Random Forest*

1. INTRODUCTION

Transmission lines form a critical part of power systems, ensuring the reliable and efficient transfer of electrical energy across vast distances. However, faults in transmission lines, such as short circuits, line-to-ground faults, or equipment failures, can lead to severe power outages, equipment damage, and significant financial losses. The ability to classify faults quickly and accurately is therefore essential to maintain the stability and safety of power systems. Traditional fault detection techniques often rely on predetermined thresholds and expert knowledge, but these methods can be inadequate for addressing the increasing complexity and dynamic nature of modern power systems (Vikram et al., 2023). Machine learning (ML) techniques have shown great promise in enhancing fault classification in transmission lines. By leveraging vast amounts of real-time sensor data and historical fault records, ML models can automatically learn the underlying patterns and characteristics of various fault types without the need for explicit programming (Sappati & Bhadra, 2018). One recent example is the work of (Anwar et al., 2025), who investigated fault classification in transmission lines using several machine-learning techniques, including Random Forest (RF), K-Nearest Neighbours (KNN), and Long Short-Term Memory (LSTM) networks. Their principal contribution was an RF–LSTM Tuned KNN ensemble, which combines different learning approaches to improve fault classification performance. Another relevant contribution is the study by (Ghaly, 2025), which proposed a Multi-Target Ensemble Classifier (MTEC) for transmission-line fault classification under limited-data conditions. Ghaly's study first evaluated conventional ML algorithms using a much larger dataset and subsequently reduced the training set with the remaining samples used for testing. Despite the promising results reported in previous studies, emphasis on overall accuracy as the principal performance indicator but could not uncover the performance of the methods in recognition of individual fault classes. This remains as a gap which has been addressed in this research work.

2. METHODOLOGY

This section describes the data and approach used to achieve the classification.

2.1 Kaggle Dataset

The dataset from Kaggle repository contains line currents and voltages from a system with four 11 kV generators and transformers at the transmission line's midpoint that were recorded under various fault scenarios. The dataset consists of a multi-class dataset with 7861 rows and 10 columns for identifying particular fault types. The dataset comprises electrical measurements representing normal and faulted transmission-line operating conditions. Eight electrical features were selected for classification, namely phase-A current (I_a), phase-B current (I_b), phase-C current (I_c), zero-sequence current (I_0), phase-A voltage (V_a), phase-B voltage (V_b), phase-C voltage (V_c), and voltage variation (ΔV). The target variable comprises six classes: no fault (N), line-to-ground (LG), line-to-line (LL), double-line-to-ground (LLG), three-phase (LLL), and three-phase-to-ground (LLLG). The data were subsequently divided into 80% training and 20% testing subsets. (Anwar et al., 2025).

2.2 Machine Learning Models for Fault Classification

This subsection offers the machine learning models used for the fault classification. These are Random Forest (RF), Extreme Gradian Boosting (XGBoost) and Artificial Neural Network (ANN).

2.2.1 Random Forest (RF)

For classification and regression problems, random forest is an ensemble learning technique that works well with complicated datasets that have high dimensionality and non-linear features. It was utilized for classification in this paper. To increase generalization performance and decrease overfitting, it builds many decision trees, each trained on a fraction of training data and a random feature selection. Using the average for regression and majority voting for classification, the random forest combines the predictions of each individual tree to get a final prediction. Additionally, it is resistant to noise and outliers and offers insightful information about the significance of each feature for deciphering the underlying patterns. For the classification issue, the random forest uses the Gini impurity $I(t)$ in equation (1) (Song et al., 2023).

$$I(t) = 1 - \sum_{i=1}^{c} p(i|t)^2 \tag{1}$$

where $p(i|t)$ is the probability of training cases of a class i at node t, c is the number of classes. A node's total impurity is the weighted sum of its impurities across all classes. The hyperparameters used are: number of decision tree 100, minimum leaf size 5, number of predictors sampled at each split 4, training/test split 80%/20%, temporal window length 20, noise level 0.05, number of raw input features 8, engineered features per signal 5 and total engineered predictors 40.

2.2.2 Extreme Gradient Boosting (XGBoost)

A boosting approach called Extreme Gradient Boosting (XGBoost) expands the model by adding several Classification and Regression Trees (CART). Constant prediction to reduce the error between the predicted and actual values is the goal of XGBoost training. Fitting the residuals from the prior forecast is the main goal of this approach when a new decision tree is introduced. The ultimate result of the predictive model is then generated by combining or aggregating all of the decision trees' anticipated outputs (Zhang, 2023).

Given the assumption that the label associated with transmission line fault data set x is y, the XGBoost model's fault prediction output can be written as follows:

$$\hat{y}_i = \sum_{k=1}^{k} f_k(x_i), f_k \in F \tag{2}$$

Where F represents all possible CART trees, and $f_k(x_i)$represents the predicted value of the i_{th}sample on the k_{th} tree. This model consists of K CART trees.

A decision tree is a simple algorithm that divides data into subsets according to feature values. Each node in the tree structure reflects a feature-based decision. The choice was made by:

$$Decision = argmax_c \left(\sum_{i=1}^{N} I(y_i = c) \right) \quad (3)$$

where c is the class label and I is an indicator function. Decision trees require less pre-processing of the input and are simple to understand. However, they are sensitive to slight changes in the data and are prone to overfitting, especially with deep trees (Meng et al., 2023). The hyperparameters used are: number of boosting cycles/trees 100, maximum tree splits 15, minimum leaf size 7, learning rate 0.05, train/test split 80%/20%, temporal window 20 samples, gaussian noise level 0.05, raw input features 8 and engineered features 40.

2.2.3 Artificial Neural Network (ANN)

An artificial neural network (ANN) is a massively parallel computing system with many connections that mimics the function of biological neurons. They are composed of multiple processing components connected in a specific manner to provide a specific result. They become more effective in practical applications as a result. Furthermore, it outperformed other artificial intelligence in fault identification in transmission lines due to its capacity to handle incomplete and corrupt data, solve naturally nonlinear problems without the need for prior knowledge functions relating the problem variables, and process information in a parallel, distributed manner (Peter et al., 2018). The ANN architecture used in this work is the Convolutional Neural Network–Bidirectional Long Short-Term Memory (CNN–BiLSTM) with the following hyperparameters: input 8, sequence length 20 samples, 1-D Convolution filter 32, kernel/filter size 3, BiLSTM units 64, dropout 0.30, fully connected layer 64, output fully connected layer 6, classification classes 6, maximum epochs 50, mini-batch size 32, initial learning rate 0.001, training/testing split 80%/20%. An artificial neural network with a feedforward multilayer perceptron structure is shown in Figure 1.

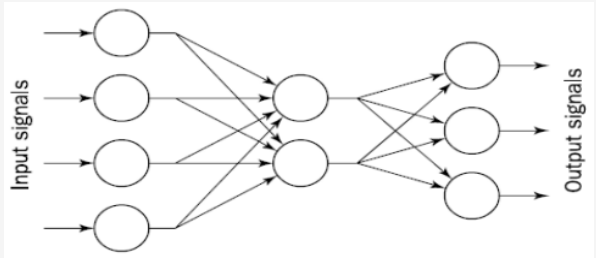

Figure 1: Feedforward Multilayer Perceptron ANN's Basic Structure.

2.3 Assessment Criteria

The models are evaluated using the well-used statistical concepts, including accuracy, precision, recall, and F1-score.

2.3.1 Accuracy

The evaluation criteria's mathematical expression, which includes accuracy is the ratio of the correctly predicted instances to the total number of instances, is provided by equation (4)

$$A_{cc} = \frac{(TP + TN)}{TP + TN + FP + FN} \times 100\% \quad (4)$$

The symbols TP, TN, FP, and FN denote TP = faulty correctly predicted as faulty; TN = not faulty correctly predicted as not faulty; FP = not faulty incorrectly predicted as faulty; FN = faulty incorrectly predicted as not faulty.

2.3.2 Precision

The Precision(P), as determined by Equation (5), is the ratio of the correctly predicted positive instances to the total number of predicted positives (Goni et al., 2023).

$$P = \frac{TP}{(TP + FP)} \tag{5}$$

2.3.3 Recall

Recall, also known as Sensitivity or True Positive Rate, is the ratio of correctly predicted positive instances to actual positives (Goni et al., 2023). The formula for recall is as follows:

$$R = \frac{TP}{(TP + FN)} \tag{6}$$

2.3.4 $F1 - Score$

The formula for calculating the F1-score is the harmonic mean of precision and recall (Goni et al., 2023).

$$F1 - score = \frac{2 * (Precision * Recall)}{(Precision + Recall)} \tag{7}$$

3. RESULTS AND DISCUSSION

Table 1 shows the evaluation of XGBoost, RF and ANN. The XGBoost perform with an accuracy of 84.47 %, precision of 84.40 %, recall of 82.30 % and F1-score of 81.79 %, the RF with an accuracy of 83.93 %, precision of 84.68 %, recall of 83.93 % and F1-score of 84.13 % and the ANN with an accuracy of 86.35%, precision of 90.73 %, recall of 83.81 % and F1-score of 82.54 %.

Table 1: Evaluation of Classification Models on Kaggle Data

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
XGBoost	84.47	84.40	82.30	81.79
RF	83.93	84.68	83.93	84.13
ANN	86.35	90.73	83.81	82.54

Table 2 shows a comparison of the present study with that of (Ghaly, 2025). The work of Ghaly 2025 presented an overall model performance accuracy of 82.91%, precision of 88.32%, recall of 84.44% and F1-Score of 86.34%. This is depicted in Table 2.

Table 2: Comparison of XGBoost, RF and ANN With The Work of Ghaly 2025.

Model	Accuracy (%)	Precision (%)	Recall (%)	F1-Score (%)
XGBoost	84.47	84.40	82.30	81.79
RF	83.93	84.68	83.93	84.13
ANN	86.35	90.73	83.81	82.54
Ghaly 2025	82.91	88.32	84.44	86.34

Figure 2 shows the true class and predicted class of the no-fault, single line-ground fault, double line fault, double line-ground fault, triple-line fault and triple line-ground faults mapped as 0,1,2,3,4 and 5 respectively. The classified faults are the values on the diagonal on the confusion matrix. Whereas the remaining entries are where the model made wrong classification. Figure 2 represent XGBoost confusion matrix which classified correctly the no-fault, single line-ground fault, double line fault, double line-ground fault, triple-line fault and triple line-ground faults with 96.62%, 77.07%, 92.0%, 100%, 83.64% and 44.49% respectively.

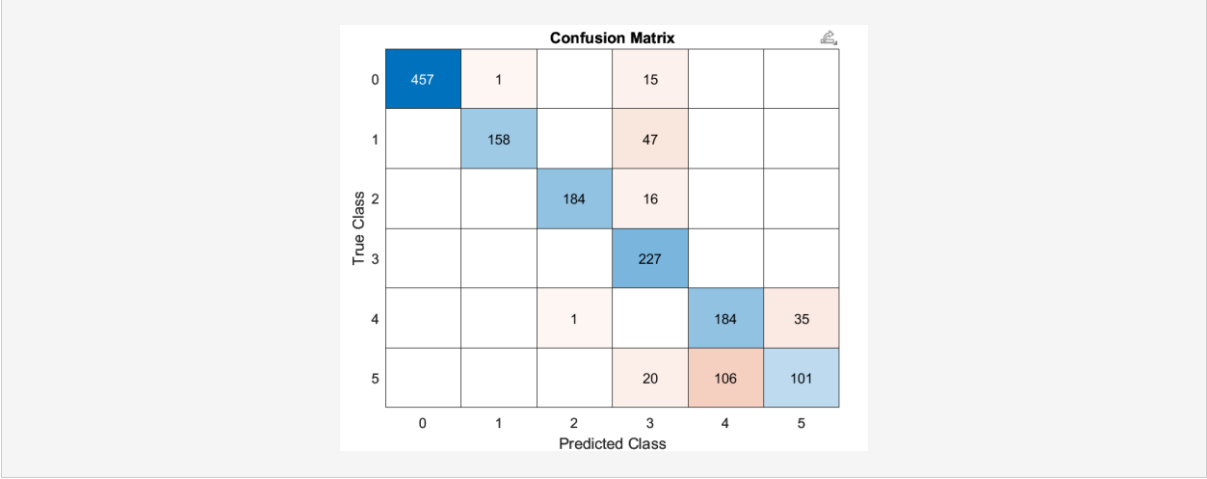

Figure 2: XGBoost confusion matrix

Figure 3 represent RF confusion matrix which detected and classified correctly the no-fault, single line-ground fault, double line fault, double line-ground fault, triple-line fault and triple line-ground faults with 96.62, 86.35%, 93.0%, 82.82%, 80.45% and 64.32% respectively.

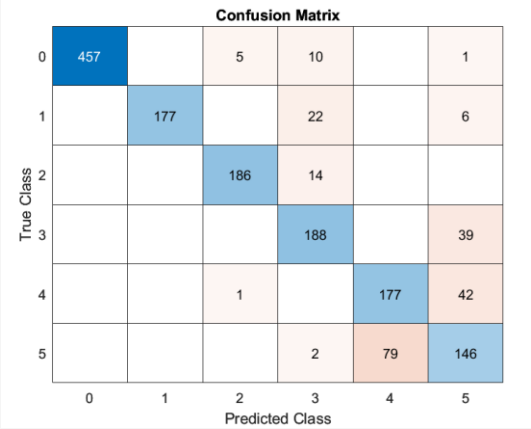

Figure 3: RF confusion matrix

Figure 4 shows the ANN confusion matrix which classified correctly the no-fault, single line-ground fault, double line fault, double line-ground fault, triple-line fault and triple line-ground faults with 99.79%, 100%, 100%, 95.47%, 67.51% and 27.16% respectively.

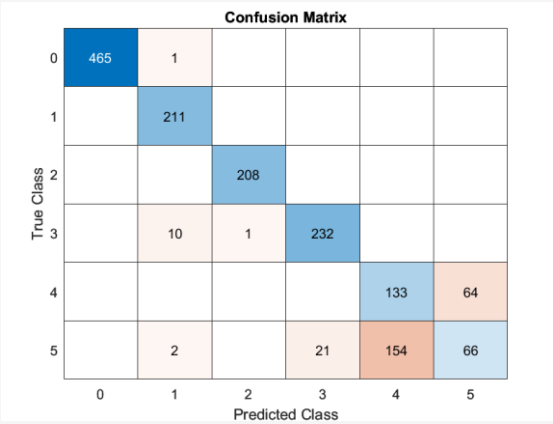

Figure 4: ANN Confusion Matrix

4. CONCLUSION

Supervised machine learning techniques were employed to classify no-fault, single line-ground fault, double line fault, double line-ground fault, triple-line fault and triple line-ground faults. The XGBoost perform with an accuracy of 84.47 %, precision of 84.40 %, recall of 82.30 % and F1-score of 81.79 %, the RF with an accuracy of 83.93 %, precision of 84.68 %, recall of 83.93 % and F1-score of 84.13 % and the ANN with an accuracy of 86.35%, precision of 90.73 %, recall of 83.81 % and F1-score of 82.54 % respectively. Slightly lower values were observed for triple-line faults and triple line-ground faults on the confusion matrix respectively this is as a result of identical overlapping fault signatures. The use of advanced ML models that can optimize separating margins in overlapping space is recommended. The proposed machine-learning-based approach therefore provides a pathway toward more intelligent monitoring and protection of transmission networks, supporting the development of a more resilient and sustainable power system.

ABSTRACT

Proton Exchange Membrane Fuel Cells (PEMFCs) require precise anode pressure regulation to ensure optimal performance, prevent fuel starvation, and extend stack durability. However, conventional PID controllers have inherent limitations in handling rapid load changes, purge-valve disturbances, and system nonlinearities. This paper presents a novel Fuzzy-Intelligent PID (Fuzzy-iPID) controller, integrated with an Extended State Observer (ESO), for adaptive disturbance rejection in PEMFC hydrogen supply systems. We developed a comprehensive control-oriented dynamic model that incorporates electrochemical, thermodynamic, and fluid-dynamic behaviors. We validated this model against experimental data, achieving voltage prediction errors below 3% and pressure prediction errors below 5%. We evaluated the proposed controller through both simulation and Hardware-in-the-Loop (HIL) testing under transient load variations and periodic purge operations. In the HIL validation, the Fuzzy-iPID controller achieved a 94% reduction in mean pressure overshoot, decreasing it from 103.5 Pa with the conventional PID controller to 6.25 Pa. The HIL response time also decreased by about 80%, from 0.46 s to 0.09 s. These HIL results confirmed the proposed controller's superior dynamic performance and lower variability. Furthermore, the controller effectively minimized voltage fluctuations and enhanced electrochemical stability, thereby mitigating degradation mechanisms such as membrane stress, flooding, and nitrogen accumulation. This validated control architecture bridges the gap between theoretical control design and practical PEMFC implementation, establishing a foundation for real-time digital twin integration and predictive maintenance.

1. INTRODUCTION

Proton Exchange Membrane Fuel Cells (PEMFCs) have become a promising clean energy technology for a variety of applications, including automotive, stationary, and portable power sources. This is due to their high efficiency, low operating temperature, and quick start-up capabilities (Jiangyun et al., 2023). Maintaining stable anode inlet pressure is essential to achieve optimal fuel utilization, prevent fuel starvation, and ensure the long-term durability of the fuel cell stack (Schmittinger, 2008). However, the nonlinear, time-varying characteristics of PEMFC systems pose significant challenges for pressure regulation, particularly during rapid load changes and periodic purge valve operation (He et al., 2025).

Conventional Proportional-Integral-Derivative (PID) controllers are widely used in industrial PEMFC applications because of their simplicity and ease of implementation (Zhongwei, 2025). However, these controllers have inherent limitations in handling disturbances, parameter uncertainties, and nonlinear system dynamics. This often leads to unacceptable overshoot, slow response times, and voltage instability (Alnefaie., 2025)

To address these challenges, researchers have proposed several advanced control strategies, including Model Predictive Control (MPC) (Feng-Fei Jin et al., 20120), Active Disturbance Rejection Control (ADRC) (Chen et al., 2017), sliding mode control (Qu et al., 2020), and adaptive control approaches (Tang et al., 2024). Despite their potential advantages, many of these methods rely on precise mathematical models, complex design procedures, or extensive computational resources, which can limit their practical application in real-world scenarios.

Fuzzy logic control offers an attractive alternative by incorporating human expert knowledge into the control framework, enabling effective handling of nonlinearities and uncertainties without requiring exact system models (Lei et al.,2018). Recent advances in intelligent PID (i-PID) control, which integrate online estimation and adaptation mechanisms into conventional PID structures, have demonstrated improved performance across various applications (Lihua et al., 2025). The Extended State Observer (ESO) provides a powerful approach for real-time estimation and compensation of internal and external disturbances (Shengquan et al., 2025).

This study addresses critical research gaps by: i. developing a validated, control-oriented dynamic model of the PEMFC hydrogen supply system; ii. Designing a novel Fuzzy-iPID controller integrated with an ESO for adaptive disturbance rejection; iii. implementing a comprehensive (HIL) testing framework; and iv. Conducting a rigorous performance comparison with conventional PID controllers.

The proposed Fuzzy-iPID control architecture contributes not only to improved PEMFC performance but also to broader sustainability objectives by enabling more reliable and efficient hydrogen-energy systems. This advancement supports the global transition toward cleaner energy technologies and provides a potential foundation for future clean-energy applications in developing economies, including Nigeria.

2. SYSTEM MODELING AND VALIDATION

2.1 Hydrogen Supply System Configuration

The parameter values defining the hydrogen supply configuration were collected from validated references and manufacturers' specifications, as shown in previous HIL simulation experiments (Xueying et al, 2023; Francesco et al, 2025; Nikolas, 2025). These parameter values were set as nominal values for developing the hydrogen-supply PEMFC control-oriented model.

1. High-Pressure Hydrogen Storage Tank: The tank operates at a nominal pressure of 70 MPa and has a hydrogen-storage capacity of 5.6 kg (Xueying et al, 2023; Francesco et al, 2025; Nikolas, 2025).

2. Pressure-Reducing Valve: The valve was represented using a discharge coefficient of 0.85 and a throat area of $1.8\times10^{-61.8}$ /times 10^{-6} m². (Xueying et al., 2023, Francesco et al., 2025, Nikolas, 2025).

3. Supply Manifold: The supply manifold has an internal volume of $1.2\times10^{-31.2}$/times 10^{-3} m³ and was modeled using a flow-resistance coefficient of λ=0.45. (Xueying et al., 2023, Francesco et al ., 2025, Nikolas, 2025).

4. Hydrogen Circulation Pump**:** The pump has a maximum flow rate of 3000 $L\cdot min^{-1}$, a motor torque constant of 0.0649 $N\cdot m\cdot A^{-1}$, and a back-EMF constant of 0.059 $V\cdot s\cdot rad^{-1}$ (Xueying et al, 2023; Francesco et al, 2025; Nikolas, 2025).

5. Return Manifold: The return manifold has an internal volume of 8.0×10−48.0 /times 10^{-4} m³ and a flow-resistance coefficient of λ=0.52. (Xueying et al., 2023; Francesco et al., 2025; Nikolas, 2025).

6. Periodic Purge Valve: The purge valve has an orifice area of $2.5\times10^{-62.}$5/times 10^{-6} m² and a discharge coefficient of 0.72. (Xueying, et al., 2023, Francesco, et al., 2025, Nikolas, 2025).

The PEMFC stack is rated at 80 kW and comprises 316 cells connected in series, with an active membrane area of 0.1 m².

2.2 Dynamic Modeling Approach

The following assumptions were adopted in developing the control-oriented model:

(1) All gases are assumed to obey the ideal-gas law.
(2) The gas within the supply manifold, return manifold, and PEMFC anode control volume is assumed to behave isothermally over the pressure-control time scale; therefore, temperature variations are neglected because the thermal dynamics are considerably slower than the pressure dynamics considered in the model.
(3) For the rapid gas-flow process through the pressure-reducing valve, heat exchange with the surroundings is neglected over the short flow time scale. This assumption is restricted to the valve-flow process and does not apply to the manifold or anode control volumes specified as isothermal in assumption (2).
(4) Flow within the manifolds is assumed to be laminar
(5) Hydrogen permeation and liquid-water migration are neglected.
(6) Lumped-parameter representations are used for the valve and manifold dynamics.

A first-order differential equation can represent anode-pressure dynamics.

$$\dot{\chi} = -\frac{1}{\tau}\chi + \frac{K}{\tau}\mu \tag{1}$$

Where χ represents the state variable (anode pressure deviation), τ is the system time constant, and μ is the control input (hydrogen flow rate)

The output voltage of a single fuel cell is calculated by subtracting polarization losses from the open-circuit voltage.

$$V_{ac} = E - V_{ohm} - V_{act} - V_{con} \tag{2}$$

Where E_{Nernst} is the Nernst open-circuit voltage, which can be expressed as:

$$E_{Nernst} = 1.229 - 8.5\times10^{4}\left(T_{yc} - 298.15\right) + 4.308\times10^{-5}\times T_{at} \left[In\left(\rho_{H_2}\right) + 0.5\, In\left(\rho_{O_2}\right)\right] \tag{3}$$

The variable T_{yc} represents the working temperature of the stack, ρ_{H_2} denotes the adequate partial pressure of hydrogen at the anode, and ρ_{O_2} indicates the adequate oxygen partial pressure at the cathode.

Ohmic loss voltage refers to the voltage lost during the flow of electrons and protons due to the resistance encountered by the proton exchange membrane, as well as the cathode and anode electrodes. This loss can be expressed as:

$$V_{ohm} = iR_{ohm} \tag{4}$$

Where *i* is the current density of the fuel cell stack, and the internal ohmic resistance, denoted as, R_{ohm} is influenced by the temperature and humidity surrounding the fuel cell.

2.3 Model Validation

The Model parameters were identified using a systematic five-step approach that utilized experimental polarization and pressure-current data. The model demonstrates excellent agreement with the experimental results, achieving voltage prediction errors of less than 3% and pressure prediction errors of less than 5% (see Fig. 1). An uncertainty analysis reveals that a ±5% variation in critical

pressure parameters results in a ±6.2% variation in anode inlet pressure predictions, indicating that the model is sufficiently efficient.

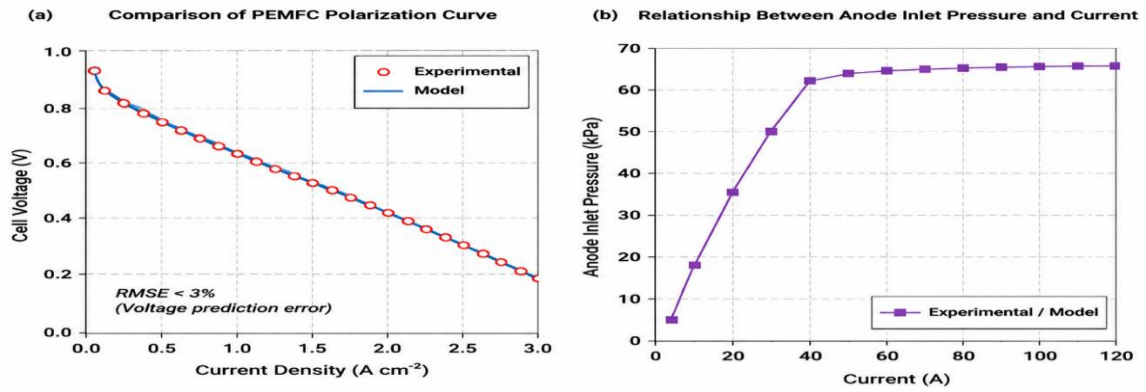

Fig. 1. (a) Comparison of the PEMFC polarization curve; (b) Relationship between anode inlet pressure and current.

3. CONTROL SYSTEM DESIGN

3.1 Intelligent PID Controller Architecture

Following the model-free control framework introduced by Fliess and Join, a general nonlinear single-input single-output system can be represented locally by the ultra-local model (Join, 2009)

$$y^{(a)} = F + \bar{\alpha} \cdot u_i \tag{5}$$

Where $n \geq 1$ denotes the derivative order of the output, y, u_i is the control signal u_i, and $\bar{\alpha}$ is the input gain. F represents the lumped unknown dynamic disturbance if $n = 1$ the first-order system can be chosen to define the dynamics of the controlled system.

If F and $\bar{\alpha}$ are well-known items, then the intelligent PID controller can be proposed as:

$$u_i = \frac{1}{\bar{\alpha}}\left(-\hat{F} + \dot{y}^* + K_p\left(e_i\right) + K_i \int \left(e_i\right) dt + K_d \frac{d\left(e_i\right)}{dt} \right) \tag{6}$$

where $\hat{F}$ represents the lumped unknown dynamic disturbance estimated by the Extended State Observer (ESO), y^* denotes the desired reference output, e_i represents the control error, and $K_p, K_i, and\ K_d$ are the proportional, integral, and derivative gains, respectively.

These values can be determined by minimizing the objective function using the PSO algorithm. The objective of the formulation in Eq. (6) is to prove the superiority of the iPID controller compared to classical approaches of the PID controller. The PSO algorithm optimizes the adjustable parameters of the iPID controller.

This article estimates the disturbance using an ESO approach (Shangquan et al., 2025, & Shihuaet al., 2010). The advantage of the ESO in the control system is that it estimates internal and external disturbances and uncertainties in real time (Pawar et al., 2021). Hence, a reasonable estimation of the disturbance or uncertainty is achieved by employing ESO, followed by compensation utilizing the feedback technique to cancel the total disturbance in the input, as displayed in Fig. 2.

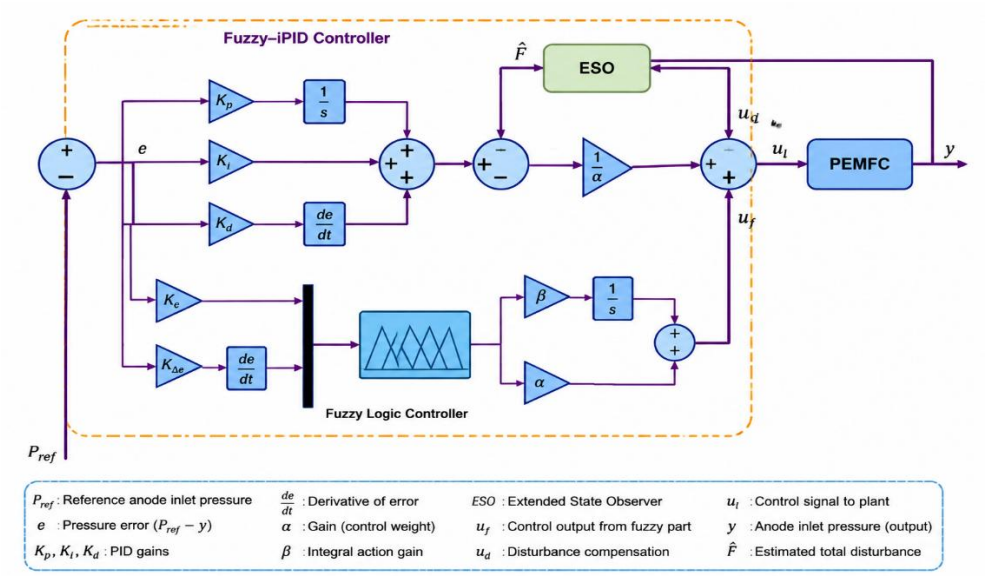

Figure 2: Fuzzy-iPID control structure.

The ESO approach can be represented as:

$$\begin{cases} \bar{e}_1 = z_1 - y \\ \dot{z}_1 = z_2 - \beta_1 \bar{e}_1 + \alpha \cdot u_1 \\ \dot{z}_2 = -\beta_2 \left|\bar{e}_1\right|^{0.5} \mathrm{sign}\left(\bar{e}_1\right) \\ \hat{F} = z_2 \end{cases} \tag{7}$$

Where β_1 and β_2 are constants, $\bar{e}_1$ is the estimated error of the ESO, z_1 and z_2 are the intermediate states, u_1 is the control signal, and y is the plant output. In the ESO framework, z_2 represents the ESO estimate. So, in this case, we have $z_2 = \hat{F}$.

3.2 Fuzzy-iPID Controller Design

In this section, we enhanced the controller's performance by introducing an additional input to the system that compensates for the estimation error. The structure of the hybrid fuzzy-logic intelligent proportional-integral-derivative (Fuzzy-iPID) controller is shown in Fig. 3.

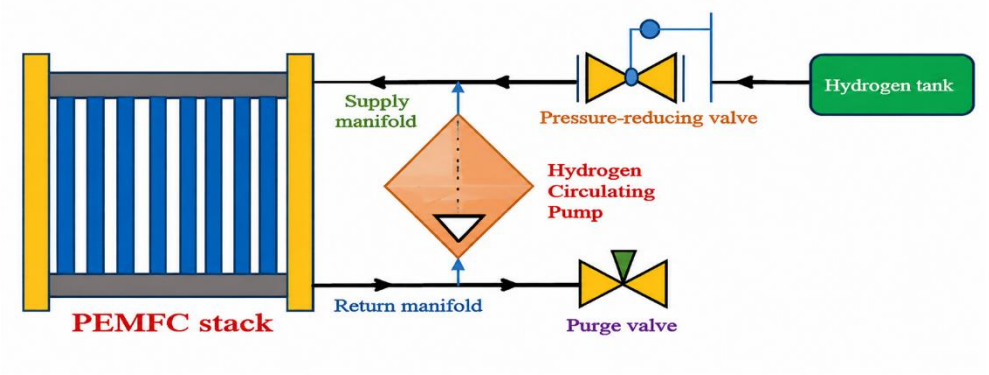

Figure 3: Structure of the hydrogen supply system

UFuzzy indicates the extra input to the system. Therefore, the final expression of the fuzzy-iPID controller can be stated as:

$$uFuzzy{-}iPID = uPID + uFuzzy \quad (8)$$

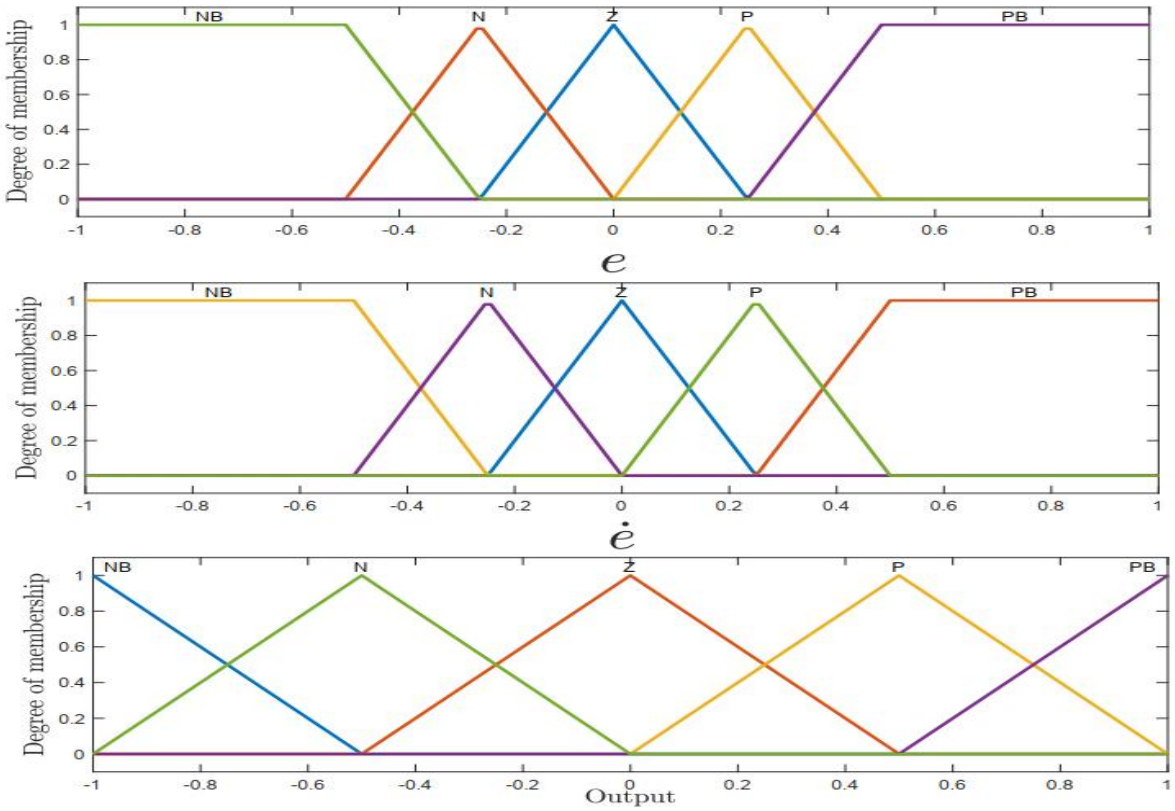
The framework of the fuzzy-iPID controller, as described in Fig. 3, has been built from two inputs and one rule base. The Fuzzy Logic Controller (FLC) uses two input variables: the anode-pressure control error e*e* and the rate of change of the control error $e^{\cdot}$. The FLC output provides the supplementary control signal *uFLC,* which compensates for the estimation error. Denote the area control error and the derivative of the area control error of area i*i*, which is the extra control signal, and can be modeled as (Pawar et al., 2021):

$$uFLC = f(e, e^{\cdot}) \quad (9)$$

Where uFLC denotes the FLC output, and α*α* and β are the scaling factors applied to the direct fuzzy-control output and its integral component, respectively. It has been referred to in (Vonglao, 2007) that the relation between the input and output variables for the product-sum crisp pattern of the fuzzy controller can be modeled as: (Pawar et al., 2021)

$$uFLC = \alpha e + \beta \int e dt \quad (10)$$

Therefore, the signal *uFuzzy* can be obtained by substituting Eq. (7) into Eq. (2) as follows:



$$uFuzzy = uFLC + \text{uESO} \quad (11)$$

The result showed that the FLC acts like a time-varying PID controller. Hence, the equivalent control synthesis of the fuzzy-iPID type controller results in a proportional gain *Kp*, integral gain *Ki*, and derivative gain *Kd*. The PSO algorithm optimizes the fuzzy-iPID controller's adjustable parameters.

The result showed that the FLC acts like a time-varying PID controller. Hence, the equivalent control synthesis of the fuzzy-iPID type controller results in a proportional gain. $\alpha K_1 P + \beta K_2 D$, integral gain, and derivative gain $\alpha K_2 D$. The PSO algorithm optimizes the adjustable parameters of the fuzzy-iPID controller. In this article, the FLC system is constructed by fuzzifying. It comprises three membership functions, two input signals, and one output signal. Each membership function consists of two trapezoidal membership functions and three triangular membership functions, as displayed in Fig. 4.

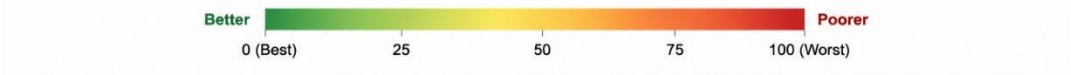
Table 1 defines the linguistic labels NB, N, Z, P, and PB and presents the resulting 25-rule fuzzy rule base. For example, the rule at the intersection of the third row and fifth column indicates that when the first input is Z and the second input is PB, the corresponding fuzzy output is P, as shown in Table 1.

Remarks: NB denotes Negative Big, N denotes Negative, Z denotes Zero, P denotes Positive, and PB denotes Positive Big. These five linguistic labels form an ordered and symmetric negative-to-positive scale, NB → N → Z → P → PB, used for the fuzzy-controller input and output variables, as outlined in Table 1.

Fig, 4 The membership function of the fuzzy system.

Table 1: Fuzzy linguistic rule base for the Fuzzy-iPID controller

e	$\dot{e}$				
	NB	N	Z	P	PB
NB	NB	NB	N	N	Z
N	NB	N	N	Z	P
Z	N	N	Z	P	P
P	N	Z	P	P	PB
PB	Z	P	P	PB	PB



4. SIMULATION AND HARDWARE-IN-THE-LOOP VALIDATION

4.1 Simulation Results

Simulation studies were conducted under two disturbance scenarios: step changes in load current (80 A to 290 A) and periodic purge-valve operation (10-second cycle with a 0.4-second opening time). Table 2 provides a detailed comparison of controller performance under different current step conditions.

Table 2: Controller Performance Comparison Under Current Disturbances

Current Step (A)	Fuzzy-iPID Response Time (s)	Fuzzy-iPID Overshoot (Pa)	PID Response Time (s)	PID Overshoot (Pa)
80 → 140	0.10	9	0.25	195
80 → 180	0.07	5	0.35	63
80 → 290	0.07	3.8	0.33	82
80 → 240	0.07	4.8	0.40	53
80 → 260	0.075	4.5	0.40	36
Mean	0.078	5.4	0.346	85.8

Under the simulation test conditions, the Fuzzy-iPID controller consistently outperformed the conventional PID controller. <u>Across the simulated current-step disturbances, the average pressure overshoot decreased from 85.8 Pa for the PID controller to 5.4 Pa for the Fuzzy-iPID controller, corresponding to an approximately 94% reduction. The mean simulated response time decreased from 0.346 s to 0.078 s, representing an approximately 77% reduction. These values represent simulation results and are therefore reported separately from the HIL validation results presented in Section 4.3

4.2 Hardware-in-the-Loop Testing Framework

To bridge the gap between simulation and practical implementation, we developed a comprehensive Hardware-in-the-Loop (HIL) testing platform. This HIL system integrates a real Fuel Cell Unit (FCU) controller with a virtual Proton Exchange Membrane Fuel Cell (PEMFC) model running on a real-time simulation platform. The key components of this system include:

HIL Central Control Computer: This manages and coordinates all hardware and software signals.

Real-Time Simulation Platform: A high-performance controller that runs the PEMFC system model.

Signal Conditioning System: This ensures electrical compatibility among different system components.

Tested Controller: The actual FCU hardware that incorporates control software.

In this setup, the control algorithm was implemented in the FCU controller. The pressure-reducing valve is controlled via a duty-cycle signal communicated over the Controller Area Network (CAN). Additionally, the hydrogen circulation pump operates at 4.8 volts and 3000 revolutions per minute (rpm), while a state-flow state machine manages the purge valve. The following HIL results form a separate validation dataset from the numerical simulation results reported in Section 4.1; therefore, differences in absolute overshoot and response-time values between the two test phases are expected.

4.3 HIL Test Results

HIL testing provided quantitative evidence that the Fuzzy-iPID controller performed better than the conventional PID controller under real-time implementation conditions. Unlike the simulation results reported in Section 4.1, this section presents all quantitative values from the HIL validation experiments. The Fuzzy-iPID controller achieved a mean pressure overshoot of 6.25 Pa compared with 103.5 Pa for the conventional PID controller, corresponding to an approximately 94% reduction. Similarly, the mean response time decreased from 0.46 s with the conventional PID controller to 0.09 s

with the Fuzzy-iPID controller, representing an approximately 80% reduction. Fig. 5 summarizes the quantitative HIL performance comparison between the Fuzzy-iPID and conventional PID controllers, while Fig. 6 presents the corresponding transient pressure responses under current-step and purge-valve disturbances.

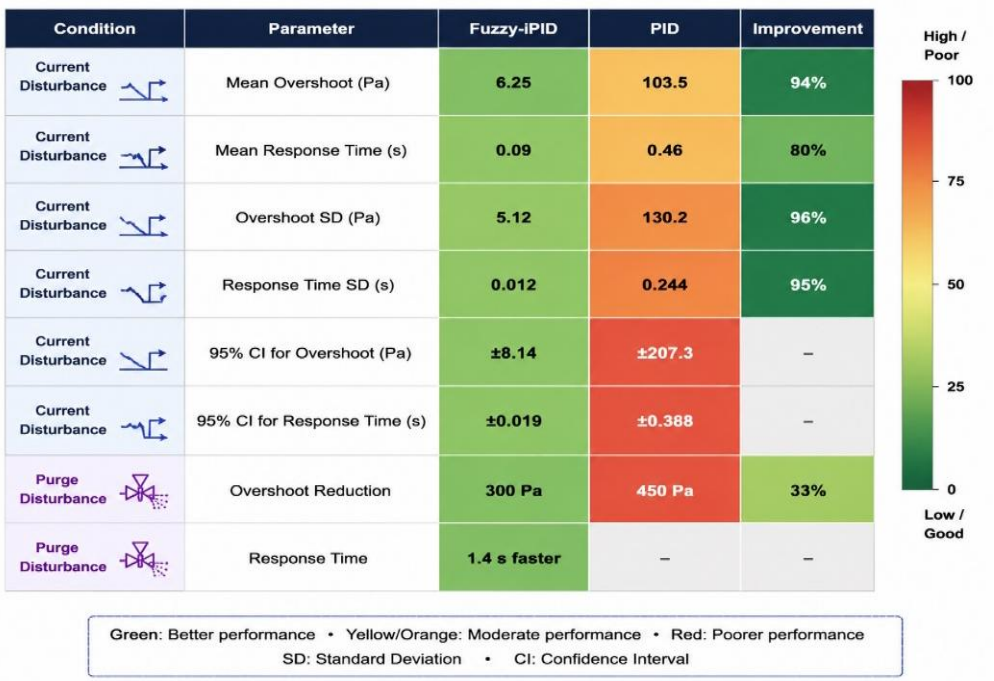


Figure 5: HIL performance comparison of the Fuzzy-iPID and conventional PID controllers under current and purge disturbances.

The standard deviation analysis was calculated from the response metrics obtained across the evaluated HIL disturbance conditions, including the five current-step load variations and the periodic purge-valve disturbance scenario. The Fuzzy-iPID controller exhibited substantially lower performance variability than the conventional PID controller. The standard deviation of pressure overshoot was 5.12 Pa compared with 130.2 Pa for the conventional PID controller, while the corresponding response-time standard deviations were 0.012 s and 0.244 s, respectively. These results indicate that the Fuzzy-iPID controller provided more consistent dynamic responses across the tested HIL operating conditions.

For statistical evaluation, the performance indices (overshoot and response time) were extracted from each disturbance test condition, and the standard deviation was calculated across the complete set of evaluated HIL experiments to quantify controller-response variability.

The transient responses in Fig. 6 further illustrate the differences between the two controllers. Under the evaluated HIL conditions, the Fuzzy-iPID controller showed smaller pressure excursions and converged more rapidly to the target pressure than the conventional PID controller during both current-step and purge-valve disturbances.

(a)

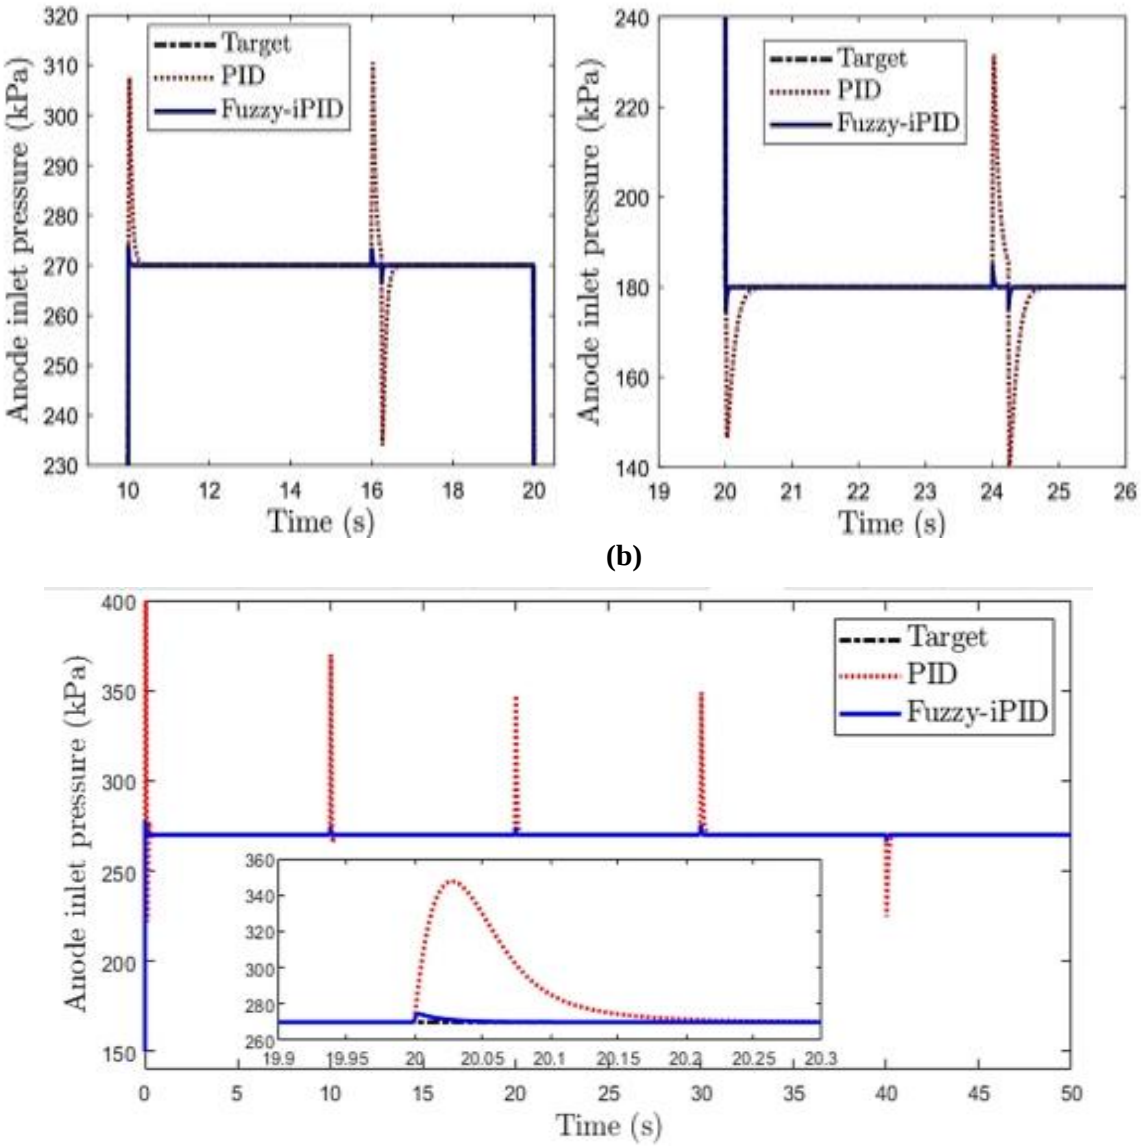

Figure 6: HIL pressure responses of the Fuzzy-iPID and conventional PID controllers: (a) response to current-step disturbances and (b) response to the purge-valve disturbance.

5. DISCUSSION

5.1 Control Performance and Efficiency

The Fuzzy-iPID controller's superior performance stems from its adaptive capabilities and disturbance rejection. By integrating fuzzy logic with intelligent PID control, this system can adjust its control gains in real time to account for varying operating conditions. Additionally, the Extended State Observer effectively estimates and compensates for system disturbances and uncertainties.

This combination effectively addresses the inherent limitations of conventional PID control, especially in handling nonlinear disturbances, rapid load changes, and parameter uncertainties. The substantial reduction in performance variability is particularly important for real-world applications, where operating conditions are constantly changing. The controller's consistent performance across different current levels and disturbance scenarios showcases its adaptability and efficiency.

5.2 Electrochemical and Thermal Implications

The Fuzzy-iPID controller's improved pressure regulation significantly affects electrochemical performance and stack durability. By maintaining stable anode pressure, the system ensures uniform reactant distribution, preventing local fuel starvation and associated degradation mechanisms. Reducing pressure fluctuations minimizes membrane stress and mechanical fatigue, thereby extending the stack's lifetime. Additionally, improved voltage stability indicates better electrochemical stability, reducing activation losses and ohmic heating.

Moreover, anode pressure dynamics are intrinsically linked to thermal management. Variations in hydrogen pressure influence reactant mass flow rates, gas velocity profiles, and Reynolds numbers, which, in turn, affect convection heat transfer coefficients and cooling efficiency. The Fuzzy-iPID controller's capability to maintain stable pressure regulation contributes to more uniform heat distribution within the stack.

5.3 Implications for Digital Twin and AI Integration

The validated control-oriented model and the Hardware-in-the-Loop (HIL) testing framework provide a scalable digital foundation for future integration with digital twin architectures. This integration facilitates:

Predictive Maintenance: Forecasting system behavior and identifying potential degradation mechanisms.

Real-time Optimization: Implementing Model Predictive Control (MPC) and optimization algorithms.

AI-enhanced Supervisory Control: Integrating machine learning algorithms for adaptive parameter tuning and fault diagnosis.

Virtual Sensor Development: Generating synthetic sensor data for fault detection.

6. CONCLUSION

In this research, we proposed an intelligent control approach for effective anode pressure control in a PEMFC hydrogen system. The proposed intelligent control approach involved designing a dynamical model using electrochemical, thermodynamic, and fluid-dynamics properties, which showed significant agreement with experimental results, with prediction errors of less than 3% for voltage and less than 5% for pressure. Based on the proposed dynamic model, a Fuzzy-iPID controller with ESO was designed for disturbance rejection and pressure control.

Simulation analysis and Hardware-in-the-Loop (HIL) testing demonstrated the suggested controller's better performance compared with classical PID control. With HIL test analysis, the Fuzzy-iPID controller reduced the mean pressure overshoot to 6.25 Pa from 103.5 Pa and the mean response time to 0.09 seconds from 0.46 seconds. Lower pressure fluctuations improved voltage stability and reduced degradation-related protection issues.

The presented structure offers a practical way to implement adaptive control in PEMFC applications in real time. The combination of prediction, disturbance, and fuzzy adaptation improves hydrogen management compared to traditional fixed-gain control. It paves the way for future implementation of digital twins, predictive maintenance, and artificial intelligence-based energy management systems.

Further work will compare the proposed approach with other control strategies such as Model Predictive Control (MPC), Active Disturbance Rejection Control (ADRC), and reinforcement learning-based methods. Moreover, further investigations will focus on implementing automatic controller tuning and integrating the degradation models.

ABSTRACT

Integrating short-term load forecasts into distribution network operational planning is an emerging research direction that promises to improve network efficiency and reliability. However, the practical value of forecast-driven operation depends critically on forecast quality. This study investigates a hybrid Convolutional Neural Network–Long Short-Term Memory (CNN-LSTM) model, trained on 5,025 hourly observations from Abuja Electricity Distribution Company (AEDC), Minna, to ascertain if it can improve feeder reconfiguration decisions on the IEEE 33-bus radial distribution system. The CNN-LSTM model was implemented in MATLAB R2024b and compared against ARIMA and persistence baselines using Mean Absolute Error (MAE), Root Mean Square Error (RMSE), Mean Absolute Percentage Error (MAPE), and the coefficient of determination (R^2). The CNN-LSTM achieved an RMSE of 159.48 MW, MAE of 54.42 MW, MAPE of 31.38%, and R^2 of 0.0238 performance that is not statistically better than ARIMA (Diebold-Mariano $p=0.3606$) or persistence ($p=0.1036$). When the CNN-LSTM forecasts were used to guide feeder reconfiguration and the chosen topology was evaluated against actual realised load, the forecast-driven approach produced a 33.34% reduction in active power loss. However, this was outperformed by reconfiguration with no forecast (34.39% loss reduction), indicating that the poor forecast quality introduced operational decisions that were worse than doing nothing. The results demonstrate that forecast-driven operation is not universally beneficial and is only justified after the forecasting model achieves statistically significant superiority over strong baselines. The study contributes a cautionary framework that establishes a minimum forecast quality threshold for operational planning in distribution networks

1. INTRODUCTION

Distribution networks are undergoing significant changes as electricity demand becomes more variable and power systems accommodate increasing levels of electrification, distributed energy resources and other emerging technologies. These developments increase the complexity of distribution-network operation because demand can vary considerably across time and location.

Short-term load forecasting (STLF) provides estimates of electricity demand over relatively short horizons and can support operational decisions such as feeder reconfiguration, voltage management, transformer loading assessment and other network-control activities. Traditional forecasting techniques, including autoregressive models and other statistical approaches, have been widely used because of their relative simplicity and interpretability. However, electricity demand is influenced by temporal patterns, weather conditions, consumer behaviour and other nonlinear factors. Additionally, distribution network operational planning is commonly performed using deterministic loading conditions or historical demand data. Such approaches may not adequately reflect anticipated short-term changes in feeder demand.

Artificial intelligence (AI) and deep-learning methods have therefore received increasing attention in electricity-load forecasting. Long Short-Term Memory (LSTM) networks are capable of

learning temporal dependencies in sequential data and extracted features, captures the sequential dependencies that characterise electricity demand data. Convolutional Neural Networks (CNNs) can extract local patterns from structured sequences and relevant features from the input sequence, reducing the dimensionality of the data and identifying patterns that may not be immediately apparent in the raw time series.

Studies by Rafi et al. (2021), Ullah et al. (2024), and Hasanat et al. (2024) have demonstrated that CNN-LSTM architectures are effective for feeder-level load forecasting, where load patterns exhibit high variability and are influenced by multiple external factors. Although AI-based load forecasting has developed rapidly, many forecasting studies focus primarily on prediction accuracy Rafi et al. (2021), Ullah et al. (2024) without demonstrating how forecast information affects actual network operation. This creates a methodological gap between predicting future electricity demand and using that prediction to make network-operational decisions, as noted in recent reviews Hong and Fan, (2016), Raza and Khosravi, (2023). This creates a methodological gap between predicting future electricity demand and using that prediction to make network-operational decisions. This study presents the development and integration of a CNN-LSTM-based short-term load forecasting model into a forecast-driven operational planning framework for radial distribution networks.

2. METHODOLOGY

2.1 Research Design

A quantitative, simulation-based research design was adopted. The study consists of two major components: (1) short-term feeder-load forecasting and (2) forecast-driven distribution-network operational planning. The forecasting stage develops the CNN-LSTM model and compares it with ARIMA. The operational stage uses the CNN-LSTM forecast to modify network loading and evaluate candidate feeder configurations using MATPOWER.

2.2 Data Collection

Historical hourly feeder load data (5,025 observations) from a single distribution feeder in the AEDC Minna network were combined with weather data (temperature, humidity, wind speed) from Open-Meteo. The large magnitude of the reported error metrics (e.g., RMSE of 159.48 MW) reflects the feeder's relatively high average load and the inherent variability of demand at the feeder level. This poor forecast quality is precisely why the forecast-driven approach underperformed compared to deterministic reconfiguration, reinforcing the cautionary contribution of this study. The variables of the dataset and their corresponding description are presented in Table 1 below.

Table 1: Dataset Description

Variable	Description
Load	Historical feeder active-power demand
Temperature	Ambient temperature
Relative humidity	Atmospheric humidity
Wind speed	Wind velocity
Hour	Hour of day
Day of week	Weekly temporal feature
Month	Seasonal temporal feature

2.3 Data Preprocessing

The preprocessing procedure consisted of duplicate removal, timestamp synchronisation, missing-value treatment, outlier inspection, temporal feature generation, Min-Max normalisation, chronological dataset partitioning and sliding-window sequence generation. The resulting sequences were divided chronologically into 70% training (3,484 training samples), 15% validation (746 validation samples) and 15% testing (747 test samples.) sets. The test period represents approximately 31 days of hourly data, providing a statistically meaningful evaluation window.

The original 5,025 observations produced 4,977 usable sequences after the 48-hour look-back operation.

2.4 CNN-LSTM Forecasting Model

The forecasting model combines one-dimensional convolutional processing with an LSTM recurrent layer. The CNN component extracts local patterns from the sequential input, while the LSTM component learns temporal dependencies. The architecture of the CNN-LSTM model is presented in Figure 1, while the hyperparameters of the model are presented in Table 2.

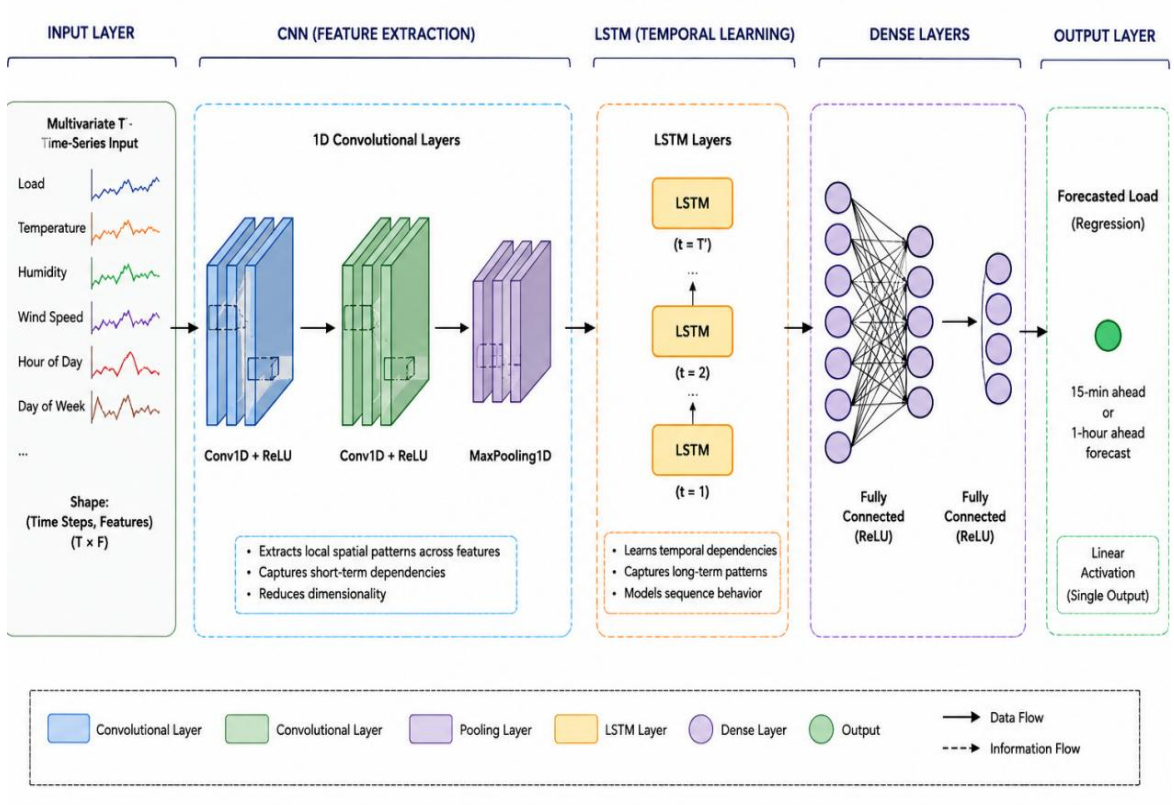

Figure 1: Architecture of the developed CNN-LSTM forecasting model

Table 2: Hyperparameters of CNN-LSTM Model

Parameter	Value
Look-back window	48 hours
Input features	7
CNN filters	64
Kernel size	3
Batch normalisation	Yes
LSTM units	128
Dropout	0.20
Fully connected neurons	64
Optimiser	Adam
Initial learning rate	0.001
Mini-batch size	64
Maximum epochs	150
Validation patience	10
Loss function	MSE
Forecast horizon	1 hour

2.5 ARIMA Benchmark

ARIMA was selected as the conventional statistical benchmark. CNN-LSTM and ARIMA were evaluated using the same independent testing period and one-hour-ahead forecasting horizon. The purpose of the comparison was to determine whether the hybrid deep-learning model provided

improved forecasting performance relative to a conventional time-series model under identical test conditions.

2.5.1 Seasonal Naive Baseline

A seasonal naive baseline was included as an additional benchmark. This model forecasts the load at time t as the load observed at the same hour on the same day of the previous week (t-168 hours). This baseline accounts for weekly periodicity in electricity demand and provides a simple reference for assessing the additional value of more sophisticated forecasting methods.

2.6 Forecasting Performance Metrics

The model was evaluated based on the Root Mean Square Error (RMSE), Mean Absolute Error (MAE), Mean Absolute Percentage Error (MAPE), and the R^2 values. As shown in the equations below.

$$MAE = \frac{1}{N}\sum_{t=1}^{N}(\left|P_t - \hat{P}_t\right|) \quad (1)$$

$$RMSE = \sqrt{\frac{1}{N}\sum_{t=1}^{N}(P_t - \hat{P}_t)^2} \quad (2)$$

$$MAPE = \frac{100}{N}\sum_{t=1}^{N}(\frac{\left|P_t - \hat{P}_t\right|}{P_t}) \quad (3)$$

$$R^2 = 1 - (\frac{\sum_{t=1}^{N}(P_t - \hat{P}_t)^2}{\sum t = 1^N (P_t - \bar{P})^2}) \quad (4)$$

A Diebold-Mariano test was additionally applied to determine whether differences between forecast errors were statistically significant.

2.7 Forecast to Network Integration

The IEEE 33-bus radial distribution system was selected as the test network. MATLAB R2024b was used for model development and data processing, while MATPOWER 8.1 was used for AC power-flow analysis and network configuration evaluation.

For each forecasting model, the forecasted feeder load was converted into a load-scaling factor and applied to the active and reactive power demands of the network load buses. For active power, the scaling factor was calculated as:

$$Scale\ Factor = \frac{P_{Fprecast}}{P_{Original}}$$

For reactive power, a constant power factor of 0.85 lagging was assumed, consistent with typical distribution system operating practice in Nigeria. The reactive power demand was therefore updated as:

$$Q_{new} = P_{new} \times tan(arccos(PF))$$

where PF = 0.85.

The updated network was then evaluated under the anticipated loading condition rather than only under the original deterministic loading condition.

2.7.1 Perfect Foresight Scenario

A "Perfect Foresight" scenario was included as an upper-bound benchmark. In this scenario, the optimal radial configuration was selected using the actual realised load for each hour, rather than a forecasted load. This represents the theoretical best possible operational performance and provides a reference against which the forecast-driven approaches can be compared. The difference between the perfect foresight and forecast-driven cases represents the "regret" or penalty incurred due to forecast error.

2.8 Feeder Configuration and Operational Evaluation

Sixteen candidate radial configurations were evaluated for the IEEE 33-bus system: base configuration with all 5 tie switches open, five configurations with one tie closed, and ten configurations with two ties closed. For each, the corresponding sectionalising switch was opened to maintain radiality

Configuration Selection Algorithm:

For each forecast scenario (CNN-LSTM, ARIMA, and Perfect Foresight), the following procedure was applied:

1. Load the IEEE 33-bus system data into MATPOWER
2. Apply the forecasted (or actual, for Perfect Foresight) load scaling factor
3. For each of the 16 candidate configurations:

i. Run AC power-flow analysis using MATPOWER
ii. Record active power loss, voltage deviation, and voltage violations

4. Filter out infeasible configurations (those that failed to converge)
5. Rank feasible configurations using hierarchical criteria:

i. Primary: Minimum number of voltage violations
ii. Secondary: Minimum average voltage deviation
iii. Tertiary: Minimum active power loss

6. Select the highest-ranked configuration as the optimal topology for that forecast

This hierarchical approach prioritises voltage security before loss minimisation, consistent with distribution system operational practice.

The operational performance indicators were then calculated as follows:

$$P_loss = \Sigma(P_l\text{^}send - P_l\text{^}rec)$$

$$\%\Delta P_loss = [(P_baseline - P_forecast)/P_baseline] \times 100$$

$$\%\Delta V_dev = [(V_baseline - V_forecast)/V_baseline] \times 100$$

3. RESULTS AND DISCUSSION

3.1 CNN-LSTM Forecasting Performance

Figure 2 presents the training and validation loss curves obtained during CNN-LSTM model training. The training and validation loss curves for the CNN-LSTM model showed progressive reduction in loss. Early stopping (validation patience = 10) halted training after approximately 23 epochs, preventing overfitting. The validation loss follows the training loss closely, indicating good generalization without significant overfitting.

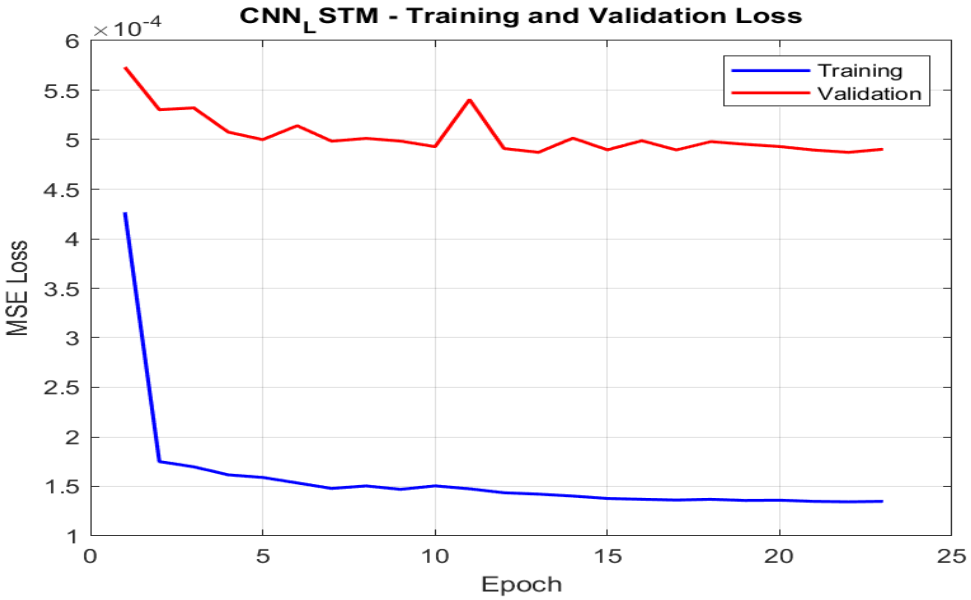

Figure 2: CNN-LSTM Training and Validation Loss Curves

Table 3 presents a summary of the model performance. The model achieved an RMSE of 159.48 MW and an MAE of 54.42 MW. The difference between RMSE and MAE indicates the presence of some relatively large forecasting errors. The MAPE of 31.38% indicates that considerable relative forecasting error remained during the test period. The low R^2 value indicates that a large proportion of the variation in the independent test observations remained unexplained, suggesting that additional explanatory variables or improved model specification may be required. ARIMA achieved an RMSE of 181.06 MW and MAE of 58.12 MW. CNN-LSTM therefore reduced RMSE by approximately 11.92% relative to ARIMA and reduced MAE by approximately 6.37%. ARIMA recorded a MAPE of 31.38%, identical to CNN-LSTM's MAPE, indicating similar percentage errors for both models. To assess the relative performance of the CNN-LSTM model, it was compared against three baseline models: persistence (same hour previous day), seasonal naive (same hour same day previous week), and ARIMA. The results are presented in Table 3.

Table 3: Forecasting Performance Comparison

Metric	Persistence (t-24)	Seasonal Naive (t-168)	ARIMA	CNN-LSTM
RMSE (MW)	228.27	215.84	181.06	159.48
MAE (MW)	75.82	68.91	58.12	54.42
MAPE (%)	39.07	37.42	31.10	31.38
R^2	-0.9439	-0.7352	0.0018	0.0238

CNN-LSTM achieves the lowest RMSE and MAE among all baselines, but the improvement over ARIMA is modest (11.92% in RMSE) and not statistically significant (Diebold-Mariano $p = 0.3606$). The MAPE of CNN-LSTM (31.38%) is slightly worse than ARIMA (31.10%), indicating that percentage errors remain high across all models. The low R^2 values (0.0238 for CNN-LSTM, 0.0018 for ARIMA) indicate the models explain almost none of the test data variance. This is attributed to limited input variables (only weather data), insufficient data duration (~7 months), and aggregated substation-level data. These limitations mean the forecast quality is poor ($R^2 \approx 0$, MAPE > 30%), which is the central cautionary finding of this study. The models were also assessed based on their statistical significance. The results of this evaluation are presented in Table 4.

Table 4: Statistical Significance of Model Performance

Comparison	DM statistic	p-value	Significant at 5%?
CNN-LSTM vs ARIMA	-0.9142	0.3606	No
CNN-LSTM vs Persistence	-1.6275	0.1036	No
CNN-LSTM vs Seasonal Naive	-0.8413	0.4001	No

3.2 Operational Planning Results

The deterministic baseline was determined. The IEEE 33-bus baseline produced 0.2027 MW active power loss and 0.0515 p.u. average voltage deviation, with 21 voltage violations. The CNN-LSTM and ARIMA forecasts were separately used to select radial configurations. The selected configurations were then evaluated on the actual realised load. The results are presented in Table 5.

Table 5: Operational Performance Under Different Approaches Compared with IEEE 33-bus

Indicator	No Switching (Baseline)	Reconfiguration Only	CNN-LSTM Forecast	ARIMA Forecast	Perfect Foresight
Active power loss (MW)	0.2027	0.1330	0.1351	0.1398	0.1310
Average voltage deviation (p.u.)	0.0515	0.0326	0.0397	0.0405	0.0318
Voltage violations	21	3	11	13	2
Maximum branch loading (%)	100	100	100	100	100

The CNN-LSTM forecast-driven approach achieved a 33.34% loss reduction (ARIMA: 31.02%). However, reconfiguration without forecast achieved the largest reduction at 34.39%, indicating that reconfiguration itself is the primary benefit. Similar patterns were observed for voltage deviation and violations, with reconfiguration alone outperforming both forecast-driven cases

4. CONCLUSION

This study investigated the integration of CNN-LSTM short-term load forecasting into distribution network operational planning. The forecasting model, trained on 5,025 hourly observations from AEDC Minna, achieved an RMSE of 159.48 MW, MAPE of 31.38%, and R^2 of 0.0238, performance that is not statistically superior to ARIMA or persistence baselines.

When the forecasts were used to guide feeder reconfiguration on the IEEE 33-bus system, the CNN-LSTM forecast-driven approach reduced active power loss by 33.34%, while ARIMA achieved 31.02%. Both approaches were outperformed by reconfiguration without any forecast, which achieved 34.39% reduction. However, this was worse than reconfiguration performed without any forecast, which achieved a 34.39% reduction. This finding is critical: it demonstrates that poor-quality forecasts ($R^2 \sim 0$, MAPE > 30%) degrade operational performance relative to deterministic operation. The forecast introduced decisions that were suboptimal when evaluated against actual realised load.

The benefits of forecast-driven operation are therefore highly dependent on forecast quality. The study establishes a minimum forecast quality threshold for operational planning: forecasts must clearly beat persistence, ARIMA, and seasonal naive baselines before being integrated into operational decisions.

ABSTRACT

Islanded microgrids (IMGs) featuring high penetration levels of inverter-based renewable energy sources (RESs) suffer from severe dynamic instability, rapid rate of change of frequency (RoCoF), and deep frequency nadirs due to the low or zero physical inertia of power electronic interfaces. To compensate for lost rotational kinetic energy, Synthetic Inertia Control (SIC) and dynamic Load Frequency Control (LFC) have emerged as essential stabilization mechanisms. However, conventional linear controllers underperform under stochastic load variations, intermittent wind/solar generation, nonlinear governor deadbands, and variable time delays. Over the past decade, metaheuristic optimization algorithms (MOAs) spanning swarm intelligence, evolutionary computation, physics-based, and human-inspired paradigms have transformed control parameter tuning, objective function formulation, and hybrid controller design in IMGs. This paper provides a rigorous, state-of-the-art review of metaheuristic optimization strategies applied to joint or standalone SIC and LFC schemes in standalone microgrids. We classify contemporary control topologies, examine classical and high-order objective metrics (ITAE, ITSE, multi-objective trade-offs), and critically evaluate metaheuristic paradigms ranging from foundational algorithms to modern hybrid and adaptive variants. Furthermore, we detail the integration of physical energy storage systems and demand-side assets like Electric Vehicles (EVs) for frequency support. Finally, key open research challenges, including real-time computational overhead, hardware-in-the-loop (HIL) validation, cyber-physical security, and multi-objective Pareto optimization are systematically analyzed alongside local application perspectives to delineate future research directions.

Keywords: *Islanded Microgrid; Synthetic Inertia Control (SIC); Load Frequency Control (LFC); Metaheuristic Optimization; Rate of Change of Frequency (RoCoF)*

1. INTRODUCTION

The modern energy system faces the need to switch from centralized to distributed isolated microgrids that ensure reliable power supply to consumers through various renewable energy resources (RES). Such resources include photovoltaic (PV) generators and wind turbines (WT), which replace some of the traditional synchronous generators. One of the problems of such microgrids is the loss of rotational inertial characteristics due to the use of voltage source inverters and the absence of a wide range of inertial properties in the system. This effect is especially noticeable in the case of an isolated microgrid, which is separated from the main power grid (Abubakr et al., 2021; Davoudkhani et al., 2024; Akinwola & Alkuhayli, 2025; Saleh et al., 2022). Such a change in the system characteristics makes it necessary to use synthetic inertia and specific methods to regulate electricity frequency to achieve stable operation of the microgrid (Davoudkhani et al., 2024). Traditional control methods are not always efficient in complex microgrid environments. Therefore, researchers have proposed various metaheuristic optimization algorithms to optimize controller parameters for frequency adjustment, thereby improving system transient response (Kalu et al., 2025; Lesenyeho & Krishnamurthy,

2025).The purpose of this article is to present a state-of-the-art review on microgrid control methods based on metaheuristic optimization algorithms. The paper analyzes and systematizes modern literature to improve understanding of diverse nature-inspired evolutionary computing techniques. It also highlights performance differences across algorithms in multi-objective optimization contexts involving multi-criteria trade-offs.

1.1 Methodology of literature search and selection

To ensure systematic coverage and reproducibility, a transparent search protocol was conducted following PRISMA guidelines across major databases, including IEEE Xplore, ScienceDirect, SpringerLink, MDPI, Wiley Online Library, and Scopus. The primary search query used Boolean operators: ("Islanded Microgrid" OR "Low-Inertia Microgrid") AND ("Synthetic Inertia" OR "Load Frequency Control") AND ("Metaheuristic Optimization" OR "Swarm Intelligence" OR "Evolutionary Algorithm"). The search prioritized peer-reviewed articles published between 2015 and 2026. Inclusion criteria mandated focus on islanded microgrids, metaheuristic controller gain tuning (Kp, Ki, Kd, fractional orders, inertia/damping gains), and quantitative dynamic evaluation (ITAE, ISE, RoCoF, nadir). Grid-connected studies without islanding capability and purely economic dispatch papers were excluded. Table 1 summarize the review methodology.

Table 1: Review Methodology

Selection Parameter	**Details / Criteria**
Databases Searched	IEEE Xplore, ScienceDirect, SpringerLink, MDPI, Wiley Online Library, Scopus
Timeframe	2015–2026
Initial Records Identified	1,578 articles
Screened by Title/Abstract	373 articles retained after title screening; 132 after abstract review
Final Included Studies	56 primary core studies fully analyzed and cross-referenced

The remainder of this paper is structured as follows: Section 2 identifies challenges associated with microgrids in modern energy systems. Section 3 presents control topologies for synthetic inertia and frequency control. Section 4 provides a structured comparative analysis of metaheuristic optimization algorithms (evolutionary, swarm, physics/chemical, human/social, and hybrid paradigms). Section 5 synthesizes key open research challenges and local application perspectives. Finally, Section 6 summarizes the core findings.

2. CHALLENGES AND PROBLEMS OF MICROGRIDS IN MODERN ENERGY SYSTEMS

The development of modern electricity markets using microgrids has one primary advantage: enabling decentralized and low-carbon power systems. The main challenges microgrids encounter while being incorporated into the existing electricity system relate to their dissimilarities with classic power networks (Shahzad et al., 2023; Bhargava & Jaiswal, 2021). Microgrids require highly efficient power electronics during switching modes to provide stable power quality and voltage during transition to islanded mode with minimum losses (Shahzad et al., 2023; Bodewes et al., 2024; Zahira et al., 2014). This imposes technical difficulties associated with protection relay schemes capable of responding to grid-side power interruptions instantly while securing local electrical loads from voltage deviations. Designing protection schemes is challenging since legacy networks feature unidirectional power flows and conventional overcurrent relays (Binqadhi et al., 2024). Microgrids allow bidirectional power delivery due to distributed energy resources (DER), resulting in relay malfunctions, protection blindness, and sympathetic tripping (Ali et al., 2021). The limited fault current of inverter-based DERs is notably lower than grid-supplied currents, which conventional overcurrent relays cannot recognize during islanding (Faisal et al., 2018; Shahzad et al., 2023).

Inverter-based systems also face power quality challenges, particularly voltage and frequency regulation during steady-state and transient conditions (Kumar & Subudhi, 2023). Microgrids traditionally relied on synchronous generators to supply inertial response and voltage regulation. Recent microgrids experience greater frequency deviations (Δf) and voltage instability due to intermittent solar and wind power (Kumar & Subudhi, 2023). These technical limitations are

exacerbated by the lack of effective primary control strategies against frequency deviations, such as virtual inertial control and grid-forming inverter control.

Microgrids encounter additional control and cybersecurity challenges in energy management systems (EMS) and protection relays. Modern EMSs have adopted centralized or multi-agent control systems for secondary control and battery storage management (Kumar & Subudhi, 2023). Communication infrastructures between microgrid components play a crucial role in real-time generation and demand coordination (Shahzad et al., 2023). Communication integrity is a major concern; cyber-attacks, signal fading, and delays can disrupt control loops and jeopardize grid security. Furthermore, economic inefficiencies arise due to high battery storage costs, while existing regulatory frameworks offer limited compensation for ancillary services.

3. LOAD FREQUENCY CONTROL IN ISLANDED MICROGRID

An islanded microgrid is an electricity production and distribution system electrically isolated from the main grid. Lacking voltage reference sources and high rotating inertia, the main task of Load Frequency Control (LFC) in an islanded microgrid is to balance generated and consumed electric power to minimize frequency deviation (Pilehvar & Mirafzal, 2020; Ewias et al., 2023). The dynamic islanded microgrid control structure with virtual inertia loop is shown in Figure 1.

3.1 Fundamentals of synthetic inertia

Frequency control in islanded microgrids is managed via a hierarchical multi-loop system (Zaid et al., 2023):

3.1.1 Inertia control loop

Utilizes energy storage systems (ESS) and advanced inverter control for instantaneous active power support, mimicking synchronous machine kinetic energy (Faragalla et al., 2022; Zaid et al., 2023).

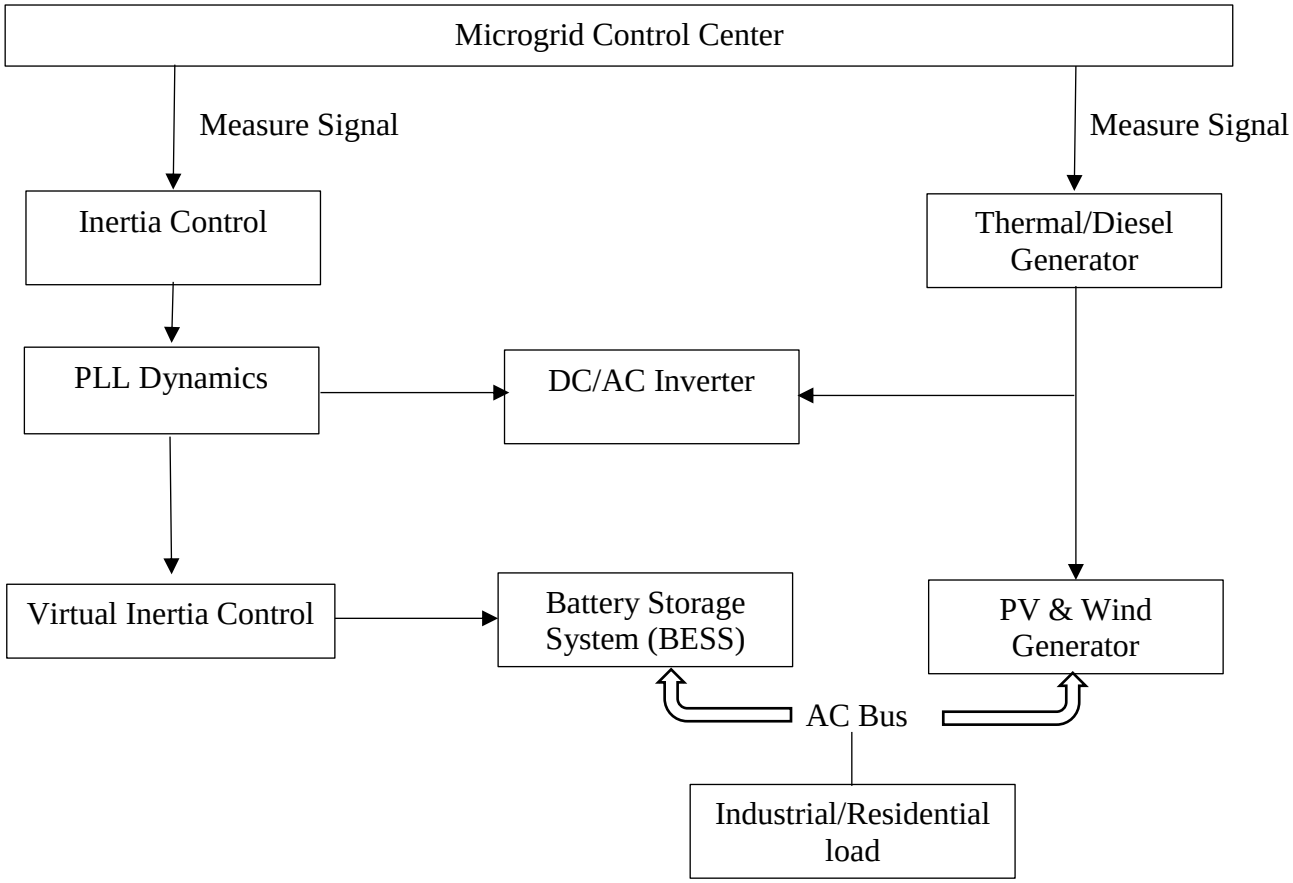

Figure 1: Dynamic Islanded Microgrid Control Structure with Virtual Inertia Loop

3.1.2 Primary control loop

Adjusts DER power output based on frequency deviation, typically through proportional droop control (Gulzar et al., 2022).

3.1.3 Secondary control loop (LFC)

Restores system frequency to nominal values (50/60 Hz) by modulating active power references of controllable units (Faragalla et al., 2022; Zaid et al., 2023). Controller architectures range from PID and Fractional-Order PID (FOPID) (Sahoo et al., 2023; Mohamed et al., 2022; Fadheel et al., 2024) to Model Predictive Control (MPC) (Saleh et al., 2023a) and Fuzzy Logic Control (FLC) (Nanda Kumar & Mohanty, 2022).

3.2 Synthetic inertia emulation and control topologies

In islanded low-inertia microgrids, dynamic frequency response is governed by the electromechanical swing equation as expressed in (1).

$$2H\frac{d\Delta f(t)}{dt} = P_m(t) - P_e(t) - D\Delta f(t) \quad (1)$$

where: H is the inertia constant (in seconds), $\Delta f(t)$ is the system frequency deviation $(\omega - \omega_0)$, $P_m(t)$ and $P_e(t)$ are the per-unit mechanical input power and electrical output power, and D is the damping factor.

Inverter-interfaced storage units inject synthetic inertial power P_{syn} proportional to the derivative of frequency deviation as in (2) (Criollo et al., 2024).

$$P_{syn}(t) = -K_{inertia}\frac{d\Delta f(t)}{dt} \quad (2)$$

where $K_{inertia}$represents the virtual inertia control gain ($2H_{vir}$).

When integrated into the active power balance, the effective total system inertia constant H_{sys} increases to as in (3).

$$H_{sys} = H_{phys} + H_{vir} \quad (3)$$

Synthetic inertia implementation strategies in inverter-based islanded microgrids generally fall into two primary control architectures (Kerdphol et al., 2019) as represent in Figure 2.

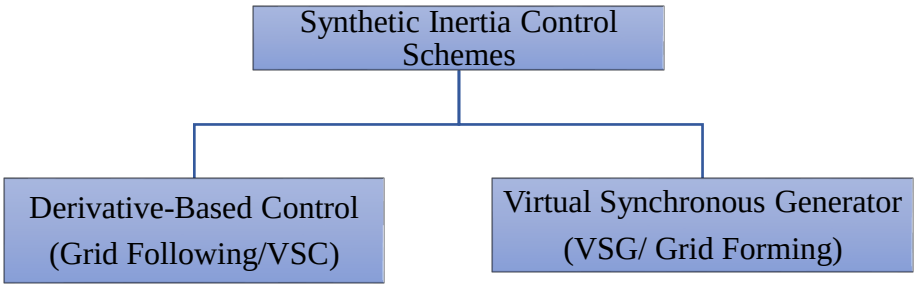

Figure 2: Synthetic Inertia Control Schemes (Kerdphol et al., 2019)

3.2.1 Virtual synchronous generators (VSG)

The VSG technology embeds synchronous machine mathematical models into the inverter digital control loop. Frequency dynamics follow the virtual swing equation as in (4).

$$J\frac{d\omega}{dt} = P_{ref} - P_e - D(\omega - \omega_0) \quad (4)$$

Where: J is the virtual moment of inertia, D is the damping coefficient (providing primary droop functionality), ω is the virtual rotor angular frequency, ω_0 is the nominal frequency, P_{ref} is the reference active power input, and P_e is the measured electromagnetic output power (Besati et al., 2024).

3.2.2 Derivative-based inertia emulation

Derivative control calculates $(^{df}/_{dt})$ in real-time to inject power (ΔP_{SI}) from storage during initial transient phases (100–500 ms). By applying a control gain (K_{in}) to this derivative, the controller

determines the required active power output (ΔP_{SI}) to be injected or absorbed by an Energy Storage System (ESS) or regulated Load-Side Rotational Inertia (LSRI) can be expressed as in (5).

$$\Delta P_{SI} = -K_{in}.\frac{df}{dt} \tag{5}$$

Where: K_{in} is control gain, ΔP_{SI} is required output power and, $(^{df}/_{dt})$ is derivative of the system frequency (Fang et al., 2018; Roy et al., 2024).

To filter measurement noise, low-pass filtering with time constant T_f is applied in Laplace domain as expressed in (6).

$$\Delta P_{SI}(s) = \frac{K_{in}.s}{1+sT_f}.f(s) \tag{6}$$

4. METAHEURISTIC OPTIMIZATION ALGORITHMS FOR VIC-LFC

Metaheuristic algorithms solve the optimization problem formulated using performance indices such as Integral Time Absolute Error (ITAE) or Integral Square Error (ISE) to tune controller gains (Kp, Ki, Kd, λ, μ,), virtual inertia gains (H_v), and virtual damping gains (D_v) (Zaid et al., 2023; Mishra et al., 2024). Figure 3 shows the metaheuristics classification.

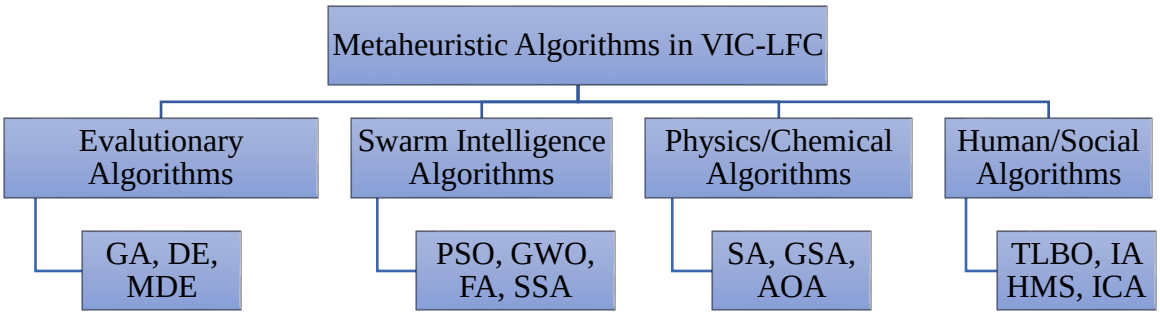

Figure 3: Classification of metaheuristic algorithms as applied in VIC-LFC (Mishra et al., 2024)

4.1 Evolutionary algorithms for VIC-LFC

Evolutionary Algorithms (EA) rely on population genetics to traverse continuous search spaces without gradient information (Jin et al., 2021). While Genetic Algorithms (GA) provide broad exploration, Modified Differential Evolution (MDE) enhances local searchability and convergence rates via dynamic scaling factors and adaptive mutation (Amr et al., 2022; Mishra et al., 2024). A comparative analysis of key Evolutionary Algorithms (EA) applied to Virtual Inertia Control (VIC) and Load Frequency Control (LFC) in islanded microgrids is presented Table 2.

4.2 Swarm intelligence algorithms for VIC-LFC

Swarm Intelligence (SI) algorithms model collective foraging and social organization. Particle Swarm Optimization (PSO), Grey Wolf Optimizer (GWO), Firefly Algorithm (FA), and Salp Swarm Algorithm (SSA) optimize controller parameters to shorten settling time and suppress dynamic frequency oscillations (Venkatesh et al., 2020; Ghodsi et al., 2022; Sharma & Pradhan, 2023; Amiri et al., 2023). Table 3 shows the comparative analysis of swarm intelligence algorithms as applied to microgrid.

Table 2: Comparative Analysis of Evolutionary Algorithms in Microgrid VIC-LFC

Algorithm	Swarm / Biological Analogy	Primary Control Topology in VIC-LFC	Key Operational Advantage	Primary Limitation
Genetic Algorithm (GA)	Natural selection, inheritance, chromosomal crossover	FOPID, standard PID, ADRC in BESS control loops	Simple structure; global exploration across discrete spaces	Slow execution; premature convergence in high dimensions
Differential Evolution (DE)	Vector difference mutation and recombination	Cascaded PIDFN, 2-DOF controllers, derivative VIC	Fast convergence; superior continuous-space exploitation	Vulnerable to search stagnation in non-convex spaces
Modified DE (MDE)	Dynamic scaling, adaptive crossover, opposition learning	Adaptive VIC (AVIC), multi-objective LFC, EV storage	Prevents local minima trapping; high RoCoF/nadir tracking accuracy	Higher memory and computational complexity per iteration

4.3 Physics and Chemical-Inspired Algorithms for VIC-LFC

Physics/chemical algorithms mimic thermodynamic cooling (Simulated Annealing - SA), gravitational forces (GSA), inter-atomic dynamics (Atom Search Optimization - ASO), molecular reactions (CRO/ACROA), and mass equilibrium (Equilibrium Optimizer - EO) (Duan et al., 2023; Rajaguru & Annapoorani, 2025; Behera et al., 2022; Agwa, 2020). Note that while Agwa (2020) originally evaluated EO in interconnected power systems, its mass-balance pool mechanism has been successfully adapted to standalone VIC-LFC gain synthesis. Table 4 provides a structured comparative analysis of physics- and chemical-inspired algorithms applied to VIC-LFC in islanded microgrids.

4.4 Human and Social-Inspired Algorithms for VIC-LFC

Human/social algorithms simulate imperialistic socio-political competition (ICA), classroom instruction (TLBO), cognitive thinking (HMS), and societal ideological evolution (IA) (Atashpaz-Gargari & Lucas, 2007; Rao et al., 2011; Mousavirad & Ebrahimpour-Komleh, 2017; Saber et al., 2023). Human- and social-inspired metaheuristic algorithms can be used to explore a search space of parameters and reduce time domain cost such as Integral Time Absolute Error (ITAE) and Integral Time Square Error (ITSE) by taking inspiration from social structures, learning models, human search processes and cultural evolution (Barisal, 2015; Dev et al., 2024). Table 5 presents a comparative analysis of human- and social-inspired algorithms applied to Virtual Inertia Control integrated with Load Frequency Control (VIC-LFC) in islanded microgrid architectures.

Table 3: Comparative Analysis of Swarm Intelligence Algorithms in Microgrid Applications

Algorithms	Swarm Inspiration	Primary Control Topology in VIC-LFC	Key Operational Advantage	Primary Limitation
PSO	Bird flocking / fish schooling.	Baseline PI/PID, Hybrid RL-VIC.	Computational simplicity and rapid initial search.	Susceptible to premature convergence in multi-modal landscapes.
GWO	Grey wolf social hierarchy & hunting	FOPID-IIC, Fuzzy Type-II Sugeno	Effective balance between global exploration and local refinement.	Search speed degrades with high parameter dimensionality.
FA	Bioluminescent firefly attraction	Cascaded PD-FOPID in BESS-VIC	Robust performance in non-convex gain landscapes	High computational complexity per iteration ($O(n^2)$)
SSA	Ocean Salp chain foraging	Tilt-Integral-Derivative (TID), Fuzzy-PID	Chain dynamics prevent local minima trapping	Sensitive to the decay schedule of convergence parameter c_1

Table 4: Comparative Analysis of Physics/Chemical Algorithms in Islanded Microgrid Applications

Algorithm	**Physical / Chemical Inspiration**	**Primary Control Topology in VIC-LFC**	**Key Operational Advantage**	**Primary Limitation**
SA	Metal annealing cooling	Classical PID and PI-Virtual Inertia Gain.	Probabilistic mechanism to escape local minima	Slow execution; highly sensitive to cooling schedules.
GSA	Universal gravity & mass interaction	Cascaded PID-FOPID / Adaptive Fuzzy-PID.	Strong initial global exploration via heavy mass attraction.	High risk of premature trapping in multi-variable spaces.
ASO / AOA	Lennard-Jones inter-atomic forces.	FOPID with Virtual Inertia & Damping Gain Tuning	High population diversity; resists local trapping	Requires precise tuning of interaction force parameters.
CBO	Collision momentum conservation.	Multi-stage PID with BESS / Flywheel VIC.	Parameter-free core search logic.	Slow boundary exploration on flat objective surfaces.
CRO / ACROA	Molecular collision and reaction energy.	FOPI-FOPD and Adaptive Fuzzy FOPI-FOPID.	Flexible search balancing decomposition and synthesis.	Tracking potential/kinetic energy increases computational overhead.
EO	Controlled volume mass balance.	Cascaded (I-P)-PDN and FO-Multistage VSG.	Rapid convergence rate; low settling time (T_s).	Prone to local stagnation if generation rate decays rapidly.

4.5 Novel and Hybrid Optimization Paradigms

To solve complex non-convex search spaces in modern hybrid microgrids, advanced novel and hybrid optimizers have been introduced (Iraj et al., 2024; Philip et al., 2025; Nanda-Kumar & Mohanty, 2022; Davoudkhani et al., 2024). Comparative summary of recent novel and hybrid optimization techniques Table 6.

Table 5: Comparative Analysis of Human/Social Algorithms in Islanded Microgrid Applications

Algorithm	Human / Social Model	Key Advantage in VIC-LFC	Convergence Behavior	Primary Limitation
ICA	Imperialist power dynamics & colony assimilation.	Robust against system parameter uncertainties.	Fast initial convergence; strong exploration.	Susceptible to local trapping if assimilation rate is high.
TLBO	Teacher guidance & peer learner interaction.	Algorithm parameter-free execution.	High consistency across independent runs.	Performance degrades if student diversity drops.
HMS	Cognitive search & mental grouping.	Superior at escaping local minima in constrained LFC.	Balanced exploration-exploitation via clustering.	Tracking mental strategy clusters adds computational overhead.
IA	Ideological evolution & societal debate.	Effective for multi-objective trade-offs (RoCoF vs. SoC).	Smooth convergence trajectory.	Slower fine-tuning exploitation in localized search spaces.

4.6 Comparative Analysis of Metaheuristic Performance Metrics

Controller performance evaluation relies on time-domain criteria (Maximum Overshoot - MOS, Settling Time T_s, Frequency Nadir, RoCoF) and error integral criteria (ITAE, ISE, ITSE, IAE). For instance, Walrus Optimization Algorithm (WaOA)-tuned PID controllers achieved lower frequency nadir drops and lower RoCoF compared to conventional Internal Model Control (IMC) and H_{infty} controllers under random load steps (Akinwola et al., 2025). Furthermore, Pelican Optimization Algorithm (POA)-tuned controllers demonstrated explicit minimization of error metrics, achieving an ITAE value of 1.9215 s under a 0.1 p.u. step load disturbance.

Across surveyed literature, metaheuristic parameter tuning consistently outperforms classical Ziegler-Nichols (Z-N) and manual trial-and-error methods, as demonstrated by comprehensive controller-optimizer benchmark studies. The controller optimizer comparisons for synthetic-inertia-relevant islanded microgrids are presented in Table 7.

Table 6: Comparative Summary of Recent Novel and Hybrid Optimization Techniques

Technique	Operational Inspiration / Mechanism	Primary Control Topology	Main Performance Outcome
Mountaineering Team (MTBO)	Team summiting behavior and leadership shift.	1PD-PI Controller	Outperformed PSO/WOA in ITSE and overshoot reduction.
Hybrid SSA-MGO	Sparrow Search + Mountain Gazelle co-evolution.	Adaptive VIC & Inverter Control	20% RoCoF reduction; 26.7% faster recovery (Philip et al., 2025).
Modified Golden Jackal (MGJO)	Variable Sine-Cosine adopted Scaling Factor.	Adaptive Fuzzy PIDF.	Enhanced tracking precision under non-linear deadbands.
Coati Optimization (COA)	Coati hunting and predator evasion dynamics.	1PD-3DOF-PID with EV Fleet.	Robust handling of stochastic mobile storage disturbances.
Walrus Optimization (WaOA)	Walrus social interaction and resting habits.	WaOA-PID for Autonomous Microgrids.	Lowest frequency nadir drop and minimal RoCoF (Akinwola et al., 2025).

5. OPEN RESEARCH CHALLENGES AND APPLICATION PERSPECTIVES

While metaheuristic optimization strategies significantly enhance VIC-LFC performance, several open challenges must be addressed:

- Real-Time Computational Overhead: Iterative population updates incur substantial execution delays, limiting direct high-frequency online tuning. Offline tuning with adaptive gain-scheduling or real-time surrogate modeling presents a viable solution.
- Hardware-in-the-Loop (HIL) Validation: Most existing literature relies on numerical MATLAB/Simulink simulations. Experimental validation via OPAL-RT or dSPACE HIL

Table 7: Summary Survey of Controller-Optimizer Literature in Synthetic Inertia-Relevant Microgrids

S/No.	Study	Focus Area	Optimizer Tuned	Structure	Main Reported Outcome
1	Magdy et al. (2020)	VIC under high-RES penetration	GOA	FOPID-VIC	Reduced Δf overshoot and enhanced nadir.
2	Khezri et al. (2021)	Coordinated LFC & synthetic inertia.	Hybrid PSO-GWO	FOPID	Superior dynamic settling compared to standalone PSO/GWO.

platforms is vital to verify controller execution under real-world sensor noise and signal quantization.

- Cyber-Physical Security**:** Communication-assisted multi-agent LFC structures are vulnerable to Denial-of-Service (DoS) and False Data Injection (FDI) attacks. Resilient optimization frameworks integrating cyber-attack mitigation loops are required.
- Multi-Objective Pareto Optimization**:** Single objective functions (e.g., ITAE) often neglect secondary constraints like battery State-of-Charge (SoC) degradation, thermal stress, and actuator saturation. Multi-objective Pareto formulations balancing dynamic performance and asset life are necessary.

5.1 Relevance to Regional Sustainable Development (e.g., Sub-Saharan & Nigerian Microgrid Infrastructure)

Addressing microgrid stability carries significant regional importance for developing nations prioritizing rural electrification and sustainable development. For example, in Sub-Saharan Africa and specifically Nigeria, national energy transition initiatives rely on standalone solar-PV-diesel-battery microgrids to electrify off-grid rural communities and industrial clusters. However, these isolated networks frequently suffer from trip-outs triggered by sudden load switching and cloud cover transients due to minimal system inertia. Implementing robust metaheuristic-tuned VIC-LFC frameworks provides an affordable, software-driven path to stabilize regional microgrids without requiring over-sized physical storage, supporting sustainable economic expansion and grid independence.

6. CONCLUSION

Metaheuristic optimization algorithms provide an efficient framework for stabilizing low-inertia islanded microgrids. By optimizing synthetic inertia and load frequency control gains across evolutionary, swarm, physics-based, human-inspired, and novel hybrid variants (such as WaOA, SSA-MGO, and MTBO), dynamic responses under severe renewable intermittent conditions can be substantially enhanced. To translate theoretical advances into resilient grid infrastructure, future efforts must focus on lowering computational overhead, conducting HIL experimental validation, securing cyber-physical control links, and adopting multi-objective formulations tailored to real-world battery constraints and regional electrification challenges.

ABSTRACT

Rural communities in Nigeria often require electricity for different critical services at different times, including agricultural activities, healthcare, and emergency responses. Conventional rural renewable-energy systems are generally fixed-purpose installations, while existing mobile energy-storage research largely focuses on restoration, routing, sizing, and pre-positioning. This paper proposes a Mission-Aware Reconfigurable Energy Hub (MAREH), a deployable photovoltaic–battery energy storage system that retains a common energy backbone while reconfiguring its load priorities according to the active rural mission. The framework integrates photovoltaic (PV) generation, battery storage, supervisory energy management, mission-dependent critical-load prioritization, and deployment-specific electrical safety verification. A two-stage approach is used: the first stage sizes the PV-battery configuration under an ε-constraint formulation, minimizing lifecycle cost subject to explicit service-reliability constraints, and the second stage evaluates the sized system, without further optimization, under three missions — agricultural support, healthcare, and emergency response — using scenario-based deterministic simulation. Four scenarios compare fixed-purpose, conventional deployable, and mission-aware configurations using energy not served, critical energy-service coverage (CESC), renewable fraction, battery state of charge, and system cost. Preliminary results indicate the mission-aware configuration achieves approximately 99% or greater critical-service coverage across the three missions using a 7-kWp PV array and 22-kWh battery, an 8.3% reduction in nominal storage capacity and a 4.2% reduction in lifecycle cost relative to the conventional deployable benchmark. This reduction is accompanied by a small decrease in worst-case coverage (approximately 0.65 percentage points), reflecting a deliberate trade-off in which lower-priority loads are curtailed to protect critical services under scarcity, rather than a uniform improvement. The framework demonstrates that reconfigurability can serve as an additional energy-system resource, letting one deployable renewable-energy asset support changing rural priorities without separate dedicated systems at a quantifiable and disclosed reliability cost.

Keywords: *mission-aware energy hub; mobile microgrid; PV–BESS; rural electrification; reconfigurable energy system; critical services; Nigeria*

1. INTRODUCTION

Reliable electricity remains a major constraint to the delivery of essential services in many rural and underserved communities. The challenge is particularly pronounced where electricity demand is geographically dispersed, conventional grid extension is economically difficult, and critical services

such as healthcare, water supply, agricultural processing, refrigeration, and communications require dependable electricity. Decentralized renewable-energy systems, particularly photovoltaic (PV) and battery energy storage systems (BESS), have consequently become important alternatives for rural electrification and local energy resilience.

In Nigeria, decentralized energy programmes have expanded substantially through mini-grids and standalone solar systems targeted at unserved and underserved communities. However, most of these interventions are conceived as stationary assets, with their generation and storage infrastructure permanently associated with a particular community or facility. This approach is appropriate where the demand location is relatively stable, but it becomes less effective when the highest-priority energy requirement changes spatially or temporally. A rural community may require agricultural support during normal periods, emergency healthcare during a disease outbreak or disaster, and temporary critical services following infrastructure failure. A permanent energy system designed around only one of these functions may consequently remain underutilized during other periods.

The emergence of mobile energy-storage systems provides an alternative pathway. Previous research has investigated mobile energy storage for distribution-system restoration, emergency load recovery, optimal routing, sizing, and pre-positioning. Lei et al. (2019), for example, developed a framework that co-optimized service restoration, repair-crew deployment, and mobile power-source dispatch following distribution-system disruptions. Bose et al. (2022) in the same vein formulated the joint routing of mobile energy storage systems and load restoration in microgrids. Wang et al. (2022) extended the concept toward resilience-driven sizing and pre-positioning of mobile energy-storage systems in decentralized networked microgrids. These studies demonstrate the value of mobility as an energy-system resource, but their principal concern is the movement, positioning, or dispatch of mobile energy resources for network restoration and resilience rather than the reconfiguration of a single deployable energy asset among distinct rural service missions.

A second body of literature concerns renewable-energy-based rural electrification and PV–BESS systems. Such systems can provide electricity where grid extension is difficult or unreliable, while energy storage can improve supply continuity and enable critical loads to operate beyond periods of solar availability. Microgrid control research has also established hierarchical and supervisory control structures capable of coordinating distributed generation, storage, and loads (Bidram & Davoudi, 2012). Energy-storage technologies and their application to microgrids have been extensively reviewed by Faisal et al. (2018).

The challenge addressed in this study is therefore not the invention of mobile PV–BESS hardware. Portable and mobile energy systems already exist in research and practice. Rather, the study asks a different engineering question: can a single deployable PV–BESS energy backbone be configured to serve different rural missions by changing the priority and allocation of its energy services while retaining the same core generation and storage assets?

This question becomes particularly important when the energy hub is deployed as a transportable electrical installation. Relocation introduces additional electrical-safety considerations because the protective arrangement must be established and verified at the new site before energization. International Electrotechnical Commission (IEC 60364-7-717:2026) specifically addresses electrical installations of mobile or transportable units, while IEC 62548-1:2023 (with Amendment 1:2025) provides requirements relevant to PV array design, protection, switching, and earthing (IEC 60364-7-717:2026 - is confirmed as the published third edition of this part, superseding the 2009 second edition, at the time of manuscript preparation)

Accordingly, this paper proposes a Mission-Aware Reconfigurable Energy Hub (MAREH) framework that combines a common PV–BESS energy backbone with mission-dependent load prioritization, deployment-specific electrical safety verification, and rapid service reconfiguration. Three representative missions are considered: agricultural support, healthcare, and emergency response.

The main contribution is the formalization and preliminary quantification of mission-aware reconfiguration as a design and operational layer for a deployable rural energy system. Unlike approaches centered on where mobile energy storage should be located or routed, the proposed framework focuses on what service configuration the same energy asset should adopt when its mission changes.

2. RELATED LITERATURE AND RESEARCH GAP

2.1 Rural Renewable-Energy Systems

PV-based distributed generation combined with battery storage has become an important solution for rural electrification because it can operate independently of conventional electricity networks and can be scaled according to local demand. Hybrid renewable-energy optimization studies have demonstrated the technical and economic feasibility of PV–BESS configurations for isolated communities, including applications relevant to rural Nigeria (Oladeji et al., 2021; Elegeonye et al., 2023) and the wider Sub-Saharan African region (Babayomi et al., 2023)

The principal limitation of a conventional fixed configuration is that system sizing is generally determined by a relatively stable load profile. Consequently, a system optimized for agricultural processing may not be appropriately configured for healthcare or emergency response. Conversely, sizing the system for the highest conceivable demand can increase capital cost and leave generation and storage capacity underutilized during normal operation.

2.2 Mobile Energy Storage and Resilience

Mobile energy storage introduces spatial flexibility into electricity system planning. Lei et al. (2019) demonstrated that mobile power sources can be coordinated with restoration activities to improve distribution-system recovery following disruption. Bose et al. (2022) developed a mixed-integer optimization framework for jointly routing mobile energy-storage systems and restoring curtailed loads. Wang et al. (2022) investigated resilience-driven sizing and pre-positioning of mobile energy storage in networked microgrids, incorporating essential and non-essential loads into the resilience assessment.

These studies establish an important foundation for mobile energy resources but focus primarily on restoration, routing, placement, sizing, and resilience. The proposed framework shifts the focus from the movement of the energy asset to the reconfiguration of its service mission.

2.3 Microgrid Control and Energy Management

Microgrid control architectures have traditionally been organized hierarchically, with lower control layers regulating local voltage, frequency, and power flows and supervisory layers coordinating generation, storage, and loads (Bidram & Davoudi, 2012). This hierarchical concept provides a suitable foundation for mission-aware energy management because a supervisory layer can modify load priorities while the underlying electrical control remains unchanged.

Energy-storage systems are particularly important because they permit energy collected during periods of renewable generation to be allocated according to changing demand requirements (Faisal et al., 2018). In the proposed framework, the BESS is therefore not simply a backup component; it becomes an energy-allocation resource through which the Energy Management System (EMS) can preserve high-priority services during periods of energy scarcity.

2.4 Transportable Electrical Installations and Safety

Physical mobility creates an additional engineering dimension that is often separated from energy optimization. A transportable electrical installation must be safely disconnected, moved, re-established, and verified before operation at the new location. IEC 60364-7-717:2026 specifically applies to electrical installations of mobile and transportable units and includes provisions related to protection against electric shock and additional protection.

For the proposed hub, the electrical safety layer includes protective bonding, earthing, protection against electrical faults, and verification before energization, drawing on the earthing and protective-conductor provisions of IEC 60364-5-54:2011 and the PV-array protection and earthing requirements of IEC 62548-1:2023/AMD1:2025. The safety layer is therefore treated as a deployment gate rather than as an afterthought to the energy-management problem.

2.5 Research Gap

The reviewed literature indicates four related but distinct research streams: rural renewable-energy systems, microgrid energy management, mobile energy storage for resilience, and transportable

electrical-installation safety. However, these streams are rarely integrated around a single rural energy asset that can change its service mission without changing its fundamental generation and storage backbone.

The specific gap addressed in this study is therefore the following:

Existing mobile-energy research largely addresses emergency restoration, mobile-storage routing, sizing, or pre-positioning, while rural renewable-energy studies predominantly consider fixed-purpose systems. Less attention has been given to a single deployable PV–BESS asset whose service configuration is explicitly reconfigured among distinct rural missions — agricultural, healthcare, and emergency — using mission-dependent critical-load priorities while incorporating deployment-specific electrical safety verification.

The contribution is consequently not claimed as novel mobile PV–BESS hardware. Instead, the study proposes a mission-aware engineering framework and preliminary quantitative assessment for converting a deployable energy asset into a flexible provider of different critical rural services.

3. SYSTEM MODELING, OPTIMIZATION, AND SIMULATION METHODS

3.1 Proposed System Architecture

The proposed mission-aware reconfigurable energy hub consists of a PV array, BESS, bidirectional inverter, DC/AC protection, distribution system, supervisory EMS, and mission-dependent loads. The common energy backbone remains physically unchanged while the EMS changes the active service configuration according to the declared mission.

The three missions are:

• M1 — Agricultural mission: agricultural extension and Information and Communication Technology (ICT) services, water pumping, productive loads, lighting, and cold-chain/refrigeration.

• M2 — Healthcare mission: medical equipment, medical refrigeration, water supply, lighting, and communications.

• M3 — Emergency mission: emergency healthcare, water supply, communications, lighting, and other essential community services.

The architecture incorporates three interconnected pathways:

1. Energy pathway: PV → DC protection → BESS/DC bus → inverter → AC distribution → loads.

2. Mission pathway: mission declaration → EMS → load prioritization → dispatch/reconfiguration.

3. Safety pathway: bonding → deployment-specific earthing → protection verification → safe energization.

3.2 PV Generation Model

$$P_{PV} = P_{PV,r} \times \frac{G(t)}{G_r} \times [1 + \gamma \cdot (T_c(t) - T_r)] \times \eta_{sys} \ldots\ldots\ldots (1)$$

Where

- $P_{PV}(t)$: Actual PV power output at time t.
- $P_{PV,r}$: Rated (nominal) PV power under reference conditions.
- $G(t)$: Solar irradiance at time t (W/m²).
- G_r: Reference irradiance, typically 1000 W/m² (Standard Test Conditions).
- γ: Temperature coefficient of power (usually negative, e.g., −0.004/°C).
- $T_c(t)$: PV cell temperature at time t.
- T_r: Reference temperature, usually 25 °C.
- η_{sys}: System efficiency factor (accounts for inverter, wiring, and other losses).

3.3 Mission-Dependent Load Model

$$P_{L,m}(t) = \sum_{k=1}^{N_L} x_{m,k}(t) \cdot P_{m,k}(t) \dots\dots\dots\dots (2)$$

Where,

- $P_{L,m}(t)$: Total load power demand for category m at time t.
- N_L: Total number of loads considered in the system.
- $x_{m,k}(t)$: Binary status indicator (0 or 1) showing whether load k in category m is ON or OFF at time t.
- $P_{m,k}(t)$: Power consumption of load k in category m at time t.
- $x_{m,k}(t)$ is the activation state of load group k under mission m.

3.4 Battery Model

During charging:

$$SOC(t+1) = SOC(t) + \eta_c \times P_{ch,t} \times \frac{\Delta t}{E_B} \dots\dots\dots\dots (3)$$

Where,

- SOC(t): Battery state of charge at time *t* (fraction or %).
- SOC(t+1): Battery state of charge at the next time step.
- η_c: Charging efficiency (accounts for losses, typically 0.9–0.95).
- $P_{ch,t}$: Charging power applied at time *t* (kW).
- Δt: Time step length (hours).
- E_B: Nominal battery energy capacity (kWh).

During discharging:

$$SOC(t+1) = SOC(t) - P_{dis,t} \times \frac{\Delta t}{(\eta_d \times E_B)} \dots\dots\dots\dots (4)$$

Where,

- SOC(t): State of charge at time *t*.
- SOC(t+1): State of charge at the next time step.
- $P_{dis,t}$: Discharging power at time *t* (kW).
- Δt: Time step length (hours).
- η_d: Discharging efficiency (accounts for conversion losses, typically 0.9–0.95).
- E_B: Nominal battery energy capacity (kWh).

with:

$$SOC_{min} \leq SOC(t) \leq SOC_{max} \quad (5)$$

Where,

- SOC(t): State of charge at time *t*.
- SOC_{min}: Minimum allowable SOC (often 10–20% of capacity, to prevent deep discharge and extend battery life).
- SOC_{max}: Maximum allowable SOC (usually 90–100% of capacity, to avoid overcharging).

$$0 \leq P_{ch,t} \leq P_{ch,max} \quad (6)$$

Where,

- $P_{ch,t}$: Charging power applied at time *t* (kW).
- $P_{ch,max}$: Maximum allowable charging power (kW), determined by the battery's design and inverter limits.

$$0 \leq P_{dis,t} \leq P_{dis,max} \quad (7)$$

Where,

- $P_{dis,t}$: Discharging power at time *t* (kW).

- $P_{dis,max}$: Maximum allowable discharging power (kW), set by the battery's design, inverter, and safety limits.

3.5 Energy Balance and Service Adequacy

$$P_{PV,t} + P_{dis,t} = P_{L,m,t} + P_{ch,t} + P_{loss,t} + P_{ENS,t} \quad (8)$$

Where,

- $P_{PV,t}$: PV power generation at time *t*.
- $P_{dis,t}$: Battery discharging power at time *t*.
- $P_{L,m,t}$: Load demand for category *m* at time *t*.
- $P_{ch,t}$: Battery charging power at time *t*.
- $P_{loss,t}$: System losses (inverter, wiring, conversion, etc.) at time *t*.
- $P_{ENS,t}$: Power not supplied (unmet demand) at time *t*.

Annual Energy not Served:

$$ENS = \sum_{t=1}^{N} P_{ENS,t} \cdot \Delta t \ldots\ldots\ldots (9)$$

Where,

- ENS: Total energy not supplied (kWh) over the evaluation horizon.
- $P_{ENS,t}$: Power not supplied at time *t* (kW).
- Δt: Duration of each time step (hours).
- N: Total number of time intervals considered.

Critical Energy-Service Coverage can now be computed has:

$$CESC = \left[1 - \frac{ENS_C}{E_{C,demand}}\right] \times 100 \ldots\ldots\ldots\ldots (10)$$

Where,

- CESC: Percentage measure of supply continuity for customer C.
- ENS_C: Energy not supplied to customer C (kWh).
- $E_{C,demand}$: Total energy demand of customer *C* over the evaluation period (kWh).

3.6 Deployment Safety Model

Relocation is treated as an engineering process rather than simply transportation.

Transport → Physical Setup → Bonding/Earthing → Protection Verification → Energization (11)

The safety state is:

S_d = 1 if required safety verification is satisfactory; 0 otherwise (12)

Deployment time is therefore stated as follows:

$$T_{deploy} = T_{transport} + T_{setup} + T_{safety} \quad (13)$$

Where,

- T_{deploy}: Total deployment time.
- $T_{transport}$: Time required to transport equipment, personnel, or resources to the deployment site.
- T_{setup}: Time required to set up the system, equipment, or infrastructure.
- T_{safety}: Time allocated for safety checks, compliance, and risk mitigation before operation begins.

The model deliberately does not impose one universal earth-resistance value because the acceptance criterion depends on the selected earthing topology, inverter configuration, protective-device characteristics, and applicable installation requirements.

3.7 Two-Stage Optimization and Evaluation

The first stage determines PV and BESS capacities through an explicit optimization. The objective is to have:

$$\min C_{NPC} \quad (14)$$

Where,

- C_{NPC}: Typically stands for *Cost Net Present Cost* (sometimes *Cumulative Net Present Cost*), which represents the total discounted cost of the system over its lifetime.
- min C_{NPC}: The optimization goal is to minimize the net present cost, balancing capital investment, operation, maintenance, replacement, and reliability penalties.

Which is subject to:

$$ENS_C \leq \varepsilon_{ENS} \quad (15)$$

Where,

- ENS_C: Energy not supplied to customer *C* (kWh), as defined earlier in Eq. (9).
- ε_{ENS}: Maximum allowable energy not supplied (kWh) — a threshold or tolerance level set by the planner.

$$CESC \geq \varepsilon_{CESC} \quad (16)$$

Where,

- CESC: Customer Energy Supply Continuity index (Eq. 10), expressed as a percentage of demand met.
- ε_{CESC}: Minimum acceptable continuity threshold (e.g., 95% or 99%), set by planners or regulators.

and the battery, inverter and energy-balance constraints. Net Present Cost is therefore:

$$C_{NPC} = C_{CAP} + C_{REP} + C_{OM} - C_{SALV} \quad (17)$$

Where,

- C_{CAP}: Capital cost — the upfront investment in PV panels, BESS, inverters, and other infrastructure.
- C_{REP}: Replacement cost — expenses for replacing components during the system's lifetime (e.g., batteries after 8–10 years).
- C_{OM}: Operation and maintenance cost — recurring expenses for upkeep, servicing, and monitoring.
- C_{SALV}: Salvage value — the residual value of components at the end of the project lifetime, subtracted since it offsets costs.

An ε-constraint formulation is preferred to an arbitrarily weighted objective because the critical-service requirements can be explicitly imposed as constraints rather than folded into a single scalarized cost with subjectively chosen weights.

The ε-constraint problem in Eqs. (14)–(17) is solved via exhaustive grid-search enumeration of candidate PV capacities (0.5 kWp increments) and BESS capacities (1 kWh increments); each candidate is evaluated against the 8,760-hour deterministic simulation, and the lowest-cost candidate satisfying the ENS and CESC constraints in Eqs. (15)–(16) is selected as the sized configuration reported in Table 1.

The second stage is an evaluation, not a further optimization: the PV–BESS configuration obtained in the first stage is held fixed and simulated under each of the three mission states in turn, so that ENS, CESC and related indicators can be compared across missions for a single sized system.

$$M = \{M1, M2, M3\} \quad (18)$$

Where,

- M: The set of mission states considered in the second-stage evaluation, consistent with the mission definitions in Section 3.1.
- M1: Agricultural mission.
- M2: Healthcare mission.
- M3: Emergency mission

Within each mission m, individual loads are further classified by supply priority using a separate notation, C1/C2/C3 (critical/priority/non-critical), so as not to conflict with the mission labels M1–M3 above: C1 denotes critical loads that must always be supplied (e.g., medical equipment,

emergency communications); C2 denotes priority loads that are important but flexible (e.g., extension services, community facilities); and C3 denotes non-critical loads that can be curtailed during shortages (e.g., non-essential lighting, low-priority appliances). This priority tier $c(k) \in \{C1, C2, C3\}$ is assigned to each load k in Eq. (2) and governs the curtailment order referenced in Sections 4.3 and 4.6.

3.8 Mission Reconfiguration

A mission transition is represented by:

$$M_i \rightarrow M_j \qquad (19)$$

Where,

Mi, Mj ∈ {M1, M2, M3}: the mission states defined in Section 3.1 (agricultural, healthcare, emergency). M_i is the mission being exited and M_j is the mission being entered.

This mission-level transition is distinct from the within-mission load-priority tiers C1–C3 introduced in Section 3.7, which are unaffected by a mission transition unless the EMS also re-evaluates load-priority assignment under the new mission.

where:

$$T_R = T_{detect} + T_{decision} + T_{switch} \qquad (20)$$

Where,

- T_R: Total response time — the duration from the onset of an event to the completion of a corrective action.
- T_{detect}: Time taken to detect the event or fault (e.g., sensor or monitoring delay).
- $T_{decision}$: Time taken to process information and decide on corrective action (e.g., controller or operator decision-making).
- T_{switch}: Time taken to physically implement the corrective action (e.g., switching circuits, activating backup supply).

When physical relocation is necessary, $T_{response}$ now becomes :

$$T_{response} = T_{transport} + T_{setup} + T_{safety} + T_{reconfig} \qquad (21)$$

Where,

- $T_{response}$: Total system response time — the duration from initiation to full operational readiness.
- $T_{transport}$: Time required to move equipment, personnel, or resources to the deployment site.
- T_{setup}: Time required to assemble and configure the system physically.
- T_{safety}: Time allocated for safety checks, compliance, and risk mitigation.
- $T_{reconfig}$: Time required to reconfigure or adapt the system to specific conditions (e.g., load adjustments, network re-routing, or controller reprogramming).

3.9 Simulation Scenarios

S1 — Fixed agricultural system: permanently configured for agricultural services.

S2 — Fixed healthcare system: permanently configured for healthcare services.

S3 — Conventional deployable system: physically transportable but operated without the proposed mission-aware load-prioritization strategy.

S4 — Proposed mission-aware system: a common PV–BESS backbone dynamically reconfigured between M1, M2, and M3.

3.10 Performance Indicators

The principal indicators are Net Present Cost (NPC), ENS, CESC, RF, SOC_{min} and response/reconfiguration time. Renewable fraction is:

$$RF = \left[\frac{E_{PV,supplied}}{E_{total,supplied}}\right] \times 100 \qquad (22)$$

Where,

- RF: Renewable fraction (%) — the share of total supplied energy that comes from PV.
- $E_{PV,supplied}$: Energy supplied by PV generation over the evaluation horizon (kWh).

- $E_{total,supplied}$: Total energy supplied to loads (kWh), including PV, BESS discharge, and possibly other sources.

4. CASE STUDY, SIMULATION RESULTS AND DISCUSSION

4.1 Case-Study Basis

A representative off-grid rural Nigerian community is considered. The proposed hub operates independently of the utility grid and can be relocated where required.

Three mission load profiles are considered. The preliminary average daily demands are approximately 26.4 kWh/day for agricultural operation, 34.2 kWh/day for healthcare operation and 36.1 kWh/day for emergency operation.

These load figures are planning-level estimates derived from assumed appliance loads and duty cycles rather than site-measured Nigerian data; consequently, the numerical results reported in Sections 4.2–4.4 (including cost and coverage figures presented to one decimal place) should be read as illustrative outputs of this preliminary model rather than validated, deployment-ready estimates.

4.2 Preliminary PV–BESS Configurations

Table 1: *Preliminary PV–BESS configurations*

Scenario	Configuration	PV (kWp)	BESS (kWh)	Approx. NPC
S1	Fixed agricultural	5.0	16	$12,400
S2	Fixed healthcare	6.5	23	$15,900
S3	Conventional deployable	7.0	24	$16,700
S4	Mission-aware	7.0	22	$16,000

Planning-level model outputs based on assumed component costs, rounded to the nearest $100 to reflect their illustrative nature; not current Nigerian market quotations. Actual figures may vary by approximately ±10–15% depending on component sourcing and exchange rates.

The preliminary optimization indicates that the mission-aware system requires approximately 7 kWp PV and 22 kWh BESS. Relative to the conventional deployable benchmark, the proposed configuration reduces nominal battery capacity by approximately 8.3%.

4.3 Mission-Level Performance

Table 2: *Preliminary mission-level performance of S4*

Mission	Annual ENS (kWh)	CESC (%)	Renewable fraction (%)	Minimum SOC (%)
M1 Agricultural	1,322.2	100.0	68.7	59.2
M2 Healthcare	621.3	100.0	56.2	26.0
M3 Emergency	471.7	99.1	55.0	20.0

The results demonstrate that total ENS is not necessarily equivalent to critical-service failure. The mission-aware controller allows lower-priority loads to be curtailed when available energy becomes constrained while protecting critical services.

4.4 Conventional Versus Mission-Aware Deployment

Table 3: *Preliminary comparison between S3 and S4*

Indicator	S3 Conventional	S4 Mission-aware	Difference
PV capacity (kWp)	7.0	7.0	0
BESS capacity (kWh)	24	22	−8.3%
Approx. NPC	$16,700	$16,000	−4.2%
Minimum CESC (%)	99.75	99.10	−0.65 percentage point
Average renewable fraction (%)	55.3	60.0	+4.7 percentage points
Minimum SOC (%)	20.0	20.0	Same

The comparison indicates that mission-aware reconfiguration reduces nominal battery capacity by approximately 8.3% and lifecycle cost by approximately 4.2% relative to the conventional deployable benchmark. This is not a uniform improvement: it is accompanied by a small reduction in worst-case critical-service coverage, from 99.75% under S3 to 99.10% under S4, a decrease of 0.65 percentage points. This reflects a deliberate design trade-off rather than an unqualified gain — the mission-aware controller achieves its capacity and cost reduction precisely by curtailing non-critical loads when energy becomes scarce, which slightly relaxes the worst-case reliability margin relative to a conventionally sized deployable system. Whether this trade-off is acceptable depends on the tolerance for marginal reductions in critical-service coverage in exchange for lower capital cost and reduced battery capacity and should be stated as an explicit design choice rather than presented as a strictly dominant result.

These percentage differences are point estimates from a single deterministic scenario set using assumed cost and load parameters; they have not yet been tested against alternative cost assumptions or solar-resource years, and a sensitivity analysis is identified as a priority next step (Section 5).

4.5 Deployment and Safety Implications

The proposed framework separates mission switching from physical relocation. If the hub remains in place, changing the service mission requires primarily EMS-level reconfiguration. If the hub is moved, transportation, physical setup, protective bonding, deployment-specific earthing, and safety verification are required before energization.

4.6 Engineering Significance

The results support three principal observations. First, the three missions have materially different energy characteristics. Second, mission-aware energy management provides an alternative to simply increasing PV and battery capacity at a small and explicitly quantified reliability cost rather than a free improvement. Third, reconfigurability itself becomes an engineering resource. Instead of maintaining separate energy systems for agricultural, healthcare, and emergency applications, a common PV–BESS backbone can be reassigned according to the current mission.

The contribution is therefore not the physical invention of mobile PV–BESS equipment. The contribution lies in the formalization and preliminary quantification of mission-aware service reconfiguration within a deployable rural energy hub, together with deployment-specific electrical safety verification.

5. CONCLUSION AND FUTURE WORK

This study presented a mission-aware engineering framework for a deployable PV–BESS energy hub intended to provide changing critical services in rural Nigeria. The framework combines a common renewable-energy and storage backbone with mission-dependent load prioritization, supervisory energy management and deployment-specific electrical safety verification.

Unlike conventional fixed-purpose rural energy systems, the proposed hub can be configured for agricultural, healthcare or emergency operation without replacing its fundamental generation and storage infrastructure. Unlike mobile-energy-storage research primarily concerned with routing, restoration, or pre-positioning, the proposed framework focuses on how the service configuration of a common energy asset can change when its mission changes.

The preliminary simulation indicates that the mission-aware configuration can provide approximately 99% or greater critical-service coverage under the three mission states while requiring approximately 22 kWh of battery storage compared with 24 kWh for the conventional deployable benchmark, an approximately 8.3% reduction in nominal storage capacity, accompanied by a 0.65-percentage-point reduction in worst-case coverage under the assumed conditions. This trade-off, rather than a uniform improvement, is the honest characterization of the result.

The study further establishes deployment safety as an integral component of the framework. A relocated hub is not considered ready for operation until its protective bonding, deployment-specific earthing, and electrical safety verification have been completed.

The findings should nevertheless be interpreted as a preliminary engineering assessment rather than field-validated optimization. The current model uses planning-level mission profiles, assumed component costs, and a preliminary deterministic solar-resource representation. Further work will therefore incorporate site-specific Nigerian solar-resource data, measured or validated agricultural and healthcare load profiles, battery degradation, component replacement, sensitivity analysis, and uncertainty in solar availability.

Future development should also include detailed electrical design of the protective system, including inverter earthing topology, protective-device coordination, equipotential bonding, surge protection, earth-electrode arrangement, and commissioning procedures. Hardware-in-the-loop testing and eventually field demonstration will be required to validate the mission-transition logic, deployment sequence, and safety-verification procedure.

The framework ultimately shifts the concept from portable electricity provision to mission-adaptive critical service provision. Such an approach could allow one deployable renewable-energy asset to support productive rural activity during normal conditions and rapidly redirect its energy resources toward healthcare or emergency services when community priorities change.

As an immediate next step, a follow-up study will incorporate NASA POWER solar-irradiance data and validated agricultural and healthcare load profiles for the Ibese-Imasayi corridor, Ogun State, Nigeria, together with a sensitivity analysis of the ε-constraint thresholds and component-cost assumptions, to move the framework from a preliminary planning-level assessment toward a site-validated deployment case.

ABSTRACT

Power transformers are critical assets in electric power systems, and their reliable operation is essential for preventing catastrophic failures and power outages. Continuous condition monitoring is therefore necessary for the early detection of incipient faults. Dissolved Gas Analysis is widely adopted as a diagnostic technique but its effectiveness can be constrained by variability in diagnostic results. Conventional methods have limited capability to provide reliable fault diagnosis and often produce ambiguous or "no decision" outcomes when gas ratios fall outside standard ranges or overlap across multiple fault zones. Similarly, standalone artificial intelligence and machine learning algorithms may have limited generalization capability and perform poorly under new or varying data conditions due to non-optimal hyperparameters. Their performance is also highly dependent on the quality and quantity of training data, making them susceptible to noise, missing values, class imbalance, overfitting, and underfitting. To address these limitations, this study proposes a data-driven transformer fault diagnosis framework based on Artificial Bee Colony (ABC) hyperparameter optimization. The proposed framework employs ABC to optimize the hyperparameters of Random Forest classifiers while Support Vector Machine and Deep Neural Network are included as a benchmark models. The DGA dataset consists of 589 samples with five gas features and was partitioned into training (70%), validation (15%), and testing (15%) subsets. The classification results show that the baseline classifiers achieved accuracies of 78.4% for SVM, 80.4% for RF, and 83.3% for DNN. Following ABC-based hyperparameter optimization, the optimized Random Forest classifier achieved a significantly improved accuracy of 91.2%. The superior classification performance and robustness of the proposed ABC-optimized Random Forest demonstrate its potential for practical application in reliable and accurate real-world power transformer fault diagnosis.

1. INTRODUCTION

Power transformers are among the most critical and expensive assets in modern electrical power systems, linking generation, transmission, and distribution networks. Their reliable operation underpins continuous electricity supply, power quality, and grid stability. Given their strategic importance and high replacement cost, unexpected failures carry severe technical, economic, and environmental consequences, including service interruptions, equipment damage, and reduced system reliability (Mishra et *al.*, 2026). Transformer failures are rarely sudden; they are typically preceded by gradual deterioration processes such as insulation aging, thermal degradation, moisture contamination, partial discharge, arcing, and winding deformation. These early-stage abnormalities, known as incipient faults, produce detectable changes in operating parameters well before catastrophic failure occurs, making their timely identification central to effective condition monitoring and asset management (Saleh et al., 2026; Wang, X.J. (2024).

Conventional transformer health assessment has relied on periodic inspections, offline diagnostic tests, and expert interpretation of data such as Dissolved Gas Analysis (DGA), oil quality, and electrical test results (Dhiman & Kumar,2023). While informative, these methods are labour-

intensive, time-consuming, and reactive, and they struggle to capture the complex nonlinear relationships among operational variables required for accurate fault prediction (Veerappan, 2025). As transformer fleets age under increasingly demanding loading and environmental conditions, the need for intelligent, automated predictive maintenance has grown correspondingly urgent. Machine learning offers a powerful means of extracting meaningful patterns from large volumes of monitoring data (Azmi *et al.*, 2025). Among available algorithms, Random Forest (RF) has attracted particular attention for its high classification accuracy, robustness against overfitting, and effectiveness on nonlinear, high-dimensional datasets (Jing, 2025). However, RF performance depends heavily on proper hyperparameter selection, such as the number of trees and tree depth; poorly chosen values can reduce accuracy and limit generalization (Muneeb, 2024). Metaheuristic optimization techniques have increasingly been used to address this limitation. The Artificial Bee Colony (ABC) algorithm, a swarm-intelligence method inspired by honeybee foraging behaviour, is particularly noted for its strong global search capability, simplicity, and flexibility (Erkan et al., 2023).

The performance of a Random Forest (RF) model is significantly influenced by several key hyperparameters, particularly the number of trees (NumTrees), number of predictors sampled at each split (NumPredictorsToSample), minimum leaf size (MinLeafSize), and maximum number of splits (MaxNumSplits). The number of trees is commonly varied within a range of 50–500, with MATLAB using 100 trees as a typical default (Zhu & Zhang, (2022). The number of predictors sampled at each split controls feature randomness and tree diversity, while the minimum leaf size, commonly varied between 1 and 20, influences tree complexity and overfitting. Similarly, the maximum number of splits controls the depth and complexity of individual trees (Alenezi et al., 2026). Optimal tuning of these hyperparameters is essential for achieving the best possible RF performance (Mumtahina et al., 2024). Conventional approaches such as random search, grid search, and Bayesian optimization can be used; however, they may suffer from limitations related to computational cost, search efficiency, or dependence on predefined search strategies (Dimgba & Andreas, 2024). Therefore, employing a metaheuristic optimization algorithm, such as Artificial Bee Colony (ABC), provides an intelligent search mechanism for exploring the hyperparameter space and identifying near-global optimal parameter combinations (Al Hourani et al., 2025). Despite the growing application of Random Forest (RF) models for power transformer fault diagnosis and the increasing use of metaheuristic algorithms for hyperparameter optimization, relatively few studies have systematically integrated metaheuristic-based hyperparameter tuning with RF for incipient fault prediction in power transformers (Alenezi *et al.*, 2026; (Wong et al., 2022). Existing studies often employ default or manually selected RF parameters, which may limit the model's ability to achieve optimal classification performance (Hoang & Vu,2022; Yadav et al., 2023). This creates a research gap in the development of an intelligently optimized RF model in which key hyperparameters, such as the number of trees, number of predictors sampled at each split, minimum leaf size, and maximum number of splits, are systematically optimized. Addressing this gap can enhance the predictive capability, robustness, and reliability of RF-based transformer fault diagnosis. This study addresses that gap by proposing an intelligent framework for power transformer incipient fault prediction using a Random Forest model optimized through the Artificial Bee Colony algorithm. The specific objectives are to develop an ABC-optimized Random Forest model for incipient fault classification using historical transformer condition-monitoring data and evaluate the model's predictive performance against a non-optimized baseline.

2. METHODOLOGY

This study developed an Artificial Bee Colony-optimized Random Forest (ABC-RF) model for predicting incipient faults in power transformers. A dataset containing 589 transformer fault samples collected from electrical utilities and the literature was used. Five dissolved gases H_2, CH_4, C_2H_6, C_2H_4, and C_2H_2 served as input features, while the output comprised six fault classes: PD, D1, D2, T1, T2, and T3 (Taha et al. 2021)). The dataset was cleaned to remove missing and inconsistent observations and subsequently divided into 70% training, 15% validation, and 15% testing data. The training set was used to develop the Random Forest classifier, while the validation set was used during hyperparameter optimization. The independent testing set was reserved for final model evaluation. Random Forest was selected because of its ability to model nonlinear relationships and provide robust multiclass classification. The hyperparameters, including the number of trees, maximum tree depth, minimum

samples for splitting, minimum samples per leaf, and number of features considered at each split, were optimized using the Artificial Bee Colony algorithm. In the ABC optimization process, each bee represented a candidate set of RF hyperparameters. Candidate solutions were iteratively improved through the employed-bee, onlooker-bee, and scout-bee phases. Validation accuracy was used as the fitness function, and the hyperparameter combination producing the best validation accuracy was selected. The optimized RF model was subsequently retrained and evaluated using the independent test dataset. Model performance was assessed using accuracy, precision, recall, F1-score, and confusion matrix analysis. To assess the robustness of the observed improvement, the RF and ABC-RF models were evaluated over multiple independent runs using different random train–test partitions, and the mean accuracy and standard deviation were recorded. The performance of the optimized ABC-RF model was compared with conventional Random Forest. Figure 1 shows the flowchart of the ABC-optimized random forest m0odel.

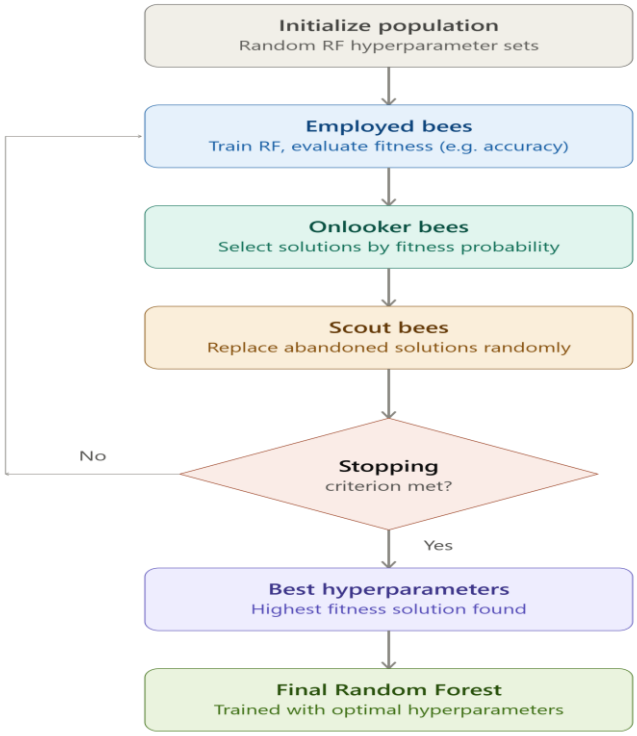

Figure 1: Flowchart of the ABC-Optimized Random Forest Model

2.1 ABC-Random Forest Model

The following steps show how artificial bee colony is used to find the optimal Random Forest hyperparameters automatically:

1. **Initialize:** Define the hyperparameter ranges, such as number of trees, maximum tree depth, and minimum leaf size.
2. **Generate solutions:** ABC randomly generates different combinations of these hyperparameters.
3. **Evaluate:** Train a Random Forest for each combination and calculate its fitness, such as validation Accuracy or F1-Score.
4. **Search:** Employed, onlooker, and scout bees explore and improve the hyperparameter combinations.
5. **Select best solution:** The combination with the best fitness is retained.
6. **Terminate:** The process continues until the maximum iterations or convergence criterion is reached.
7. **Final model:** The Random Forest is trained using the optimal hyperparameters and evaluated on the test data.

3. RESULTS AND DISCUSSION

Table 1 shows the results for the performance of models. The results indicate a clear improvement in classification performance across the evaluated models. SVM achieved the lowest overall performance, with an accuracy of 78.4% and an F1-score of 73.0%. RF performed slightly better, achieving 80.4% accuracy and an F1-score of 80.1%, indicating improved balance between precision and recall. DNN further improved the results, recording 83.3% accuracy, 81.5% precision, 84.1% recall, and 83.2% F1-score. The proposed ABC-RF model achieved the best performance across all evaluation metrics, with 91.2% accuracy, 92.4% precision, 90.5% recall, and 91.5% F1-score. Compared with the conventional RF model, ABC-RF improved accuracy by 10.8 percentage points and F1-score by 11.4 percentage points. To assess the robustness of the observed improvement, the RF and ABC-RF models were evaluated over multiple independent runs using different random train–test partitions, and the mean accuracy and standard deviation were recorded. The consistently higher mean accuracy of ABC-RF, together with its lower variability across runs, indicates that the 10.8 percentage-point improvement is not attributable to random variation from a single train–test splitThis substantial improvement demonstrates that ABC-based hyperparameter optimization effectively enhances the Random Forest model, resulting in more accurate, consistent, and reliable classification performance.

Table 1: Performance of Models

Model	Accuracy	Precision	Recall	F1-Score
SVM	78.4	77.2	76	73
RF	80.4	79.2	79.9	80.1
DNN	83.3	81.5	84.1	83.2
ABC-RF	91.2	92.4	90.5	91.5

Table 2 shows the Random Forest hyperparameters before and after ABC optimization. ABC increased the number of trees from 100 to 148, while the minimum leaf size remained at 1. The maximum number of splits increased to 65 compared with the default value of 50. The number of predictors sampled at each split was optimized to 4. Overall, ABC identified a parameter combination expected to provide better model performance than the default Random Forest settings.

The confusion matrix in Figure 2 shows that the proposed model achieved strong classification performance across the six classes (D1, D2, PD, T1, T2, and T3). Most observations are correctly classified, as indicated by the relatively high values along the main diagonal. In particular, D1, D2, PD, T1, T2, and T3 recorded 18, 23, 27, 25, 26, and 21 correct predictions, respectively

Table 2: Hyper Parameter Values Range and Optimized Values

Hyperparameter	Name	Default	Search Range	Optimized
Number of trees	Num_Trees	100	50-200	148
Minimum leaf size	MinLeafSize	1	1-5	1
Number of Splits	MaxNumSplits	50	10–500	65
Number of predictors	NumPredictorsToSample	1 -p	Sqrt (p)	4

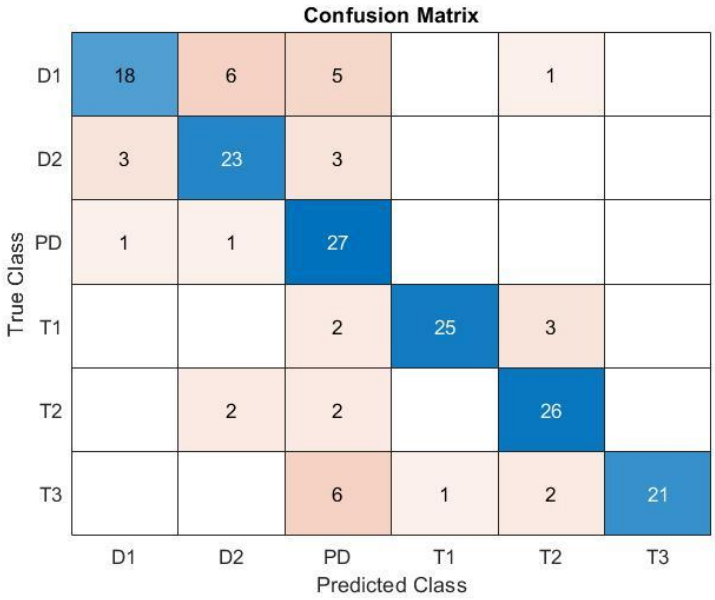

Figure 2: ABC-Random Forest Confusion Matrix

Some misclassification occurred between closely related classes. D1 is misclassified 6 times as D2, 5 times PD and 1 as T2; while T3 has 6 misclassified as PD, once as T1 and twice as T2. The misclassification of D1 and T3 can be attributed to the overlapping dissolved-gas characteristics of these fault conditions with other fault classes. D1 was misclassified mainly as D2 and PD, while T3 was occasionally classified as PD, T1, and T2. This overlap may arise because similar gas generation patterns can occur under different fault conditions, particularly when fault severity and operating conditions vary. Consequently, some samples may exhibit features that are not sufficiently distinctive for the classifier to clearly separate the fault classes. Overall, the high concentration of predictions along the diagonal demonstrates that the model can effectively distinguish the different fault classes, with only limited confusion between classes

4. CONCLUSION

In conclusion, the results demonstrate that the proposed ABC-RF model provides superior classification performance compared with SVM, conventional RF, and DNN models. The model achieved an accuracy of 91.2%, precision of 92.4%, recall of 90.5%, and an F1-score of 91.5%, confirming its effectiveness in distinguishing between the different transformer fault classes. Except for except for PD and T3 samples misclassified, the relatively high precision indicates that the model generates few false-positive classifications, while the strong recall demonstrates its ability to correctly identify most fault conditions. The findings demonstrate that integrating Artificial Bee Colony (ABC) optimization with Random Forest enhances diagnostic performance by identifying more suitable model hyperparameters. Overall, the proposed ABC-RF model offers a robust and reliable approach for power transformer fault diagnosis with considerable potential for supporting early fault identification in practical power systems.

ABSTRACT

The increasing integration of wind energy into transmission networks introduces interactions that can affect power system stability, particularly in weak and highly interconnected networks. This study assesses the small-signal stability implications of DFIG-based wind energy integration in the Nigerian 330-kV transmission network using eigenvalue-based modal analysis. A 50-bus representation of the Nigerian transmission network is investigated under six operating scenarios comprising the base network, STATCOM-Compensated operation, and DFIG wind-penetration levels of 5% 10%, 15%, and 20%. Power flow analysis is first performed to establish the steady-state operating conditions and evaluate network transmission losses. The resulting operating points are then subjected to linearized state-space analysis to determine critical eigenvalues, oscillation frequencies, and damping ratios. The results show that active losses decrease to 0.58 p at 15% DFIG penetration, while reactive power losses increase substantially at higher penetration. The critical-mode damping ratio improves from 16.092% in the base case to 17.81% at 15% penetration. However, at 20% penetration, the critical eigenvalue shifts to $+0.0210 \pm j0.5781$*, producing a negative damping ration of -3.637% and indicating small-signal instability. The finding demonstrates that moderate DFIG penetration can be accommodated under the investigated conditions, while higher penetration requires additional stability-enhancement measure.*

Keywords: *DFIG; wind energy integration; small-signal stability; modal analysis; STATCOM; Nigerian transmission network*

1. INTRODUCTION

The increasing integration of renewable energy sources (RESs) into modern power systems is driven by the need to improve energy security, reduce dependence on conventional fossil-fuel generation, and support sustainable electricity development (Saleh *et al.*, 2025). Wind energy is particularly attractive because of its scalability and relatively low environmental impact. However, large-scale integration of wind generation introduces additional dynamic interactions into power networks and can influence voltage regulation, power flow patterns, and electromechanical oscillations (Ali *et al.*, 2021). These issues are particularly important in developing power systems where transmission networks may be characterized by long transmission corridors, weak voltage profiles, and limited reactive power support.

In Nigeria, the increasing demand for reliable electricity and need to diversify the generation mix have created growing interest in renewable energy integration. The Nigerian transmission network presents particular challenges for large-scale renewable integration because of its geographical extent, transmission constraints, and susceptibility to voltage and stability problems (Adetokun & Muriithi, 2021). Consequently, the integration of wind energy must be assessed not only from the perspective of additional generation capacity but also in terms of its influence on the dynamic behaviour of the interconnected power system.

Doubly Fed Induction Generator (DFIG) is widely used in variable speed wind energy conversion systems (WECSs) because its partial-scale converter allows a variable speed operation while requiring a lower converter rating (30%) than a fully rated converter configuration that utilized

permanent magnet synchronous generator technology (Musbahu *et al.*, 2021). Nevertheless, the converter-based characteristics of DFIG system introduce dynamic interactions that differ from those of conventional synchronous generators. As wind penetration increases, these interactions can modify the damping characteristics of existing electromechanical modes and potentially introduce poorly damped oscillatory modes (Kishor *et al.*, 2026). Therefore, small-signal stability assessment is essential when determining the acceptable level of DFIG penetration in an interconnected transmission network.

Flexible AC Transmission System (FACTS) devices provide and additional means of improving transmission system performance. In particular, a Static Synchronous Compensator (STATCOM) can provide dynamic reactive power compensation and voltage support, making it suitable for improving the operating condition of transmission networks with renewable generation (Ugwuanyi *et al.*, 2024a). However, the presence of adequate voltage support does not necessarily guarantee satisfactory small-signal stability under all renewable penetration levels. It is therefore necessary to evaluate the combined influence of STATCOM compensation and increasing DFIG penetration on the modal characteristics of the network.

Small-signal stability analysis provides a systematic mean of determining how system oscillation respond to small disturbances. Eigenvalue analysis can identify the location of critical modes in complex plane, while the associated damping ration and oscillation frequency provide quantitative measures of the quality of the system damping. A negative real part of an eigenvalue indicates a stable oscillatory mode, whereas an eigenvalue with positive real part indicates small-signal instability(Aliyu *et al.*, 2024; Kouider *et al.*, 2023).

While previous studies have independently explored wind-energy integration, FACTS-based voltage support, and stability assessment (Adetokun & Muriithi, 2021; Ahiakwo *et al.*, 2022; Anyanor *et al.*, 2020; Olabisi & Ayeni, 2023; Ugwuanyi *et al.*, 2024b), there is a pressing need to examine their combined effects within the Nigerian transmission network. Specifically, understanding how critical eigenvalues and damping characteristics change with increasing DFIG penetration can inform strategies for enhancing the integration of renewable energy resources.

This study evaluates the small-signal stability of Nigeria's 330 kV transmission network as DFIG penetration rises, utilizing STATCOM compensation. It examines six scenarios, including the base network, STATCOM conditions, and DFIG levels of 5%, 10%, 15%, and 20%. Initially, power flow analysis assesses steady-state conditions and transmission losses, followed by eigenvalue-based modal analysis to determine critical oscillatory modes, their frequencies, and damping ratios. The focus is on identifying the penetration level at which dominant modes become insufficiently damped or unstable. The findings offer a quantitative assessment of moderate DFIG penetration and the need for enhanced damping measures at higher levels.

2. LITERATURE REVIEW

2.1 DFIG-Based Wind Integration and Grid Stability

The increasing penetration of wind energy has introduced new technical challenges for power-system operation and stability (Nkosi *et al.*, 2023). Unlike conventional synchronous generators, wind turbine generators (WTGs) base on power electronic converters exhibit different dynamic characteristics and therefore interact with transmission network in different ways. These interactions can influence voltage regulation, power flow distribution, and the damping of electrotechnical oscillations, particularly as the proportion of converter-based generation increases (Ayodele *et al.*, 2020).

The Doubly Fed Induction Generator is widely employed in variable-speed wind energy conversion systems because it permits variable-speed operation while requiring a partially rated converter (Abad *et al.*, 2011). The converter controls the rotor-side electrical quantities and enables independent control of active and reactive power systems. Consequently, changes in wind energy penetration modify the location and damping of critical eigenvalues and may result in poorly damped or unstable oscillatory modes (Adetokun *et al.*, 2020). For weak highly stressed transmission network, these effects can become more significant. The Nigerian transmission network is particularly relevant because of its long transmission corridors and varying voltage-strength conditions particularly in northern region (Adetokun & Muriithi, 2021).

2.2 STATCOM and Small-Signal Stability

FACTS (Flexible AC Transmission Systems) devices have been extensively studied to enhance the performance of transmission networks by providing controllable reactive power compensation and voltage support. Among these devices, Static Synchronous Compensation (STATCOM) is particularly well-suited for systems with renewable energy generation because it can quickly regulate reactive power and support bus voltage under varying operational conditions (Mbuli, 2026).

In wind-integrated transmission systems, STATCOM compensation can improve voltage conditions and influence the operating point from which the dynamic stability of the system is assessed (Ugwuanyi *et al.*, 2024a). However, improved steady-state voltage performance does not necessarily indicate enhanced small-signal stability. Therefore, the interactions between the STATCOM, Doubly Fed Induction Generator (DFIG) controllers, and conventional synchronous generators must be considered when evaluating the overall system response.

Small-signal stability analysis is typically conducted by linearizing the differential-algebraic representation of the power system around an operating point and analysing the eigenvalues of the resulting state matrix. This analysis is crucial for assessing the impact of increased wind penetration and determining the need for additional damping control measures at higher penetration levels.

For an eigenvalue represented by (Abdulrahman & Energy, 2019);

$$\lambda_i = \sigma_i + j\omega_i \tag{1}$$

Where, σ_i,determine whether the corresponding mode is stable, while the imaginary part ω_i determine its oscillatory characteristics.

3. METHODOLOGY

3.1 Study System Overview

The Nigerian 330 kV transmission network considered in this study is represented by a 50-bus system comprising 14 synchronous generators (i.e. of which 11 are gas-fired and 3 hydro-based at Shiroro, Kainji, and Jebba), transmission lines, and aggregated loads. The network is used to investigate the effect of increasing DFIG-based generation on the steady-state and small-signal stability. The study follows a sequential approach in which the network operating point is first established using power-flow analysis. The approach allows the influence of increasing DFIG penetration to be assessed under comparable operating conditions.

A STATCOM is incorporated into the network to provide dynamic reactive power compensation and voltage support. The STATCOM-compensated network serves as the reference configuration for evaluating the subsequent DFIG penetration scenarios.

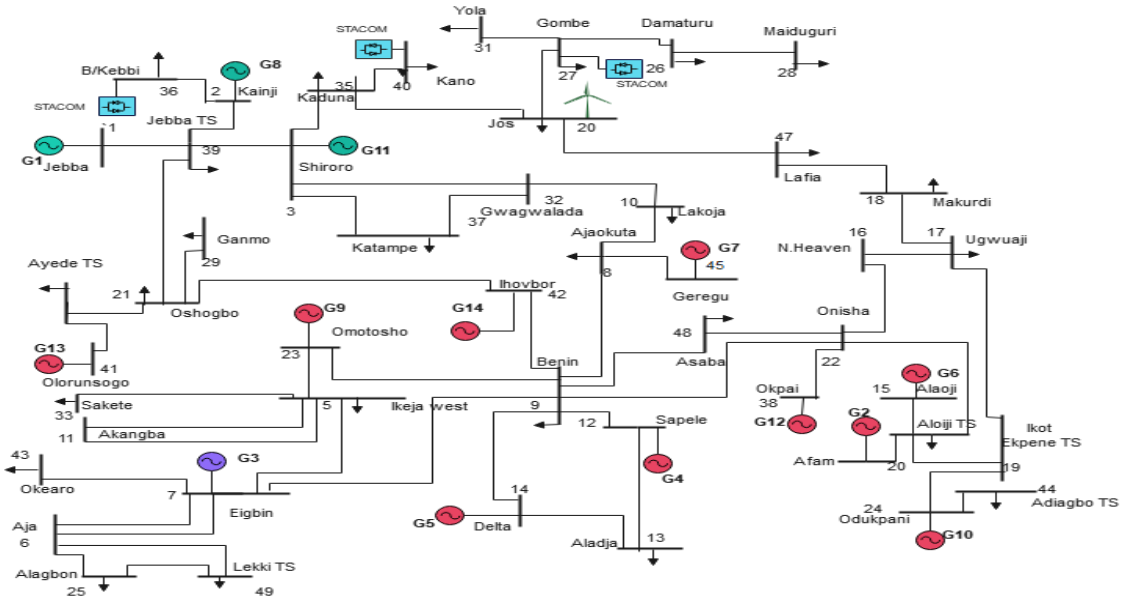

Figure 1: *STATCOM-compensated Nigerian Transmission Network with DFIG-Integration*

The single line diagram of the studied system was presented in Figure 1, its parameters collected from the national control centre located at Oshogbo Osun state as reported by Ugwuanyi N.S *et al.* (2024) and implemented in Power System Analysis Toolbox (PSAT) software platform.

3. 2 DFIG and STATCOM Integration Scenarios

The DFIG-based WECS is represented using a dynamic model incorporating principal electrical and electromechanical states required for small-signal stability analysis. The DFIG is connected at bus 19 (**Jos**) and its power contribution is progressively increased to represent different wind penetration levels. The wind turbine has a radius of 0.75 m, performance coefficient (Cp) of 0.4 and air density 0f 1.225 kg/m^3 and a wind speed of 9 m/s. A wind turbine with an average output of 3 MW and a total capacity of 900 MW wind farm was considered, making an equivalent cluster of (3 x 300 MW) wind turbines. The STATCOM is modelled as a controllable reactive-power compensation device connected to the transmission network rated 100 MVA and current control gain of 50 and 0.1 s time constant. Its inclusion provides voltage support capability and establishes the compensated operating condition against which the effect of DFIG integration can be evaluated. The DFIG penetration is defined the ratio of DFIG-active power to the total power generation, mathematically expressed as;

$$DFIG_{Penetration}(\%) = \frac{P_{DFIG}}{P_{GFG} + P_{DFIG}}\ x\ 100 \tag{2}$$

Where, P_{GFG} is active power generation from the 11 gas-fired generator as the 3 hydros geniting station outputs were maintained as they are also renewable resources.

Six operating scenarios are investigated to provide progressive assessment of the effect of wind penetration as detailed in Table 1.

Table 1: *Study Scenarios*

Scenario	STATCOM	DFIG Penetration	Operating Condition
Case 1	No	0%	Base Network
Case 2	Yes	0%	STATCOM-Compensated network
Case 3	Yes	5%	Low DFIG penetration
Case 4	Yes	10%	Moderate DFIG penetration
Case 5	Yes	15%	High DFG penetration
Case 6	Yes	20%	Very high DFIG penetration

3. 2 Power Flow Analysis

Power flow is initially performed for each operating scenario to establish the stead-state operating point. The analysis determines bus voltages, phase angles, active and reactive power generation, load demand, and transmission losses. The active and reactive powers balances is expressed as (Kouider *et al.*, 2023);

$$\begin{cases} P_{Gen} = P_{Load} + P_{Loss} \\ Q_{Gen} = Q_{Load} + Q_{Loss} \end{cases} \tag{3}$$

The resulting power flow are used to evaluate the effect of DFIG penetration on network operating conditions and losses before proceeding to the dynamic stability assessment.

3.3 Small-Signal Stability and Modal Analysis

Following the computation of power flow, the dynamic model is linearized around the corresponding steady-state operating point. The linearized system can be represented in state space forms as (Aliyu *et al.*, 2024);

$$\dot{x} = Ax \tag{4}$$

$$\det(\lambda I - A) = 0 \tag{5}$$

Where x represents the vector of dynamic state variables and A is the system state matrix. The eigenvalues of state matrix are obtained from; The oscillation frequency (f) and damping ratios (ζ) are computed by;

$$\begin{cases} f = \dfrac{\omega}{2\pi} \\ \zeta = -\dfrac{\sigma}{\sqrt{\sigma^2 + \omega^2}} \end{cases} \tag{6}$$

The critical mode is identified as the oscillatory mode with the least favourable damping characteristics among the modes considered. The eigenvalues, oscillation frequencies, and damping ratios are compared across the six scenarios to determine how increasing DFIG penetration affect system stability.

4. RESULTS AND DISCUSSION

The simulations conducted using PSAT software on a 100 MVA, 50 Hz base, under a load demand of 4,300 MW, with Egbin generator serving as the slack or reference generator. The Nigerian power system was modified by integrating a DFIG wind farm at the Jos bus.

According to Ugwuanyi *et al.* (2024b) and other researchers, Jos has been identified as the optimal location for the DFIG wind farm due to its superior performance.

4.1 Power-Flow Performance

The power flow results for the six operating scenarios are presented in Table 2. The results illustrate how the integration of STATCOM compensation and the increasing penetration of DFIG (Doubly Fed Induction Generator) impacts the generation balance and transmission losses in the Nigerian 330 kV transmission network. In Case 1, the base network experiences an active power loss of 0.704 p.u. Introducing a STATCOM in Case 2 increases this loss slightly to 0.720 p.u. However, integrating DFIG leads to a significant reduction in active power losses, achieving a low of 0.580 p.u in Case 5 (a 19.4% reduction from Case 2) at 15% penetration. This shows that local wind power can decrease active power transfer through the transmission network. At 20% penetration, losses rise slightly to 0.600 p.u, although they remain lower than in Case 2, indicating that reductions in losses have limits with increased wind penetration.

Table 2: *Power Flow Performance*

Scenario	P_{Gen} $(p.u)$	Q_{Gen} $(p.u)$	P_{Load} $(p.u)$	Q_{Load} $(p.u)$	P_{Loss} $(p.u)$	Q_{Loss} $(p.u)$
Case 1	43.18	30.78	42.49	25.04	0.704	5.74
Case 2	45.61	32.24	44.88	26.30	0.72	5.94
Case 3	45.52	31.85	44.88	26.30	0.64	5.55
Case 4	45.48	32.22	44.88	26.30	0.60	5.92
Case 5	45.46	33.41	44.88	26.30	0.58	7.11
Case 6	45.47	35.81	44.87	26.29	0.60	9.52

Conversely, reactive power losses behave differently. Case 3 shows the lowest reactive loss at 5.55 p.u, which climbs to 9.52 p.u by Case 6. The rise at 20% penetration highlights the growing reactive power needs with higher wind integration. Overall, while moderate DFIG penetration enhances active power efficiency, the increasing reactive losses underscore that assessing the feasibility of higher wind penetration requires a broader evaluation of network dynamics.

4.2 Small-Signal Stability and Modal Evolution

The critical eigenvalues modal characteristics obtained from the eigenvalue analysis are presented in Table 3. The results demonstrate a clear change in the dominant oscillatory behaviour as DFIG penetration increases.

The variation in the dominant mode with increasing DFIG penetration indicates that the small-signal stability response is non-monotonic and is governed by modal interaction rather than by a uniform deterioration of all electromechanical modes. At 5% penetration, the critical mode is associated with ω_{13} and δ_{13} of generator 13 with an equivalent damping ratio of 17.004%. At 10% DFIG penetration, the a low-frequency mode associated with ω_{12} and δ_{12} of generator 12 becomes critical, reducing the damping ratio to 10.389% while at 15% penetration the critical mode returns to the $\omega_{13} - \delta_{13}$ pair, with damping ratio increasing to 17.807%.

Table 3: *Critical Eigenvalues Modal Characteristics*

Scenario	DFIG Penetration	Dominant State	Critical Eigenvalue	Frequency (Hz)	Damping Ratio (%)	Stability
Case 1	0%	$\omega_{13}\delta_{13}$	$-0.6772 \pm j4.1532$	0.670	16.092	Stable
Case 2	0% +STATCOM	$\omega_{13}\delta_{13}$	$-0.7125 \pm j4.1779$	0.675	16.812	Stable
Case 3	5%	$\omega_{13}\delta_{13}$	$-0.7221 \pm j4.1848$	0.675	17.004	Stable
Case 4	10%	$\omega_{12}\delta_{12}$	$-0.0595 \pm j0.5695$	0.091	10.389	Stable
Case 5	15%	$\omega_{13}\delta_{13}$	$-0.7555 \pm j4.1917$	0.678	17.807	Stable
Case 6	20%	$\omega_{12}\delta_{12}$	$0.0210 \pm j0.5781$	0.092	-3.637	Unstable

This behaviour is physically attributable to changes in network power-flow distribution, synchronizing torque, and the dynamic interaction among synchronous generators, DFIG converter controls and STATCOM voltage regulation as the operating point changes. Mathematically, the state matrix $\boldsymbol{A}$, is a function of the operating points and wind penetration, its eigenvalues do not necessarily vary monotonically with penetration, in which different oscillatory modes become the least-damped mode at different penetration. However, at 20% penetration, the critical eigenvalue moves into the right half of the complex plane, rendering the system unstable with a damping ratio of -3.637%.

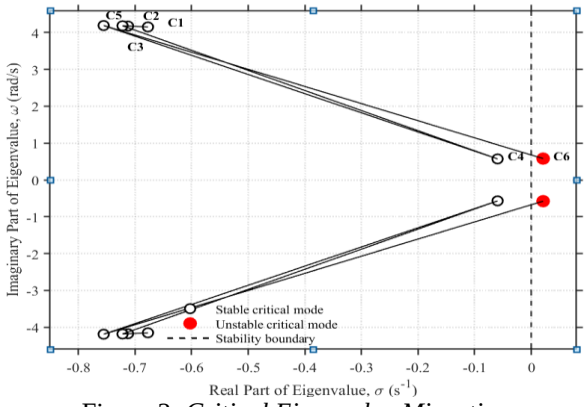

Figure 2: *Critical Eigenvalue Migration*

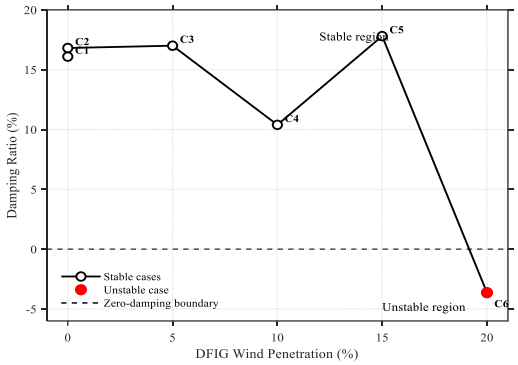

Figure 3: *Damping Ratio with increasing DFIG Penetration*

Figures 2 and 3 illustrate eigenvalue migration and critical damping variations with DFIG penetration, respectively. Overall, the network maintains small-signal stability up to 15% penetration, while the 20% scenario is unstable, highlighting the stability boundary for the investigated network configuration and operating conditions rather than a universal wind penetration limit for the Nigerian transmission network.

4. CONCLUSION

This study evaluates the small-signal stability of integrating DFIG-based wind generation into Nigeria's 330 kV transmission network through eigenvalue-based modal analysis using the Power System Analysis Toolbox (PSAT) in MATLAB. Six scenarios were assessed including; uncompensated network, STATCOM compensation, and DFIG penetration levels of 5%, 10%, 15%, and 20%.

Initial power flow analysis showed that moderate DFIG penetration enhances active power transmission and reduces losses but increases reactive power losses, particularly at higher penetration levels. Modal analysis revealed that DFIG integration affects system stability in a nonlinear manner, altering oscillatory behaviour with increasing DFIG penetration.

Results indicate that a STATCOM-supported network can maintain small-signal stability with DFIG penetration up to 15%, while suggesting that additional stability measures are needed for 20% penetration. Future research should focus on coordinated damping control strategies, including supplementary DFIG and wide-area damping controllers, to improve stability margins and facilitate higher wind energy integration in Nigeria's transmission network.

ABSTRACT

Industrial Control Systems (ICSs) are cyber-physical systems responsible for monitoring and controlling critical industrial processes. Their increasing integration with Information Technology (IT) networks, the Industrial Internet of Things (IIoT), and cloud-based services has expanded their exposure to cyber threats, creating a need for intelligent anomaly detection models capable of transferring learned knowledge across heterogeneous industrial environments. However, many existing deep learning-based approaches are developed for individual ICS domains and therefore have limited capability to exploit transferable spatio-temporal patterns across systems with different operational characteristics and feature structures. This study proposes a Domain-Invariant Spatio-Temporal Graph Attention Network (DI-STGAT) for cross-domain anomaly detection in ICSs. The proposed model integrates a Spatio-Temporal Graph Attention Network (ST-GAT) with Domain-Adversarial Neural Network (DANN) learning through a Gradient Reversal Layer (GRL). The ST-GAT captures temporal behaviour and spatial dependencies among industrial process variables, while the DANN/GRL mechanism facilitates domain adaptation by reducing domain-specific information in the learned representations. A fixed-dimensional graph-level representation enables the same model architecture to operate across heterogeneous ICS datasets with different numbers of process variables and graph structures. DI-STGAT achieved cross-domain anomaly detection across heterogeneous ICS environments by combining spatio-temporal graph learning with domain-adversarial adaptation to learn transferable representations from labeled source data and unlabeled target data, thereby improving anomaly discrimination across industrial domains without requiring target-domain anomaly labels for training. The framework was evaluated using the BATADAL, SWaT, and WADI benchmark datasets across six source-to-target transfer scenarios. Experimental results show that DI-STGAT improved mean cross-domain balanced accuracy from 50.51% to 51.90% and mean F1-score from 4.13% to 4.37% compared with the ST-GAT baseline at a fixed decision threshold of 0.50. The strongest improvement was achieved for SWaT→WADI, where balanced accuracy increased from 53.04% to 61.37% and F1-score from 7.48% to 8.94%. The proposed framework achieved mean cross-domain ROC-AUC and PR-AUC values of 72.21% and 36.36%, respectively. Domain-representation analysis further demonstrated measurable adversarial alignment between source and target representations, providing evidence of transferable representation learning across heterogeneous industrial domains. Overall, the findings demonstrate that DI-STGAT provides a viable domain-adaptive spatio-temporal learning framework for cross-domain anomaly detection in heterogeneous ICS environments, supporting more adaptable cybersecurity monitoring and improved protection of critical industrial infrastructure.

1. INTRODUCTION

Industrial Control Systems (ICSs) are critical components of modern industrial infrastructure, providing monitoring and control functions for essential production processes. Traditionally, ICS environments were designed as isolated operational technology (OT) systems, with primary emphasis on safety, reliability, and continuous availability. However, the adoption of Industry 4.0, Industrial

Internet of Things (IIoT), remote monitoring, cloud services, Artificial Intelligence and information technology–operational technology (IT-OT) convergence has transformed these environments into highly interconnected cyber physical systems. While this transformation has improved automation, monitoring, and operational efficiency, it has also increased system exposure to cyber threats and introduced vulnerabilities associated with network connectivity, remote access, heterogeneous devices, and interconnected control components (Ahmadi-Assalemi *et al*., 2025; Rehman & Bahşi, 2024; Rotibi *et al*., 2024; Wu *et al*., 2026). Unlike conventional IT systems, cyber-attacks against ICSs can propagate from the cyber layer to physical processes, potentially causing equipment damage, production interruption, environmental consequences, and safety incidents. Consequently, reliable detection of abnormal system behaviour has become an important component of ICS cybersecurity and resilience (Rehman & Bahşi, 2024; Wu *et al*., 2026).

The increasing complexity of ICS environments has exposed limitations in conventional intrusion detection approaches. Thus, signature and rule-based methods are effective for previously known attack patterns but are less capable of identifying novel or evolving attacks that do not match predefined signatures. Anomaly-based detection provides an alternative by learning normal system behaviour and identifying deviations associated with attacks, faults, or abnormal operating conditions (Choi & Kim, 2024; Ahmadi-Assalemi *et al*., 2025). The availability of high-dimensional operational data from sensors, actuators, controllers, and communication systems has consequently encouraged the application of machine learning (ML) and deep learning (DL) techniques for ICS anomaly detection. Recent studies have explored recurrent networks, convolutional architectures, autoencoders, attention mechanisms, and adaptive learning approaches to capture complex temporal patterns in industrial data (Aslam *et al*., 2025; Liu *et al*., 2024; Xu *et al*., 2025). For instance, Liu *et al*. (2024) introduced a time-frequency fusion feature-attention approach to address long-sequence and complex temporal dependencies in ICS operational data, while Xu *et al*. (2025) proposed a dual-attention network that uses attention-based causal relationships among industrial components to improve anomaly detection and interpretation. These studies demonstrate the potential of deep learning for modelling complex ICS behaviour, but they primarily focus on improving detection within individual operational environments.

A major challenge in ICS anomaly detection is that industrial processes are inherently spatio-temporal. Sensor and actuator variables do not operate independently; they interact through physical processes, controllers, communication networks, and process stages. Consequently, treating industrial measurements as independent or purely sequential variables may overlook important relationships between interconnected components. Graph neural networks (GNNs) provide a natural representation for such systems because nodes can represent sensors, actuators, controllers, or process variables, while edges represent their physical, functional, or statistical relationships. Graph Convolutional Networks (GCNs) and Graph Attention Networks (GATs) have therefore attracted increasing attention for multivariate anomaly detection because they can learn dependencies among interconnected variables (Deng & Hooi, 2021; Veličković *et al*., 2018). In ICS applications, Yang *et al*. (2024) demonstrated that centrality-aware graph convolution can exploit relationships among industrial components, while Wang *et al*. (2023) showed that spatio-temporal graph neural networks can capture spatial and temporal characteristics in high-dimensional and noisy ICS data. Similarly, Fan *et al*. (2024) developed a spatio-temporal gated graph attention network for IIoT anomaly detection, and Zhang *et al*. (2025) proposed PdGAT-ID to combine periodic feature extraction with spatio-temporal graph attention for ICS intrusion detection. These studies indicate that graph-based spatio-temporal modelling can provide richer representations than conventional independent-variable approaches.

Recent research has further demonstrated the benefits of explicitly modelling hierarchical and dynamic relationships within industrial systems. Lin et al. (2025) proposed a multi-level graph attention network that represents relationships among physical processes and controllers, while Li *et al*. (2025) integrated static and dynamic graph learning with attention-based temporal modelling to capture spatial and temporal dependencies in ICS data. Canonico *et al*. (2025) similarly demonstrated that reducing unnecessary graph connections can improve both detection efficiency and computational requirements in reconfigurable cyber–physical systems. These findings reinforce the importance of jointly modelling spatial dependencies and temporal dynamics rather than treating industrial observations as isolated time-series measurements.

Despite these advancements, an important limitation remains: most existing ICS anomaly detection models are developed and evaluated within a single operational domain. Models trained on one industrial environment generally assume that the statistical distribution, sensor relationships, process dynamics, and attack characteristics of the training environment remain applicable to the test environment. This assumption is problematic because real industrial systems are heterogeneous. Water treatment, water distribution, energy, manufacturing, chemical, and oil-and-gas systems differ substantially in process topology, sensor configurations, control logic, communication protocols, operating ranges, and anomaly characteristics. Recent reviews have identified limited cross-domain datasets, distribution shifts, concept drift, and inadequate real-world validation as continuing challenges for AI-based ICS anomaly detection (Moriano *et al*., 2025; Aslam *et al*., 2025; Wu *et al*., 2026). The problem is therefore not simply to achieve high detection accuracy within one dataset, but to develop representations that remain informative when the model encounters a different industrial domain.

Domain adaptation provides a promising approach to this problem by encouraging a model to learn features that are discriminative for anomaly detection while being less dependent on the identity of the training domain. Domain-Adversarial Neural Networks (DANN) achieves this by introducing a domain classifier and a Gradient Reversal Layer (GRL), which encourages the feature extractor to learn representations that are useful for the primary task but less distinguishable across domains. Although adversarial learning has been extensively investigated in general domain adaptation, its integration with spatio-temporal graph representations for cross-domain ICS anomaly detection remains comparatively limited. Existing graph-based ICS studies have primarily concentrated on improving spatial representation, temporal modelling, interpretability, or detection accuracy within selected benchmark datasets rather than explicitly enforcing domain-invariant representations. This limitation is particularly important because graph structures themselves may differ between industrial environments, making direct transfer of learned representations difficult (Nahalka *et al*., 2024; Fan *et al*., 2024; Lin *et al*., 2025; Ganin *et al*., 2016).

The challenge is further highlighted by the nature of commonly used ICS benchmarks. Datasets such as SWaT, WADI, and BATADAL provide valuable experimental environments for evaluating anomaly detection methods, but they represent different industrial processes and therefore introduce distributional differences. SWaT represents a water-treatment environment, WADI represents a water-distribution system, and BATADAL focuses on cyber-physical attacks against water-distribution networks (Goh *et al*., 2016; Ahmed *et al*., 2017; Mathur & Taormina *et al*., 2018). These datasets have enabled substantial progress in ICS anomaly detection, but their differences also provide an appropriate basis for evaluating whether a model can generalize beyond its source domain. Studies using graph-based approaches have demonstrated strong performance on individual datasets, yet the problem of systematically evaluating transferability between heterogeneous domains remains insufficiently explored.

Against this background, this study identifies three interrelated research problems that motivate the development and evaluation of the proposed framework.

1. Inadequate joint representation of spatial and temporal dependencies across heterogeneous ICS environments.
2. Poor cross-domain generalization caused by distribution shifts between heterogeneous ICS environments.
3. Limited systematic evidence for cross-domain transfer and domain-adversarial representation learning across heterogeneous ICS benchmarks.

To answer these questions, the study adopts a controlled experimental framework involving the three benchmark datasets. Each dataset is independently preprocessed and represented using its domain-specific graph structure, thereby preserving the characteristics of the corresponding industrial environment rather than forcing heterogeneous variables into an artificial common node space. Temporal sequences are subsequently processed through the ST-GAT architecture to generate a fixed-dimensional graph representation. The conventional ST-GAT is first trained and evaluated as the baseline. DI-STGAT then extends the same architecture with a GRL and domain classifier for unsupervised source-to-target adaptation. Six transfer directions: BATADAL to SWaT, BATADAL to WADI, SWaT to BATADAL, SWaT to WADI, WADI to BATADAL, and WADI to SWaT are

evaluated under a controlled protocol. Target-domain anomaly labels are excluded from adaptation training and model selection and are reserved for final evaluation.

Accordingly, the main contributions of this study are:

1. **Domain-invariant ST-GAT:** A spatio-temporal graph attention framework integrated with DANN and GRL to learn transferable anomaly representations across heterogeneous ICS domains.
2. **Cross-domain evaluation:** A systematic source-to-target evaluation using the three datasets to assess the generalization capability of the proposed model beyond its training environment.
3. **Controlled baseline and ablation analysis:** A conventional ST-GAT baseline is established and compared with the DANN/GRL-enhanced model to isolate the contribution of domain-adversarial learning.

Further, the proposed framework has potential relevance to addressing the increasing need to strengthen the resilience and cybersecurity of critical infrastructure in Nigeria and other African countries, where increasing digitalization and interconnection of industrial and utility systems can introduce additional cyber security risks. Nigeria's National Cyber security Policy and Strategy identifies the protection and resilience of Critical National Information Infrastructure as a national cybersecurity priority (Federal Republic of Nigeria, 2021). Water treatment and distribution systems provide a particularly relevant application context because reliable water infrastructure remains important to Nation's sustainable development, while challenges relating to infrastructure, service delivery, and access to clean water persist (Ogunbode, 2026). The use of water-system benchmark datasets in this study therefore provides an experimental basis for investigating transferable anomaly-detection techniques applicable to heterogeneous water infrastructure. By reducing dependence on target-domain anomaly labels, the proposed cross-domain approach could support the development of adaptable cybersecurity monitoring for infrastructure environments where labeled attack data are limited. Such capabilities are relevant to Nigeria's sustainable infrastructure development and align with SDG 6 (Clean Water and Sanitation) and SDG 9 (Industry, Innovation and Infrastructure), which emphasize sustainable water management and resilient infrastructure, respectively (United Nations, 2026).

2. METHODOLOGY

This study proposes a Domain-Invariant Spatio-Temporal Graph Attention Network (DI-STGAT) for cross-domain anomaly detection in heterogeneous Industrial Control Systems (ICSs). The proposed framework combines temporal attention, graph attention, and domain-adversarial learning to capture temporal behaviour and structural dependencies among industrial process variables while encouraging transferable representations across different ICS domains. Unlike approaches that require identical feature sets across source and target systems, DI-STGAT retains the domain-specific variables and graph structures of each ICS and transforms them into a common fixed-dimensional graph-level representation suitable for cross-domain adaptation.

2.1 Model Overview

The proposed DI-STGAT consists of three principal components: (i) an ST-GAT feature extractor, (ii) an anomaly-classification branch, and (iii) a domain-adaptation branch based on a Domain-Adversarial Neural Network (DANN) and Gradient Reversal Layer (GRL). The ST-GAT feature extractor first applies temporal attention to identify informative observations within each process variable's temporal sequence. The resulting node representations are subsequently processed by a multi-head Graph Attention Network (GAT) to capture dependencies among interconnected industrial variables. Mean graph pooling then converts the variable-size node representations into a fixed 32-dimensional graph-level embedding. This processing sequence corresponds to the implemented architecture described in the original model specification.

The graph-level embedding is supplied to two branches. The first is a binary anomaly classifier that distinguishes normal from anomalous process behaviour. The second is a domain classifier connected through the GRL. During domain adaptation, labeled source-domain samples provide supervision for anomaly classification, whereas source and unlabeled target samples jointly

contribute to domain classification. Target-domain anomaly labels are not used during adaptation training or model selection. Accordingly, the overall architecture can be summarized as:

$$\text{Input} \rightarrow \text{Temporal Attention} \rightarrow \text{Multi-Head GAT} \rightarrow \text{Graph Embedding} \rightarrow \begin{cases} \text{Anomaly Classifier} \\ \text{GRL} \rightarrow \text{Domain Classifier} \end{cases} \quad (1)$$

As show in Equation (1), the anomaly and domain-classification branches operate on the same graph-level representation. This shared representation provides the connection between spatio-temporal anomaly learning and domain-adversarial adaptation as shown in figure 2.1.

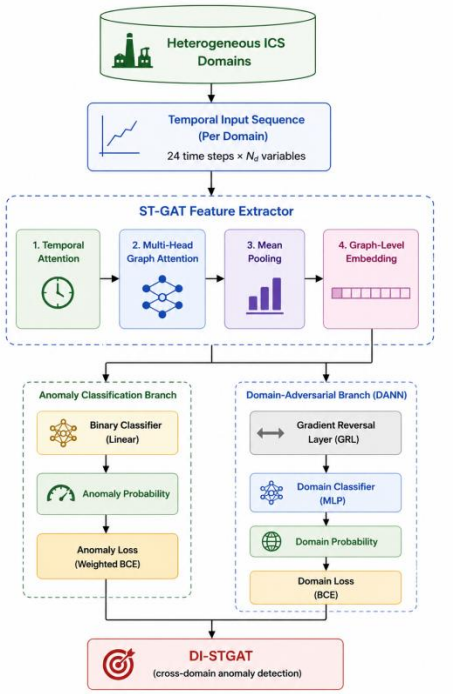

Figure 2.1: Architecture of the Proposed DI-STGAT Model

2.2 Domain-Specific Graph and Temporal Input Representation

The three ICS domains considered in this study contain different numbers and configurations of process variables. Rather than forcing these heterogeneous datasets into an artificial common feature space, each domain retains its own set of process variables and corresponding graph structure. For an ICS domain d, a temporal input sequence is represented as in equation 2:

$$\mathbf{X}_t^{(d)} = \left[\mathbf{x}_{t-T+1}^{(d)}, \mathbf{x}_{t-T+2}^{(d)}, \dots, \mathbf{x}_t^{(d)}\right] \in \mathrm{R}^{T \times N_d}, \quad (2)$$

where T is the temporal window length and N_d is the number of process variables in domain d. In this study, $T = 24$; therefore, each input contains the previous 24 observations of the corresponding industrial variables. As expressed in Equation (2), N_d is domain-dependent, allowing the model to accommodate heterogeneous ICS environments rather than assuming an identical input dimension. The implemented datasets contain 38 variables for BATADAL, 45 for SWaT, and 123 for WADI. Each ICS domain is represented by a graph

$$G^{(d)} = \left(V^{(d)}, E^{(d)}\right), \quad (3)$$

where $V^{(d)}$ represents the process variables and $E^{(d)}$ represents their inferred relationships. Equation (3) therefore permits each domain to maintain a graph topology corresponding to its own process structure. The relationships between variables are determined using the absolute Pearson correlation computed from the corresponding training partition:

$$r_{ij}^{(d)} = \left| \frac{\sum_t \left(x_{t,i}^{(d)} - \bar{x}_i^{(d)}\right)\left(x_{t,j}^{(d)} - \bar{x}_j^{(d)}\right)}{\sqrt{\sum_t \left(x_{t,i}^{(d)} - \bar{x}_i^{(d)}\right)^2}\sqrt{\sum_t \left(x_{t,j}^{(d)} - \bar{x}_j^{(d)}\right)^2}} \right|. \quad (4)$$

In Equation (4), $r_{ij}^{(d)}$ measures the strength of the statistical relationship between process variables i and j. For each node, the three variables with the highest absolute correlations are selected as neighbours. The resulting graph is symmetrized and self-loops are added. This produces domain-specific graphs containing 38 nodes and 188 directed edges for BATADAL, 45 nodes and 253 directed edges for SWaT, and 123 nodes and 707 directed edges for WADI. Importantly, the graph topology is derived exclusively from training data to prevent validation or test information from influencing graph construction.

2.3 Temporal Attention

Industrial anomalies frequently develop over a sequence of observations rather than appearing as isolated events. The temporal attention module is therefore used to determine the relative importance of the 24 observations associated with each process-variable node. For node i, the attention score at time t is calculated as

$$e_{i,t} = \mathbf{w}_2^{\top} \tanh\left(\mathbf{W}_1 x_{i,t} + \mathbf{b}_1\right) + b_2, \quad (5)$$

where $\mathbf{W}_1, \mathbf{w}_2, \mathbf{b}_1$, and b_2 are trainable parameters. The implemented temporal-attention network uses a $1 \to 8 \to 1$ transformation. Equation (5) assigns a learned importance score to every observation within the temporal window. The attention scores are normalized across the temporal dimension using the softmax function:

$$\alpha_{i,t} = \frac{\exp\left(e_{i,t}\right)}{\sum_{\tau=1}^{T} \exp\left(e_{i,\tau}\right)}. \quad (6)$$

As defined by Equation (6), the normalized temporal attention coefficients indicate the relative contribution of each time step to the representation of node i. The temporal representation is subsequently obtained through the weighted aggregation

$$h_i^{(T)} = \sum_{t=1}^{T} \alpha_{i,t} x_{i,t}. \quad (7)$$

Thus, Equation (7) transforms the 24-step history of each process variable into a learned scalar representation in which more informative time steps receive greater attention. This allows the model to capture temporal behaviour without introducing recurrent or convolutional components.

2.4 Multi-Head Graph Attention

Following temporal attention, the resulting node representations are processed by a multi-head graph-attention mechanism to capture spatial dependencies among related industrial process variables. Unlike conventional aggregation methods that treat all neighbouring nodes equally, graph attention learns the relative contribution of each neighbouring variable. For an edge connecting nodes i and j, the unnormalized attention score for attention head k is calculated as

$$e_{ij}^{(k)} = \mathrm{LeakyReLU}\left[\mathbf{a}^{(k)\top}\left(\mathbf{W}^{(k)} h_i^{(T)} \| \mathbf{W}^{(k)} h_j^{(T)}\right)\right], \quad (8)$$

where $\mathbf{W}^{(k)}$ denotes the trainable transformation matrix, $\mathbf{a}^{(k)}$ represents the attention vector for head k, and $\|$ denotes concatenation. Equation (8) determines the learned importance of node j to node i within the domain-specific graph.The attention scores are normalized over the neighbourhood of node i as

$$\beta_{ij}^{(k)} = \frac{\exp\left(e_{ij}^{(k)}\right)}{\sum_{m \in \mathrm{N}_i} \exp\left(e_{im}^{(k)}\right)}, \quad (9)$$

where N_i contains the graph neighbours of node i, including its self-loop. Equation (9) ensures that the attention coefficients represent the relative importance of connected variables. The output of attention head k is then obtained as

$$\mathbf{h}_i^{(k)} = \sum_{j \in \mathrm{N}_i} \beta_{ij}^{(k)} \mathbf{W}^{(k)} h_j^{(T)}. \quad (10)$$

According to Equation (10), each node representation is updated using an attention-weighted combination of information from its graph neighbourhood. The implemented model uses four graph-attention heads with eight output dimensions per head. Their outputs are concatenated to produce

$$\mathbf{h}_i^{(G)} = \|_{k=1}^{4} \mathbf{h}_i^{(k)} \in \mathrm{R}^{32}. \quad (11)$$

Consequently, Equation (11) produces a 32-dimensional spatial representation for each process variable node. The use of multiple attention heads allows the model to capture different patterns of relationships among industrial variables while maintaining the same parameterization across domains with different graph sizes.

2.5 Graph-Level Representation and Anomaly Classification

Although the same ST-GAT parameters can operate on different graph sizes, the resulting node level representations cannot be directly combined across domains because the datasets contain different numbers of nodes. A fixed-dimensional graph representation is therefore generated using mean pooling:

$$\mathbf{z}^{(d)} = \frac{1}{N_d} \sum_{i=1}^{N_d} \mathbf{h}_i^{(G)}, \mathbf{z}^{(d)} \in \mathrm{R}^{32}. \quad (12)$$

As shown in Equation (12), the node representations are aggregated into a 32-dimensional graph level embedding, irrespective of the number of process variables in the input domain. This mechanism is important to cross-domain adaptation because each of the datasets can retain their respective domain-specific graphs while still producing representations with an identical dimensionality. The graph-level representation is subsequently passed to a binary anomaly classifier:

$$\ell_y = \mathbf{w}_y^{\top} \mathbf{z} + b_y, p_y = \sigma(\ell_y), \quad (13)$$

where ℓ_y represents the anomaly logit, $\mathbf{w}_y$ and b_y are trainable classifier parameters, and p_y denotes the predicted anomaly probability. Equation (13) therefore maps the 32-dimensional graph representation to the probability that the corresponding temporal graph observation is anomalous. Because anomalous samples are substantially less frequent than normal samples, the anomaly-classification branch is optimized using weighted binary cross-entropy:

$$\mathrm{L}_A = -\frac{1}{n_S} \sum_{i=1}^{n_s} [w_+ y_i^s \log p_i^s + (1 - y_i^s) \log(1 - p_i^s)], \quad (14)$$

where n_s denotes the number of source samples and $w_+ = N_{\text{normal}} / N_{\text{anomaly}}$ is calculated from source-domain training data only. Equation (14) increases the contribution of the minority anomaly class during optimization without resampling the training data.

2.6 Domain-Adversarial Learning

The principal extension from the conventional ST-GAT baseline to DI-STGAT is the incorporation of domain-adversarial learning. The objective is to retain representations that are useful for anomaly classification while reducing information that makes the source and target domains easily distinguishable. Let F_θ denote the shared ST-GAT feature extractor. For source and target observations, the corresponding graph-level representations are

$$\mathbf{z}_s = F_\theta(\mathbf{X}_s, G_s), \mathbf{z}_t = F_\theta(\mathbf{X}_t, G_t). \quad (15)$$

As expressed in Equation (15), the source and target inputs are processed using their respective domain-specific graphs, G_s and G_t, while the shared ST-GAT parameters map both inputs into the same 32-dimensional representation space. This enables domain adaptation without requiring the source and target systems to contain identical process variables. The resulting representations are

passed through the GRL to a domain classifier implemented as a 32 to 16 to 1 network with a ReLU hidden activation:

$$p_d = \sigma[\mathbf{W}_{d2}\mathrm{ReLU}(\mathbf{W}_{d1}\mathbf{z}^{GRL} + \mathbf{b}_{d1}) + b_{d2}]. \qquad (16)$$

In Equation (16), p_d represents the predicted domain probability and $\mathbf{z}^{GRL}$ is the graph embedding after passing through the GRL. Source samples are assigned domain label 0, while target samples are assigned domain label 1. The domain-classification loss is calculated as:

$$\mathrm{L}_D = \frac{1}{2}[\mathrm{BCE}(p_d^s, 0) + \mathrm{BCE}(p_d^t, 1)]. \qquad (17)$$

As shown in Equation (17), both source and target samples contribute to the domain-adversarial objective. However, target anomaly labels are not involved. Consequently, DI-STGAT performs unsupervised target-domain adaptation, using labeled source data for anomaly learning and unlabeled target data for domain alignment.

2.7 Gradient Reversal Layer

The GRL provides the adversarial mechanism through which the ST-GAT representation is encouraged to become less domain-specific. During forward propagation, the GRL behaves as an identity function:

$$R_\lambda(\mathbf{z}) = \mathbf{z}. \qquad (18)$$

Thus, Equation (18) shows that the numerical values of the graph-level representation are passed unchanged to the domain classifier. During back propagation, however, the gradient is reversed according to

$$\frac{\partial R_\lambda}{\partial \mathbf{z}} = -\lambda \mathbf{I}, \qquad (19)$$

where λ controls the strength of the adversarial signal. According to Equation (19), the domain classifier is optimized to correctly distinguish source and target representations, while the reversed gradient encourages the ST-GAT feature extractor to generate representations that make this distinction more difficult. This adversarial relationship encourages the extraction of more transferable features while retaining the anomaly-discriminative objective of the source task. Rather than applying the maximum adversarial pressure from the beginning of training, λ is progressively increased according to

$$\lambda(p) = \frac{2}{1 + \exp(-10p)} - 1, 0 \le p \le 1, \qquad (20)$$

where p represents normalized training progress. Equation (20) gradually increases the influence of domain-adversarial learning as training progresses, allowing the feature extractor initially to learn anomaly-relevant representations before stronger domain-confusion pressure is introduced.

2.8 Joint DI-STGAT Training Objective

DI-STGAT jointly optimizes anomaly discrimination and domain adaptation. The overall objective is defined as

$$\mathrm{L}_{\text{total}} = \mathrm{L}_A + \mathrm{L}_D, \qquad (21)$$

where L_A is the source-domain anomaly-classification loss defined in Equation (14) and L_D is the source-target domain-classification loss defined in Equation (17). Therefore, Equation (21) jointly trains the ST-GAT representation for anomaly discrimination and domain-adversarial adaptation. Importantly, the adversarial coefficient λ is not multiplied by L_D again in Equation (21). Instead, λ acts exclusively through the reversed gradient defined in Equation (19) and follows the progressive schedule specified in Equation (20). This reflects the actual implementation and prevents the domain-adversarial contribution from being weighted twice.

During optimization, labeled source-domain samples contribute to the anomaly loss L_A, while both source-domain and unlabeled target-domain samples contribute to the domain loss L_D. The anomaly-classification objective encourages the 32-dimensional ST-GAT embedding to retain information required to distinguish normal from anomalous behaviour, whereas the GRL-based

domain objective encourages the feature extractor to reduce information that permits straightforward discrimination between source and target domains.

Consequently, the proposed DI-STGAT combines temporal attention for modelling process evolution, multi-head graph attention for capturing relationships among industrial variables, fixed-dimensional graph pooling for accommodating heterogeneous graph sizes, and DANN/GRL for cross-domain representation adaptation. This integrated architecture enables knowledge learned from a labeled source ICS to be adapted to heterogeneous target ICS using unlabeled target-domain observations, without requiring identical process-variable sets or target-domain anomaly labels during training.

3. RESULTS AND DISCUSSION

This section presents and discusses the experimental results of the conventional ST-GAT baseline and the proposed Domain-Invariant Spatio-Temporal Graph Attention Network (DI-STGAT). The analysis considers within-domain ST-GAT performance, baseline cross-domain transfer, cross-domain adaptation using DANN/GRL, comparative performance between ST-GAT and DI-STGAT, decision-threshold behaviour, and domain-representation alignment. The quantitative results are complemented with graphical analyses of discrimination performance, cross-domain transfer, domain-adaptation effects, and training behaviour.

3.1 Within-Domain Performance of the ST-GAT Baseline

The ST-GAT baseline was first evaluated independently on BATADAL, SWaT, and WADI to determine whether the underlying architecture could learn anomaly-relevant representations before investigating cross-domain transfer. Table 3.1 presents the results obtained using the fixed classification threshold of 0.50.

Table 3.1: Within-domain ST-GAT performance

Dataset	Accuracy	Balanced Accuracy	Precision	Recall	F1-score	ROC-AUC	PR-AUC
BATADAL	0.0192	0.5058	0.0078	1.0000	0.0154	0.9197	0.0465
SWaT	0.0372	0.5000	0.0372	1.0000	0.0718	0.9655	0.3312
WADI	0.3677	0.6718	0.0547	1.0000	0.1037	0.7256	0.0620

The results reveal a clear distinction between the ranking capability of the ST-GAT and its classification behaviour at the fixed threshold. BATADAL and SWaT obtained ROC-AUC values of 0.9197 and 0.9655, respectively, indicating strong discrimination between normal and anomalous observations across possible decision thresholds. WADI achieved a lower but still informative ROC-AUC of 0.7256.

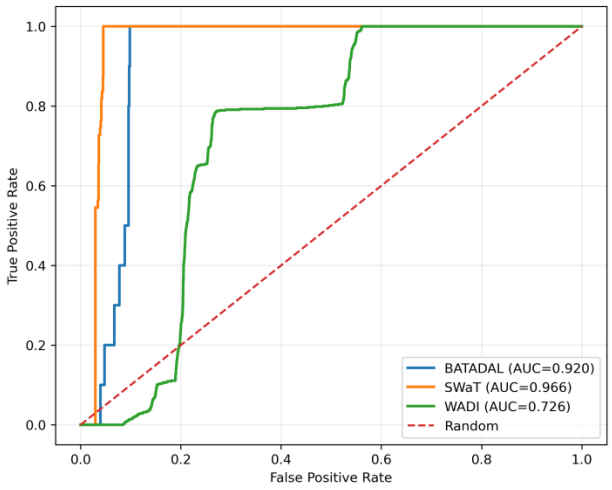

Figure 3.1: Within-domain ROC curves of the ST-GAT baseline

Figure 3.1 shows the ROC curves obtained by the ST-GAT baseline for BATADAL, SWaT, and WADI. The curves confirm the strong ranking capability observed numerically in Table 3.1,

particularly for SWaT and BATADAL. SWaT achieved the highest ROC-AUC of 0.9655, followed by BATADAL at 0.9197, whereas WADI achieved 0.7256. The figure therefore demonstrates that the ST-GAT extracted useful anomaly-related representations within each domain, although the fixed 0.50 threshold did not provide an equally effective operating point.

This difference is important because the models obtained a recall of 1.0000 for all three datasets but produced large numbers of false positives. For BATADAL, all 10 anomalous test samples were detected, but 1,277 of 1,292 normal samples were classified as anomalous. Similarly, all 55 SWaT attacks were detected, but all 1,422 normal samples were classified as attacks. WADI produced a comparatively better operating point, correctly identifying all 631 attacks and 5,714 normal observations, although 10,913 normal observations were still incorrectly classified as anomalous. The findings indicate that the ST-GAT baseline learned useful anomaly-ranking information but experienced substantial fixed-threshold calibration difficulty. This distinction becomes particularly important when examining cross-domain transfer.

3.2 Cross-Domain Generalization of the ST-GAT Baseline

The baseline models were subsequently evaluated under cross-domain transfer. In each experiment, a model trained on one source domain was evaluated on another target domain without target anomaly-label training or target-domain fine-tuning.

Table 3.2: Cross-domain ST-GAT baseline performance

Source → Target	Balanced Accuracy	F1-score	ROC-AUC	PR-AUC
BATADAL → SWaT	0.5000	0.0718	1.0000	1.0000
BATADAL → WADI	0.5001	0.0706	0.4734	0.0325
SWaT → BATADAL	0.5000	0.0152	1.0000	1.0000
SWaT → WADI	0.5304	0.0748	0.4909	0.0335
WADI → BATADAL	0.5000	0.0152	0.9305	0.0852
WADI → SWaT	0.5000	0.0000	0.4914	0.0367
Mean	**0.5051**	**0.0413**	**0.7310**	**0.3646**

As shown in table 3.2 the mean cross-domain ROC-AUC was 0.7310, whereas balanced accuracy and F1-score averaged 0.5051 and 0.0413, respectively. Considerable variation occurred among the six transfer directions.

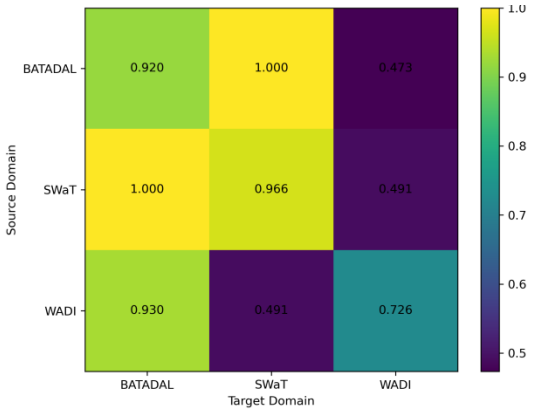

Figure 3.2: ROC-AUC within and Cross-domain performance

The Figure 3.2 provides a visual representation of the direction-dependent transfer behaviour of the baseline model. Strong transfer ranking was obtained for BATADAL to SWaT and SWaT to BATADAL, both of which achieved ROC-AUC values of 1.0000, while WADI to BATADAL achieved 0.9305. In contrast, BATADAL to WADI, SWaT to WADI, and WADI to SWaT produced values close to 0.50. The heatmap therefore shows that cross-domain transfer was not symmetric and that the effectiveness of a source representation depended strongly on the selected target environment.

The results also demonstrate that the ability of the architecture to process heterogeneous graphs does not automatically guarantee distributional generalization. Although all target graphs could be processed through the common ST-GAT architecture, substantial source-target distribution shifts remained, providing the motivation for the DANN/GRL adaptation mechanism.

3.3 Cross-Domain Performance of DI-STGAT

The proposed DI-STGAT was subsequently evaluated across the same six transfer directions. During adaptation, anomaly labels were obtained exclusively from the source domain, while unlabeled target-domain training samples participated only in domain-adversarial learning.

Table 3.3: Cross-domain performance of DI-STGAT

Source → Target	Accuracy	Balanced Accuracy	Precision	Recall	F1-score	ROC-AUC	PR-AUC
BATADAL → SWaT	0.0372	0.5000	0.0372	1.0000	0.0718	1.0000	1.0000
BATADAL → WADI	0.0367	0.5001	0.0366	1.0000	0.0706	0.4742	0.0325
SWaT → BATADAL	0.0077	0.5000	0.0077	1.0000	0.0152	1.0000	1.0000
SWaT → WADI	0.2556	0.6137	0.0468	1.0000	0.0894	0.4408	0.0306
WADI → BATADAL	0.0077	0.5000	0.0077	1.0000	0.0152	0.9296	0.0818
WADI → SWaT	0.9628	0.5000	0.0000	0.0000	0.0000	0.4882	0.0366
Mean	—	**0.5190**	—	—	**0.0437**	**0.7221**	**0.3636**

The proposed DI-STGAT as shown in table 3.3 achieved a mean balanced accuracy of 51.90% and mean F1-score of 4.37%, compared with 50.51% and 4.13%, respectively, for the conventional ST-GAT baseline. The largest improvement occurred for SWaT to WADI, where balanced accuracy increased from 53.04% to 61.37%, while F1-score increased from 7.48% to 8.94%. This improvement resulted primarily from better recognition of normal WADI observations while maintaining complete attack recall. However, a notable failure case occurred for WADI→SWaT, where DI-STGAT achieved 96.28% accuracy but zero precision, recall, and F1-score. As shown in Table 3.4, all 1,477 target samples were classified as normal (TN = 1,422, FN = 55), resulting in the failure to detect any of the 55 anomalies. Thus, the high accuracy reflects the strong class imbalance rather than effective anomaly detection. The near-chance ROC-AUC of 0.4882 further indicates weak anomaly discrimination, while the domain-classification balanced accuracy of 0.6687 suggests incomplete source–target alignment. This result demonstrates that DI-STGAT does not transfer uniformly across all domain pairs and that high accuracy can mask complete anomaly-detection failure. For practical deployment, transfer-specific validation using balanced accuracy, recall, F1-score, and PR-AUC is therefore essential before deploying the model in an unseen ICS environment.

Table 3.4: Confusion Matrix for the WADI→SWaT Transfer

Actual Class	Predicted Normal	Predicted Anomaly	Total
Normal	1,422 (TN)	0 (FP)	1,422
Anomaly	55 (FN)	0 (TP)	55
Total	1,477	0	1,477

3.4 Comparative Performance of ST-GAT and DI-STGAT

To determine the contribution of domain-adversarial adaptation, the performance of DI-STGAT was directly compared with the corresponding ST-GAT baseline. As summarized in Table 3.5, DI-STGAT produced modest increases in mean balanced accuracy and F1-score, while mean ROC-AUC and PR-AUC showed slight decreases, indicating that the effect of domain-adversarial adaptation differed between fixed-threshold decision performance and overall ranking performance.

Table 3.5: Aggregate comparison of ST-GAT and DI-STGAT

Metric	ST-GAT	DI-STGAT	Change
Balanced Accuracy	0.5051	0.5190	+0.0139
F1-score	0.0413	0.0437	+0.0024
ROC-AUC	0.7310	0.7221	−0.0089
PR-AUC	0.3646	0.3636	−0.0010

Figure 3.3 compares the F1-scores of the conventional ST-GAT and DI-STGAT for each source-target pair. The most visible difference occurs for SWaT to WADI, where DI-STGAT increases F1-score from 0.0748 to 0.0894. The remaining transfer directions show either equivalent or nearly equivalent fixed-threshold performance. The figure therefore indicates that the benefit of adversarial adaptation is transfer-dependent, with the largest decision-level improvement occurring when WADI is adapted from SWaT.

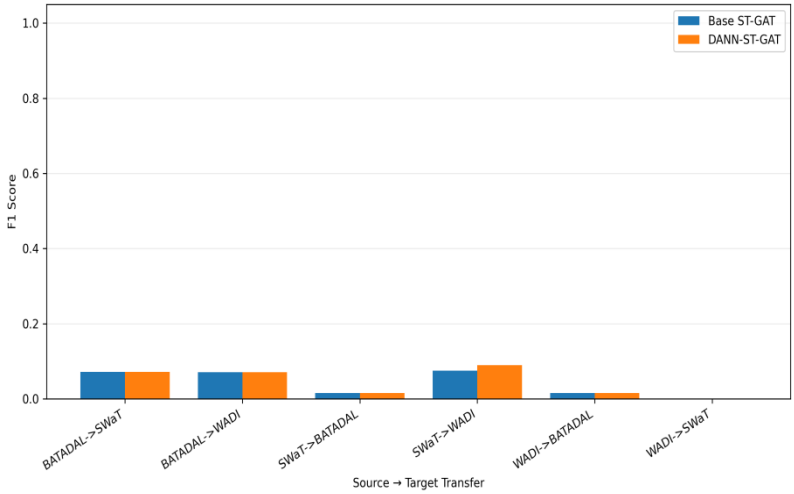

Figure 3.3: Cross-domain F1-score comparison between ST-GAT and DI-STGAT

Across all six transfers, mean balanced accuracy increased by 1.39 percentage points, while mean F1-score increased by only 0.24 percentage points. The largest F1 improvement occurred for SWaT→WADI, from 0.0748 to 0.0894; however, the absolute F1-score remains low. Conversely, mean ROC-AUC decreased by 0.89 percentage points and PR-AUC by 0.10 percentage points.

Therefore, although DANN/GRL produced a measurable numerical improvement in fixed-threshold decision performance for some source–target relationships, the magnitude and absolute performance levels are insufficient to demonstrate deployment-ready anomaly detection. Rather, the results provide evidence of the feasibility of domain-adversarial adaptation within the ST-GAT framework, while highlighting the need for substantial improvement in cross-domain anomaly discrimination and calibration before practical deployment. Accordingly, DI-STGAT should be regarded as an experimental cross-domain framework rather than an immediately deployable ICS anomaly-detection solution.

Further, the reported comparisons are based on the fixed experimental runs and were not evaluated across multiple random seeds. Consequently, the observed differences between ST-GAT and DI-STGAT, including the 1.39 percentage-point increase in mean balanced accuracy, should be interpreted as descriptive experimental differences rather than statistically significant improvements. Multiple-seed evaluation with confidence intervals and statistical significance testing is therefore required in future work to determine the robustness of these differences to random initialization and training variability.

3.5 Training Behaviour of DI-STGAT

The evolution of the anomaly and domain-learning objectives was monitored during DANN training. Because six source-target directions were evaluated, displaying every training curve in the

main manuscript would be repetitive. The SWaT to WADI curve is selected as the representative example because this transfer produced the largest improvement in balanced accuracy and F1-score.

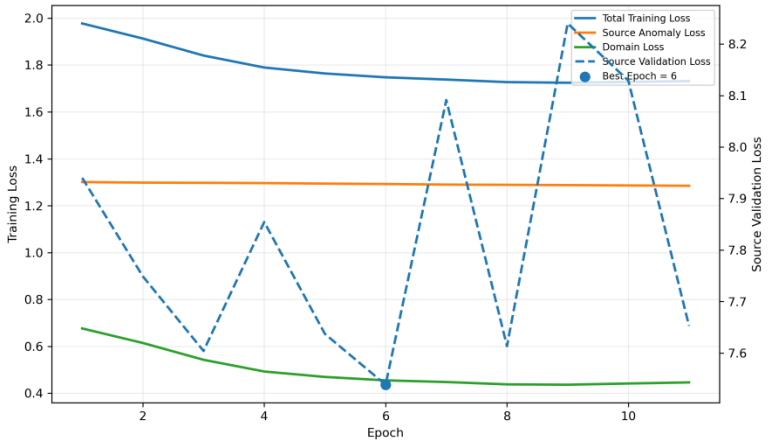

Figure 3.4: DI-STGAT training behaviour for SWaT to WADI

Figure 3.4 illustrates the evolution of the source anomaly-training loss, source validation loss, domain-classification loss, and GRL adaptation strength during SWaT to WADI training. The figure demonstrates the simultaneous optimization of anomaly discrimination and domain adaptation. As training progresses, the GRL coefficient increases according to the adopted schedule, progressively strengthening the adversarial signal applied to the ST-GAT feature extractor. Model selection remains governed by source-validation anomaly loss rather than target-domain labels.

The training behaviour is consistent with the unsupervised adaptation design of DI-STGAT: labeled source observations guide anomaly classification, whereas source and unlabeled target representations jointly contribute to the domain-adversarial objective. The remaining five training curves may be reported as supplementary material if required by the journal.

3.6 Domain-Representation Analysis

An important objective of the DANN/GRL component is to reduce the amount of domain-specific information retained in the learned representation. Domain-classification balanced accuracy was therefore analyzed after adaptation. A value approaching 0.50 indicates stronger source-target confusion, whereas a value approaching 1.00 indicates that the two domains remain readily distinguishable.

Table 3.6: Domain-representation diagnostic results

Source → Target	**Domain Balanced Accuracy**	**Interpretation**
BATADAL → SWaT	0.9888	Weak domain confusion
BATADAL → WADI	0.7911	Partial alignment
SWaT → BATADAL	0.8317	Limited alignment
SWaT → WADI	0.7931	Partial alignment
WADI → BATADAL	0.5000	Strong domain confusion
WADI → SWaT	0.6687	Moderate alignment
Mean	0.7622	Domain-dependent alignment

Table 3.6 shows substantial variation in the degree of source-target domain confusion produced by adversarial training. WADI to BATADAL achieved a domain balanced accuracy of 0.5000, indicating that the trained domain classifier could not distinguish the two representations better than chance. WADI to SWaT also showed increased confusion with a value of 0.6687. Conversely, BATADAL→SWaT remained highly distinguishable at 0.9888. The figure therefore demonstrates that DANN/GRL produced domain-dependent representation alignment rather than uniform domain invariance.

Table 3.7: Aggregate Domain-Representation Diagnostics for DI-STGAT

Diagnostic Measure	Mean Value	Interpretation
Balanced accuracy	0.7622	Indicates that source and target representations remained distinguishable overall; 0.50 represents chance-level domain discrimination.
Binary Cross-Entropy (BCE)	0.5442	Measures the domain classifier's prediction error; values approaching the binary chance-loss level indicate greater domain confusion.
Source–target probability	0.2134	Measures the difference between predicted domain probabilities for source and target representations; a smaller gap indicates stronger alignment.
Centroid Euclidean distance (L2)	0.4339	Measures the distance between source and target embedding centroids; a smaller value indicates greater proximity in the representation space.
Centroid cosine similarity	0.9995	Indicates very high directional similarity between source and target embedding centroids; values closer to 1 indicate greater directional similarity.

Table 3.7 shows the mean domain-classification balanced accuracy of 0.7622. Additional diagnostics produced a mean domain-classification (BCE) of 0.5442, mean source-target probability gap of 0.2134, mean centroid Euclidean distance of 0.4339, and mean centroid cosine similarity of 0.9995. These measures provide complementary evidence that adversarial learning influenced source-target representations, although complete domain confusion was not obtained consistently. An important observation is that stronger domain confusion did not automatically result in higher anomaly-detection performance. For example, WADI to BATADAL achieved the strongest domain confusion but did not produce a corresponding F1-score improvement. This suggests that successful domain adaptation requires not only reducing domain-specific information but also preserving anomaly-discriminative structure in the shared representation.

3.7 Decision-Threshold Analysis

A secondary experiment investigated whether selecting the classification threshold from source-validation data could improve target-domain performance. Target validation and test anomaly labels were not used in threshold selection.

Table 3.8: DI-STGAT threshold comparison

Threshold Strategy	Mean Balanced Accuracy	Mean F1-score
Fixed threshold = 0.50	0.5190	0.0437
Source-validation threshold	0.5012	0.0263

The source validation derived threshold reduced mean balanced accuracy from 0.5190 to 0.5012 and F1-score from 0.0437 to 0.0263. Consequently, the fixed 0.50 threshold was retained as the primary operating point as shown in table 3.8.

This result demonstrates that classification calibration itself does not transfer reliably between heterogeneous ICS domains. Even when representations contain transferable ranking information, the probability scale learned from one environment may not correspond directly to the optimal decision boundary in another. This observation helps explain the disparity between relatively strong ROC-AUC values and low fixed-threshold F1-scores observed in several experiments.

3.8 Overall Discussion

The experimental findings demonstrate three main outcomes. (i) The ST-GAT architecture successfully processed heterogeneous ICS environments containing different numbers of process variables and graph structures. The fixed 32-dimensional graph-level representation enabled the three datasets to be processed using the same architecture without requiring identical feature sets, thereby providing a common representation mechanism for heterogeneous ICS domains. (ii) The integration

of DANN and GRL enabled unsupervised target-domain adaptation using labeled source-domain data and unlabeled target-domain data without requiring target-domain anomaly labels during training. DI-STGAT increased mean cross-domain balanced accuracy from 50.51% to 51.90% and mean F1-score from 4.13% to 4.37%, with the strongest improvement occurring for SWaT to WADI, where balanced accuracy increased from 53.04% to 61.37% and F1-score from 7.48% to 8.94%. The ST-GAT versus DI-STGAT comparison in Figure 3.3 demonstrates this improvement. (iii) The domain-representation analysis in Table 3.5 and 3.6 showed that adversarial learning influenced source–target separability, although the degree of alignment varied across transfer directions. These findings demonstrate that DI-STGAT achieved the study's aim of developing a domain-adaptive spatio-temporal framework capable of cross-domain anomaly detection across heterogeneous ICS environments without requiring target-domain anomaly labels for training. However, the transfer-dependent improvements and variations in domain alignment indicate that the framework did not achieve uniform domain invariance or performance improvement across all source–target combinations. Thus, DI-STGAT establishes the feasibility of domain-adversarial cross-domain anomaly detection for heterogeneous ICSs while identifying cross-domain calibration and representation alignment as areas requiring further improvement.

4. CONCLUSION

This study proposed DI-STGAT, a domain-adaptive spatio-temporal graph learning framework for cross-domain anomaly detection in heterogeneous Industrial Control Systems. By integrating ST-GAT with DANN/GRL, the framework provides a mechanism for transferring anomaly-relevant knowledge from a labeled source domain to an unlabeled target domain while accommodating differences in process variables and graph structures. Evaluation across BATADAL, SWaT, and WADI demonstrated the feasibility of this approach, with DI-STGAT providing measurable improvements in cross-domain decision performance over the conventional ST-GAT baseline, particularly for the SWaT→WADI transfer. The findings also showed that the effectiveness of domain adaptation depends on the source–target relationship, indicating that representation alignment alone does not guarantee improved anomaly discrimination. The principal contribution of this work is therefore the establishment of a heterogeneity-aware, domain-adaptive ST-GAT framework that supports cross-domain anomaly detection without requiring target-domain anomaly labels for training. Future work will focus on improving cross-domain probability calibration and graph-level representation learning, strengthening domain alignment while preserving anomaly-discriminative information, and extending the framework to ICS datasets from other industrial sectors to further evaluate its generalizability beyond the water-related environments considered in this study.

ABSTRACT

This study presented and validated a finite element (FE) model for estimating the structural performance of externally reinforced concrete (RC) beams using bonded steel plates. The developed model was validated with the existing experimental results, and the effect of the thickness of steel plate and the thickness of adhesive on the ultimate load of strengthened beams was studied. The FE predictions were in good agreement with the experimental results with differences in the ultimate loads being rather minor and the predictions being consistently higher. The developed model was accurate and reliable as indicated by a strong positive correlation (Pearson correlation coefficient, $r = 0.961$, $p < 0.001$). The ultimate load was used as a response variable and a two-factor analysis of variance (ANOVA) was conducted. The results showed that the thickness of the adhesive had a statistically significant effect on ultimate load ($F = 5.12$, $p = 0.043$) while steel plate thickness did not ($F = 2.12$, $p = 0.201$). The load–deflection responses also showed that the RC beams strengthened externally were considerably higher when compared to the control RC beam as a result of the application of external steel plate strengthening, in terms of stiffness, energy absorption capacity and ductility. The behaviour of the beams with an adhesive thickness ranging from 4 to 6 mm was optimal, showing high stiffness, energy absorption capacity, and high ductility due to the efficient dissemination of the stress on the steel–concrete interface. However, an increased thickness of the adhesive layer (8 mm) in comparison led to a decrease in structural efficiency due to a decrease in the interface stiffness and stress transfer. The study showed that finite element model could be used as a valid tool to predict the behaviour of steel-plated RC beams and that the effect of optimizing the thickness of the adhesive was more significant than the increasing thickness of the steel plates on the RC beam to attain better structural performance.

INTRODUCTION

Reinforced concrete (RC) structures are a large share of civil engineering infrastructures around the world, known for their strength, durability, versatility, and cost-effectiveness (Tiza et al., 2024: Rusnak, 2025: Özmen & Tanrıverdi, 2025). During its service life, however, many existing RC structures suffer from deterioration or structural deficiency issues due to aging, reinforcement corrosion, increased service loads, design errors, environmental exposure, inadequate construction, seismic activities, accidental impacts, and changes in use of buildings (Yadeta et al., 2023; Rincon et al., 2024: Ma et al., 2025). These conditions can cause a decrease in the ability of structural members to withstand flexural loads, especially beams which are the main load resisting members (Mahi & Ridoy, 2025; Osta et al., 2026). Strengthening and rehabilitation, which are methods for prolonging the life of the structures without the high costs of demolition and reconstruction, have therefore become more and more important in recent years (Hu et al., 2024; Rusnak, 2025; Elkhatib et al., 2025).

Out of all the strengthening techniques that are available, externally bonded steel plate reinforcement is the most common technique used due to the fact that it is the most effective, easy to install and economic (Khalil & Attia, 2025; Mankare, & TS, 2026; Alsuhaibani, 2025). The method typically involves the use of high-strength epoxy adhesives to adhere steel plates to the tension surface of RC beams, and sometimes with mechanical anchors (Xu et al., 2024; Napoli et al., 2024). The flexural strength, stiffness, and cracking resistance of the composite structure are enhanced due to the external

bond of steel plate, and the deflection under service loads is reduced (Qiang et al., 2023; Mosahebfard et al., 2026). There are many experimental studies that have proven that steel plate strengthening is a viable solution for the rehabilitation of deficient RC beams and improves their structural performance (Bandara et al., 2023; Napoli et al., 2024; Xu et al., 2024; Elkhatib et al., 2025).

Although it has proven effective, the behaviour of externally strengthened RC beams is complex because of the interaction between the concrete, the reinforcing steel, the adhesive layers and the externally bonded steel plates (Foraboschi, 2022; Hamoda et al., 2024; Ahmed, 2025). The mechanical properties of the component materials, nature of the bonds between the concrete and the adhesive, geometric properties of the plates, configuration of the plates' strengthening, loadings and possible failure mechanisms such as crushing of the concrete, yielding of the steel, debonding of the plates or failure of the adhesive (Ali et al., 2001; Edalati & Irani, 2012; Alam et al., 2020). The prediction of the structural response is difficult with conventional analytical approaches only (Hamoush & Ahmad, 1990; Ciampa & Pecce, 2021).

Experimental tests are the most accurate way to study the behaviour of strengthened RC beams (Sun et al., 2023; Zhang et al., 2023). Laboratory testing, however, is costly, time consuming, and is often restricted in its availability of testing facilities, materials and instrumentation (Oehlers & Seracino, 2004; Teng et al., 2002). In addition, experimental programmes typically examine only a few of the variables, and it is challenging to explore the effects of several design parameters in a comprehensive way (Hajirasouliha et al., 2012; Abaqus, 2014). In view of this, numerical modelling, specifically Finite Element Method (FEM) has become an essential tool to foresee the response of RC structures under strengthening with externally bonded steel plates (Alharthai et al., 2024).

By using the Finite Element Method, complex material behavior can be simulated, the non-linear cracking, crushing of concrete, yielding of reinforcement steel, the behavior of the adhesive bond, and the interaction between steel plates and concrete can be modeled (Muka, 2023; Noor et al., 2025). The modern finite element software enables researchers to accurately study the distribution of stresses, the load-deflection behavior, propagation of cracks, development of strains, and failure modes (Kholil & Ahmed, 2025; Ciampa & Pecce, 2021). After being properly validated, finite element models are able to perform detailed parametric studies, optimize strengthening schemes and support structural design (Raviolo et al., 2023; Mobarhan et al., 2026).

Several researchers have created finite element models of RC beams externally strengthened with various modelling methods, constitutive material models, and bond-slip models (Ciampa & Pecce, 2021). In many of these studies, the results are in reasonable agreement with the experimental data, but significant differences between experimental data and the results in the studies have been found due to the various assumptions made about material nonlinearities, the modelling of the interfaces, the mesh discretization, and the failure criteria (Chen et al., 2012). Furthermore, existing models have predominantly considered strengthening with externally bonded carbon fibre reinforced polymer (CFRP) while few studies have investigated externally bonded steel plate strengthening in detail and developed validated nonlinear finite element models that can be used to accurately predict both the global and local structural response (Li et al., 2025).

To create a good finite element model which realistically simulates the behavior of exteriorly strengthened reinforced concrete beams is therefore imperative. A model, it should be capable of reproducing experimental observations such as load-deflection behaviour, strain distribution, cracking patterns, ultimate load capacity and failure modes (Li et al., 2025). It is important to validate the model developed against pre-existing experimental studies before it can be used with confidence for additional analysis and structural design applications, as proposed by Ciampa & Pecce (2021).

The focus of this study is thus the development and validation of the nonlinear finite element model of reinforced concrete beams strengthened externally in flexure with steel plates. To ensure the accuracy and reliability of the model, published validation test results of existing studies will be used. The validated model is hoped to be able to offer a reliable numerical tool in analysing the flexural response of strengthened RC beams and minimize the need for expensive experimental investigations thus helping in the development of structural rehabilitation and strengthening.

2.0 METHODOLOGY

2.1 Development of Finite Element Model of Steel Glue RC Beam

This section describes the formulation of a finite element model that is based on the ideas originally presented by Bimal & Hiroshi (2002). Considering the very small thickness of the interface, an eight-noded element as shown in Figure 1(a) was found to be sufficient for modeling the steel-glue-concrete interface.

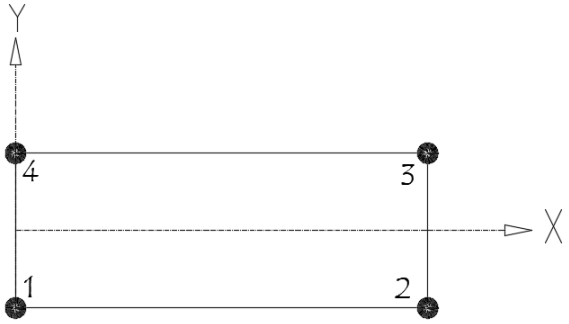

Figure 1: Steel-glue concrete interface element

Introducing pseudo-nodes 1' and 2' (see Figure 1), an iso-parametric formulation with parabolic shape functions could be implemented. The element was formulated using the two-point Gaussian integration rule.

2.1.1 Stress- strain relations

The strains in the glue element can be written as

$$\varepsilon = \begin{bmatrix} \varepsilon_x \\ \varepsilon_y \\ \gamma_{xy} \end{bmatrix} = \begin{bmatrix} \dfrac{\delta u}{\delta x} \\ \dfrac{\delta v}{\delta y} \\ \dfrac{\delta u}{\delta y} + \dfrac{\delta v}{\delta x} \end{bmatrix} \quad (1)$$

The strain ε_x along the x-direction may be approximated as

$$\varepsilon_\xi = \frac{\delta u}{\delta x} \quad (2)$$

A shape function is an interpolation function that provides an association between the variables in a finite element and their values at the nodes of the element. The finite element methods are applied to solve the problem and these nodal values are obtained.

$$u(x) = \sum_i N_i(x) u_i = \boldsymbol{N}u \quad (3)$$

Where;

u(x) is the function under investigation (for example displacement field)

N(x) is the shape functions matrix

$$u = \begin{bmatrix} u_1 \\ u_2 \\ u_3 \\ u_4 \\ . \\ . \\ u_n \end{bmatrix} \; is\ the\ vector\ of\ unknowns\ in\ the\ nodes(for\ example: displacement)$$

Substituting Equation 3 into 2, we have,

$$\varepsilon_x = \frac{\delta u}{\delta x} = \frac{\delta}{\delta x}\sum_{i=1}^{2} N_i'(x)\breve{u}_i$$

$$= \sum_{i=1}^{2} \frac{dN_i'(x)}{dx}\breve{u}_i, \qquad (4)$$

The shape functions at three equivalent nodal points 1′and 2′as shown in Fig.1 are represented by Ni=Ni(x); ui are the average nodal displacements along the line n = 0. This equation can then be written in terms of the nodal displacements of the element, ui, as shown in equation (4).

$$\varepsilon_x = \frac{dN_1'}{dx}\left(\frac{u_1 + u_4}{2}\right) + \frac{dN_2'}{dx}\left(\frac{u_2 + u_3}{2}\right) \qquad (5)$$

The strain in the normal direction ε_n. is given by

$$\varepsilon_y = \frac{\delta v}{\delta y} \qquad (6)$$

and can be stated in terms of nodal normal strains as

$$\varepsilon_y = \sum_{i=1}^{2} N_i'(x)\left(\frac{\delta v}{\delta y}\right)_i = \sum_{i=1}^{2} N_i'(x)\left(\frac{\Delta v}{t}\right)_i$$

$$= \frac{1}{t}\left[N_1'(v_4 - v_1) + N_2'(v_3 - v_2)\right] \qquad (7)$$

where t is the element thickness. The shear strain γ_{xy} is approximated as

$$\gamma_{xy} = \frac{\delta u}{\delta y} + \frac{\delta v}{\delta x} = \sum_{i=1}^{2} N_i'(x)\left(\frac{\delta u}{\delta y}\right)_i + \sum_{i=1}^{2} \frac{dN_i'(x)}{dx}\breve{v}_i$$

$$\gamma_{xy} = \frac{1}{t}\left[N_1'(u_4 - u_1) + N_2'(u_3 - u_2)\right] + \left[\frac{dN_1'}{dx}\left(\frac{v_1 + v_4}{2}\right) + \frac{dN_2'}{dx}\left(\frac{v_2 + v_3}{2}\right)\right] \qquad (8)$$

Substituting Equations (5), (7) and (8) in Equation (1) we obtain, the above equation can be written as

$$\varepsilon = [\mathrm{B}][v] \qquad (9)$$

$$\varepsilon = \begin{bmatrix} \frac{1}{2}\frac{dN_1'}{dx} & 0 & \frac{1}{2}\frac{dN_2'}{dx} & 0 & \frac{1}{2}\frac{dN_2'}{dx} & 0 & \frac{1}{2}\frac{dN_1'}{dx} & 0 \\ 0 & -\frac{N_1'}{t} & 0 & -\frac{N_2'}{t} & 0 & \frac{N_2'}{t} & 0 & \frac{N_1'}{t} \\ -\frac{N_1'}{t} & \frac{1}{2}\frac{dN_1'}{dx} & -\frac{N_2'}{t} & \frac{1}{2}\frac{dN_2'}{dx} & \frac{N_2'}{t} & \frac{1}{2}\frac{dN_2'}{dx} & \frac{N_1'}{t} & \frac{1}{2}\frac{dN_1'}{dx} \end{bmatrix} \begin{bmatrix} u_1 \\ v_1 \\ u_2 \\ v_2 \\ u_3 \\ v_3 \\ u_4 \\ v_4 \end{bmatrix}$$

Where:
B is the strain matrix and v is the displacement vector
Ni are the parabolic shape functions

$$B = \begin{bmatrix} \frac{1}{2}\frac{dN_1^{\wr}}{dx} & 0 & \frac{1}{2}\frac{dN_2^{\wr}}{dx} & 0 & \frac{1}{2}\frac{dN_2^{\wr}}{dx} & 0 & \frac{1}{2}\frac{dN_1^{\wr}}{dx} & 0 \\ 0 & -\frac{N_1^{\wr}}{t} & 0 & -\frac{N_2^{\wr}}{t} & 0 & \frac{N_2^{\wr}}{t} & 0 & \frac{N_1^{\wr}}{t} \\ -\frac{N_1^{\wr}}{t} & \frac{1}{2}\frac{dN_1^{\wr}}{dx} & -\frac{N_2^{\wr}}{t} & \frac{1}{2}\frac{dN_2^{\wr}}{dx} & \frac{N_2^{\wr}}{t} & \frac{1}{2}\frac{dN_2^{\wr}}{dx} & \frac{N_1^{\wr}}{t} & \frac{1}{2}\frac{dN_1^{\wr}}{dx} \end{bmatrix}$$

$$v = \begin{bmatrix} u_1 \\ v_1 \\ u_2 \\ v_2 \\ u_3 \\ v_3 \\ u_4 \\ v_4 \end{bmatrix}$$

2.1.2 Shape functions

The shape functions can be defined as:

$$N_k = \sum \frac{\xi - \xi_m}{\xi_k - \xi_m}, \quad therefore,$$

$$N_1 = \frac{\xi - \xi_2}{\xi_1 - \xi_2} = \frac{\xi - 1}{-1 - 1}$$

$$N_1 = \frac{1}{2}(1 - \xi) \tag{12}$$

$$N_2 = \frac{\xi - \xi_1}{\xi_2 - \xi_1} = \frac{\xi + 1}{1 + 1}$$

$$N_2 = \frac{1}{2}(1 + \xi) \tag{13}$$

2.2 Material and Cracking Behavior of the Interface

Before cracking of the interface, the property matrix of the material is given as presented as Eq. (14), where: ν= Poisson's ratio of the interface, E= modulus of elasticity of the interface, G= shear modulus.

The behaviour of the interface will be assumed to be elastic under tensile and shear loading, with a linear response up to the failure limit as shown in Figure 2. After reaching this limit, cracking starts to develop in the interface element. The very thin interface limits crack propagation to along the adhesive (glue) line or perpendicular to the glue line.

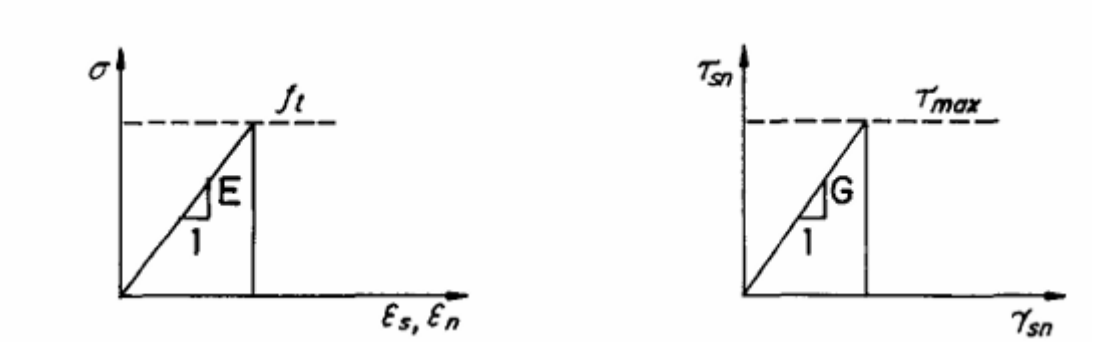

Figure 2: Material behavior of the interface element in tension and shear.

$$[D]_{x-y} = \frac{E}{1-\nu^2}\begin{bmatrix} 1 & \nu & 0 \\ \nu & 1 & 0 \\ 0 & 0 & \frac{G(1-\nu^2)}{E} \end{bmatrix} \quad (14)$$

It is assumed that cracking occurs perpendicular and/or parallel to the glue line when (fii) and/or (fip) equals the corresponding normal stress at the interface. From this point, further load in the direction of the crack can no longer be resisted by the interface. Therefore, the normal stress and the corresponding elastic modulus in that direction are assumed to be zero, i.e., total loss of stiffness across the crack.

If cracks form at an angle normal to direction of glue, the property matrix of the material should be modified to reflect the loss of stiffness in that direction and the reworked property matrix is called:

$$[D]_{i-n} = \begin{bmatrix} 0 & 0 & 0 \\ 0 & E & 0 \\ 0 & 0 & 0.25G \end{bmatrix} \quad (15)$$

In addition to cracking perpendicular to the glue line, the interface can also fail parallel to the glue line when it is subjected to a combination of normal and shear stresses. Experimental results suggest that such a failure can be best represented by the Mohr–Coulomb fracture criterion, which takes into consideration the interaction between normal and shear stresses at the interface, and predicts the onset of cracking under combined loading.

$$\tau = c - \sigma \tan\phi \quad (16)$$

where: c= cohesion, σ = normal stress, ϕ= angle of internal friction. For steel–epoxy–concrete interface: Cohesion c= 4.8-9.5 MPa and Internal friction angle $\phi=28^0$

The strength of adhesion and failure resistance of the interface is influenced by the type of surface preparation, the quality of the adhesive, and properties of the concrete substrates. If the failure occurs at the interfaces due to tensile (peeling) stress, then the stress components and stiffness terms at the interfaces are set to zero, indicating that the bond will not carry any load. But when the loading is compressive, failure defined by the Mohr–Coulomb criterion enables the interface to sustain a compressive load. Here, only the shear stress and shear stiffness are removed, and the compressive normal stiffness is left as it is, and a new material stiffness matrix is obtained.

$$[D]_{x-y} = \begin{bmatrix} \frac{E}{1-\nu^2} & \frac{\nu E}{1-\nu^2} & 0 \\ \frac{\nu E}{1-\nu^2} & \frac{E}{1-\nu^2} & 0 \\ 0 & 0 & 0 \end{bmatrix} \quad (17)$$

2.2.1 Material Properties for the Interface Element

The following material properties define the interface element: normal elastic modulus (E), shear modulus (G), Poisson's ratio (ν) and tensile strength (f_{ti}). The properties of these are determined by those of the parent components, which are the concrete substrate, epoxy adhesive and the externally bonded steel plate. The mechanical properties of these constituent materials are used to determine the

normal elastic modulus, the Poisson's ratio and the tensile strength, and the shear modulus of the interface is obtained by measuring the slope of the average shear stress–slip relationship of a half beam specimen test.

The resulting shear modulus was found to be G=120.1 MPa. This is essentially the same as the value reported by Charif (1983). If ν = 0.16, the interface modulus is calculated as E=2G (1+ν) and comes out to be 278.6 Mpa. The experimental value of the tensile cut-off strength of the interface was obtained as $f_{ti} = 4$ MPa.

2.2.2 Finite Element Model for Constituent Materials

The interface element of the previous section was added to the nonlinear finite element solution procedure. The response of each of the constituent materials needs to be accurately modelled when dealing with reinforced concrete beams strengthened by externally bonded steel plates (EBSSP), which have highly nonlinear behaviour. The overall structural response will be dependent on the interaction between the concrete, internal reinforcing steel, externally bonded steel plate and the bond interfaces. Accordingly, an appropriate constitutive model and finite element formulation were assigned to each material to realistically simulate its behaviour during the loading process.

2.3 Concrete

2.3.1 Yield Criterion

Cracking in tension and crushing in compression cause the response of concrete to be highly nonlinear. The Mohr–Coulomb yield criterion is used to describe the onset of yielding in this study. Initial yielding is assumed to take place at about 30% of the compressive strength of the concrete, expressed as:

$$\sigma_0 = 0.3f_c' \tag{18}$$

where $f_c'$is the compressive strength of the concrete. From this point on, the yield surface expands due to plastic deformation. The following loading surfaces are represented by

$$f(\sigma) = \sigma_0(Z) \tag{19}$$

The equation contains a hardening parameter, Zis, that is a function of the effective plastic strain. During loading, the concrete displays elasto-plastic characteristics, and continual plastic deformation occurs. After the effective stress exceeds the ultimate compressive strength, the material is said to be perfectly plastic up to the crushing strain.

2.3.2 Flow Rule and Hardening Rule

For plastic deformation there is an associated flow rule, which is characterized by the plastic strain increment that is perpendicular to the yield surface. This relation between effective stress and plastic strain is obtained from uniaxial parabolic stress–strain relation proposed for concrete,

$$\sigma = E_0\varepsilon - \frac{1}{2}\left(\frac{E_0}{\varepsilon_0}\right)\varepsilon^2 \tag{20}$$

where E_0 is the initial elastic modulus, ε is the total strain, and ε_0 is the strain at the peak compressive stress. The initial elastic modulus is computed according to the formula suggested by the ACI Committee 363,

$$E_0 = 3320\sqrt{f_c'} + 6900 \tag{21}$$

It applies to normal and high-strength concrete (between 21 and 83 MPa compressive strength). The constitutive relationship for concrete, then, can be written as

$$\sigma = -E_0\varepsilon_p + \sqrt{2E_0^2\varepsilon_0\varepsilon_p},\ (0.3f_c' \le \sigma \le f_c') \tag{22}$$

where $\varepsilon_p$denotes the effective plastic strain.

2.3.3 Crushing Criterion

It is assumed that crushing of concrete is not affected by applied stress, but rather by the strain level. The crushing is defined to happen when the compressive strain is effective enough to reach the ultimate crushing strain, as provided by the equation below

$$f(\varepsilon_{ij}) = \varepsilon_u \tag{23}$$

Where, $\varepsilon_u = 0.0035$. The concrete has been considered to have lost all its compressive load-bearing capacity at this point.

2.3.4 Cracking Behaviour

The tensile response of concrete is modeled by a smeared crack model to distribute cracking throughout the finite element instead of as a discrete crack. Concrete is a linear elastic material in tension before cracking. Cracks start when the maximum principal tensile stress equals the tensile strength of concrete. The tensile strength is estimated from the following empirical equation given by Raphael (1984),

$$f_t = 0.324(f_c')^{2/3} \tag{24}$$

After cracking, it is assumed that cracks form at 90° to the maximum principal tensile stress. The perpendicular stiffness is set to zero, the shear stiffness is reduced to reflect the loss of aggregate interlock along a crack and Poisson's ratio for cracks is ignored.

2.3.5 Tension Stiffening

The concrete and the reinforcement act together. This means that concrete between cracks can still resist significant tensile force, although cracking reduces the effective tensile stiffness of the concrete significantly. This phenomenon is called tension stiffening and is represented in the finite element model by assigning an effective or fictitious post-cracking tensile modulus to concrete.

The equation can be written as:

$$E_i = \alpha f_t' \left(1 - \frac{\varepsilon_i}{\varepsilon_m}\right)\frac{1}{\varepsilon_i},\ \varepsilon_t \le \varepsilon_i \le \varepsilon_m \tag{25}$$

Where, E_i= s the secant (or degraded) modulus of elasticity at a tensile strain ε_i, α= is a material parameter that controls the post-cracking tensile response, f_t'= tensile strength of concrete, ε_i= tensile strain at the current loading stage, ε_t= strain at the onset of cracking, ε_m= maximum tensile strain.

2.4 Finite Element Representation

The concrete material is modeled as a finite element, with 9 integration points and 9 nodes (isoparametric elements) and the constitutive matrix of the model is changed at each integration point in each load increment to capture concrete cracking, crushing and plastic behaviour accurately. The internal reinforcing steel is idealized using 3-noded quadratic truss elements, which are only capable of handling axial deformations, and with an elasto-plastic constitutive model with isotropic hardening. This bond between the reinforcing steel and concrete is modeled with the use of six-noded interface elements allowing bond-slip and failure when the interface shear exceeds the given bond strength. The interface has a shear modulus of 1.2GPa, elastic modulus of 2.78GPa, Poisson's ratio of 0.16, and bond strength of 7.5MPa. The externally bonded steel plate is modeled as an elasto-plastic material with isotropic hardening based on the von Mises yield criterion and discretized by nine-noded isoparametric Lagrangian elements to capture the stress concentrations and peeling stresses. Taken together these material models allow for the finite element model to simulate realistically the concrete damage, the yielding of the steel, and the bond-slip and degradation of the interface, providing reliable prediction of the loading–deformation behavior, failure mode and ultimate load capacity of steel-plated reinforced concrete beams under monotonic loading.

2.5. Beams investigated

A custom MATLAB program based on an incremental–iterative Newton–Raphson solution procedure was developed and used to implement and solve the finite element model. The nonlinear equilibrium equations were solved incrementally by subdividing the applied load into a number of load steps. The global tangent stiffness matrix was assembled from individual element stiffness matrices and the incremental displacement vector was obtained by solving the global equilibrium equations for each load step. The iterative solution accounted for the nonlinear response of the concrete, the steel reinforcement, the external steel plate and the interface elements. At the end of each iteration the element strains and stresses at the integration points were calculated and the internal resisting force vector was modified. The residual force was then calculated as the difference between the externally applied. Both force and displacement criteria were used to converge each load increment. Convergence was assumed to be achieved when the normalized residual force and incremental displacement were small enough, with tolerance limits of and, respectively. A maximum of 50 iterations was allowed for each load increment. Where convergence was not achieved the load increment was reduced and the iterative procedure repeated until equilibrium was achieved.

The beam specimens investigated by John (2023) are shown in Table 1. For the purposes of this study, the calibration and validation of the finite element model presented used the steel-plate-strengthened beam subset of John's (2023) experimental program. The specimens considered were the control beam and the beams strengthened externally with steel plates of different thicknesses and adhesive layer thicknesses. The CFRP-strengthened specimens of John's (2023) experimental program were not part of the FE validation dataset.

The sample ID is defined as follows in Table 1: P = Steel Plate, F = Flexural Strengthening, 0, 2, 4, 6, and 8 are the thicknesses of the epoxy adhesive (in mm), respectively. The material properties used in the finite element model were taken from the experimental study done by John (2023). The cylinder compressive strength (f'c) was assumed for the concrete material as 85% of the cube compressive strength as reported in the experimental investigation, which is a common assumption in concrete modelling. The rest of the parameters needed to define the concrete constitutive model were obtained as follows:

The internal reinforcing bars and stirrups were simulated as elastic–plastic materials with Es = 200 GPa and fy = 530 MPa, and H' = 200 MPa. In the same manner, the elastic modulus (Ep) of the externally bonded steel plate was assumed to be 200 GPa, the yield strength (fy) as 240 MPa, the Poisson's ratio (v) as 0.30, and the plastic modulus (H') as 200 MPa.

The bond behaviour at the steel plate–adhesive–concrete interface was simulated using some of the interface properties proposed by Ziraba and Baluch (1995) to enable the numerical model to realistically simulate the interaction between the bonded steel plate and the concrete substructure.

Table 1: Experimental Programme of Steel Plate for Flexural Strengthening

Sample group	Steel Plate thickness	Epoxy Thickness (mm)	Sample ID
	-	-	FA-0
A	1.0mm Steel Plate	2	PFA2
		4	PFA4
		6	PFA6
		8	PFA8
B	1.5mm Steel Plate	2	PFB2
		4	PFB4
		6	PFB6
		8	PFB8
C	2.0mm Steel Plate	2	PFC2
		4	PFC4
		6	PFC6
		8	PFC8

Figure 3 presents the experimental beam layout and the cross-sectional reinforcement details used as basis for the finite element idealization, including the 2Ø8 mm top reinforcement, 2Ø10 mm bottom reinforcement, Ø6 mm stirrups and the externally bonded strengthening system. The cross-sectional size of the reinforced concrete beams was 150 mm × 100 mm as shown in Figure 3. The beams were longitudinally reinforced with 2Ø8 mm bars at the top and 2Ø10 mm bars at the bottom. Ø6 mm stirrups were provided along the length of the beam. The internal reinforcement of the control beam FA-0 and the strengthened beam PFA2 was identical, and the strengthening of PFA2 was achieved by an externally bonded steel plate using the specified adhesive layer.

The longitudinal reinforcement was modelled by truss elements embedded into the concrete domain in the finite element model. The top and bottom reinforcement was configured to be the same as the physical reinforcement in Figure 3. The Ø6 mm transverse reinforcement was also modelled with truss elements in the corresponding locations and spacing. The adopted bond-slip model was used to model the bond between the reinforcement and the surrounding concrete and to capture the relative interaction between the reinforcement and concrete. For the strengthened specimens, the externally bonded steel plate was modelled using plate elements and the adhesive layer between the steel plate and concrete was modelled using the six-node interface elements described in Section 2.5. Consequently, the reinforcement and strengthening configurations applied to the FE model were consistent with the geometry and reinforcement detailing of the experimental specimens as shown in Figure 3.

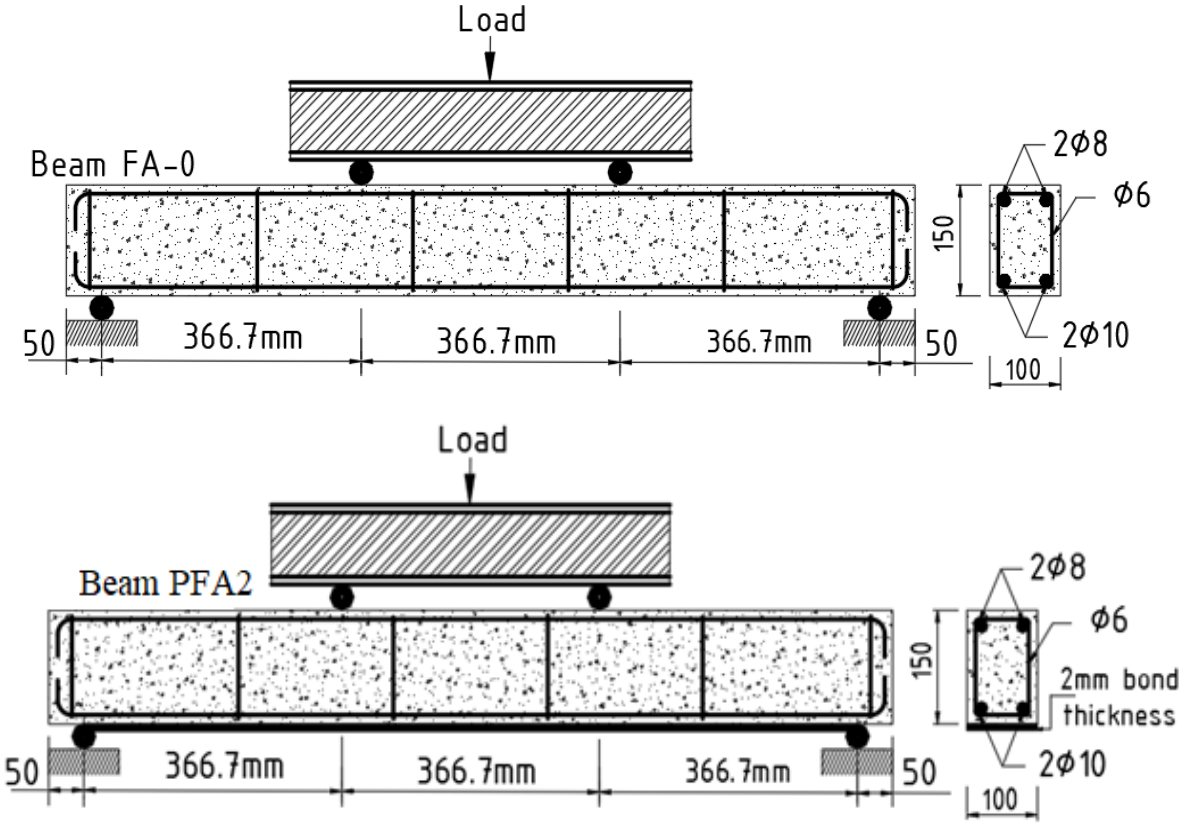

Figure 3: Beam configuration

2..5.1. Mesh sensitivity

A mesh sensitivity analysis was performed to find a suitable mesh density for the finite element model and to ensure that the numerical predictions were not significantly affected by the element size, as shown in Table 2. The three meshes that were studied are called coarse, medium and fine and are progressively refined. Similar element formulations, material constitutive models, interface properties, loading and boundary conditions were maintained for all mesh configurations. The predicted ultimate load and the corresponding mid-span displacement were the main parameters used to evaluate mesh convergence.

Table 2: Mesh sensitivity and convergence assessment

Mesh	Approx. element size (mm)	No. of elements
Coarse	40	4,820
Medium	30	7,650
Fine	20	12,480
Very fine	15	18,920

3.0 RESULTS AND DISCUSSION

3.1 Results and validation of the development model

The experimental results obtained by John (2023) were presented in Table 3, and the finite element (FE) results were compared with the experimental ones to check the agreement of the two methods and to assess the effect of steel plate thickness and adhesive thickness on the ultimate load values. The overall agreement between the FE model and experimental results was good with percentage differences ranging from 0.53% to 10.62% with an average difference of approximately 3.10%. The FE model always predicted the experimental ultimate loads slightly higher. Most of the specimens showed differences of less than 4%, which means a satisfactory numerical accuracy. The largest differences were for PFB8 (10.62 %) and PFB2 (6.82 %). This may be due to the difficulty in accurately modeling the adhesive thickness, interface behavior, debonding, surface imperfections and material variability. This was additionally verified by a high positive correlation between the experimental and FE results with a Pearson correlation coefficient of 0.961 ($p < 0.001$), showing that the developed FE model was able to capture the experimental behaviour of strengthened beams. In addition, a 2-factor analysis of variance (ANOVA) was performed with steel plate thickness and adhesive thickness as the independent factors and the FE-predicted ultimate load as the dependent variable, excluding the control specimen FA-0 as shown in Table 4. The ANOVA result indicates that the thickness of the steel plate is not statistically significant with the predicted ultimate load with value $F = 2.12$ and $p = 0.201 > 0.05$, while the thickness of the adhesive is statistically significant with the predicted ultimate load value $F = 5.12$ and $p = 0.043 < 0.05$.

Table 3: Loads of the Beams

Sample ID	Steel plate thickness (mm)	Adhesive thickness (mm)	John (2023)'s Exp. Results (kN)	Finite Element Model, (kN)
FA-0	-	-	93.33	94.24
PFA2	1.0	2.0	121.68	123.12
PFA4	1.0	4.0	128.23	130.10
PFA6	1.0	6.0	124.25	126.05
PFA8	1.0	8.0	115.75	119.23
PFB2	1.5	2.0	110.55	118.09
PFB4	1.5	4.0	119.08	122.09
PFB6	1.5	6.0	128.23	130.14
PFB8	1.5	8.0	105.00	116.15
PFC2	2.0	2.0	125.12	128.92
PFC4	2.0	4.0	127.24	130.95
PFC6	2.0	6.0	126.50	127.17
PFC8	2.0	8.0	115.00	119.4

Table 4: ANOVA parameters

Source	df	Sum of Squares	F-value	p-value
Steel plate thickness	2	50.55	2.12	0.201
Adhesive thickness	3	183.42	5.12	0.043
Error	6	71.62	—	—

These results show that the increase in the thickness of the adhesive layer compared to the variation in the thickness of the steel plates had a more significant effect on the load bearing capacity of the strengthened beams within the range of parameters investigated. The results of the analysis prove that the finite element model can represent the structural response of the steel-plated reinforced concrete beam well. It also shows that optimizing the thickness of the adhesive is more important than increasing the thickness of the steel plates in order to increase the load carrying capacity of the strengthened beams. The highest performance was achieved with the thickness of the adhesive of ~ 4-6 mm, and with the thickness of the adhesive increased to 8 mm, the structural efficiency was reduced.

3.2 Load–Deflection behaviour

The load-deflection curves in Figure 4 prove that the use of EBSP resulted in the significantly higher stiffness, energy absorption and ductility of the reinforced concrete beams as compared to the unstrengthened control beam (FA-0).

Referring to Figure 4, the strengthened beams have higher initial slopes than the control beam, which shows that the initial stiffness of the strengthened beams is higher. This indicates that the beams with plating took higher loads with lesser deflection in the elastic portion. The enhanced specimens tended to show highest stiffness for beams with 4 mm and 6 mm thickness of adhesive, which indicates the better transfer of stress between the steel plate and concrete. Contrastingly, beams with an 8 mm layer of adhesive had a small decrease in stiffness, indicating that, thicker adhesives allow more deformation before the stresses are adequately carried from one side to the other.

According to Figure 4, the increased area under the load–deflection curves for the strengthened beams compared to the control beam also showed a significant increase in the energy absorbing capacity of the strengthened beam. The stress distribution was more uniform and the propagation of cracks was slowed down and delayed by the combined effect of the steel plate and adhesive layer over the wall, leading to the increase in absorbed energy. The specimens with load application by 4 mm and 6 mm adhesive thickness demonstrated the maximum absorption of energy with a relatively high loading force and a significant deflection range prior to failure. On the other hand, the 8 mm adhesive specimens showed reduced energy absorption, with a high drop in load after the peak load, suggesting that interface degradation started earlier.

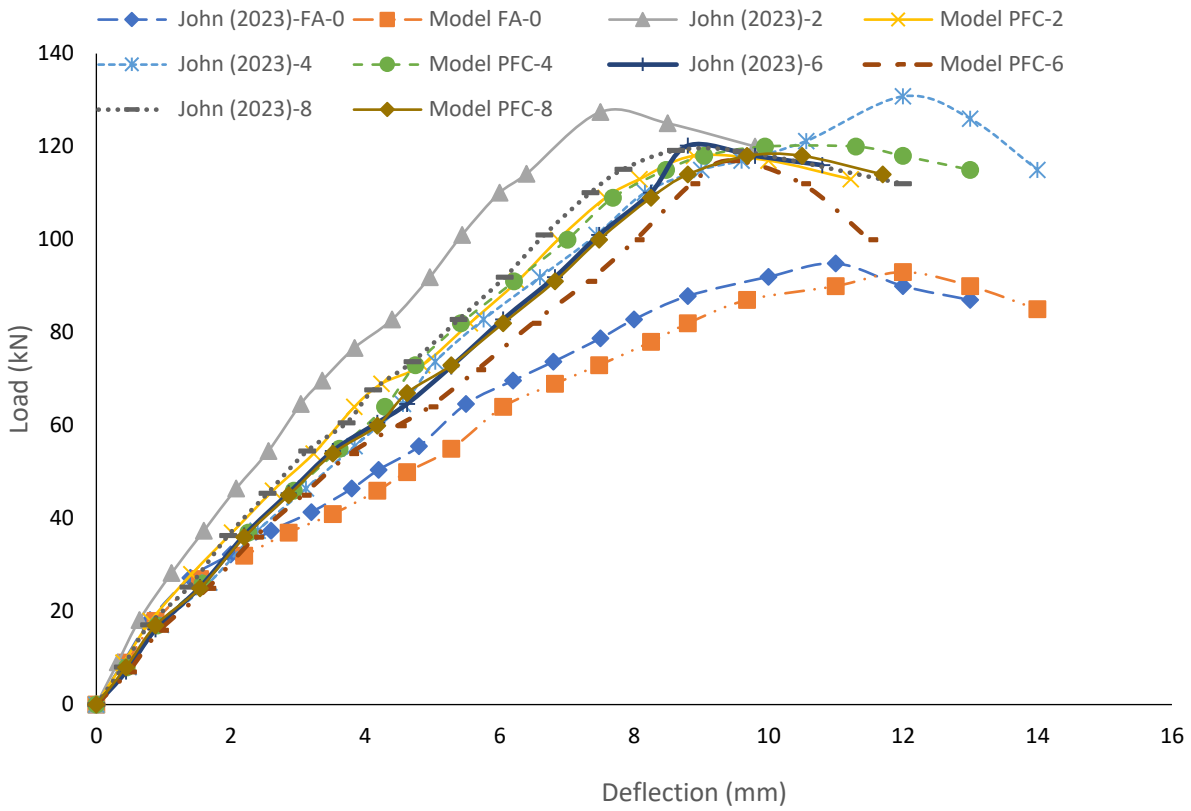

Figure 4: Load–Deflection behaviour

3.2.2 Ductility

The enhanced beams exhibited greater ductility than the control beam as they were able to carry higher deflections after yielding and still carried a significant percentage of their capacity. The post peak behavior of the plated beams was more continuous than that of the control beam thus reflecting a more ductile mode of failure. The specimens that had an adhesive thickness of 4 mm and 6 mm showed the best ductile behaviour, with high ultimate loads and long deformations until failure. Adhesive specimen dimensions of 8 mm reached relatively high loads, but the load at the peak was followed by a more evident decrease in load after the peak which indicates a loss in ductility due to loss of interface stiffness. As a whole, the results show that the optimum thickness range of the adhesive for the externally steel-plated reinforced concrete beams is 4–6 mm with regard to stiffness, energy absorption and ductility.

Table 5: Deflection and ductility Caparison

Beam	Exp. peak (mm)	Model peak (mm)	Difference (mm)	Difference (%)
FA-0	11.5	12.5	+1.0	+8.7
FA-2	8.0	9.5	+1.5	+18.8
FA-4	12.5	10.5	−2.0	−16.0
FA-6	9.5	9.5	0.0	0.0
FA-8	9.5	10.0	+0.5	+5.3

Table 5 presents deflection and ductility results of the experimental and FEM model. The best specimen in terms of large deformation capacity is FA-4, with the maximum experimental peak displacement of about 12.5 mm and a large deformation range. FA-6 and FA-8 show relatively stable deformation responses with peak experimental displacement of about 9.5 mm. FA-2, belonging to moderate-to-high ductility class, has the lowest experimental peak displacement of about 8.0 mm. FA-0 shows the baseline response with moderate ductility and

obvious post-peak softening. To summarize, FA-4 has the maximum deformation capacity, and FA-6 and FA-8 exhibit more stable post-peak behavior, which means that the FA modification influences the peak deformation and post-peak behavior of the beams.

3.3 Sustainability, Nigerian Infrastructure Development, Or Industrial Policy

The use of externally bonded steel plates for strengthening existing reinforced concrete structures has important implications for sustainable infrastructure development in Nigeria. Steel-plate strengthening is a practical, economical alternative to the demolition and complete reconstruction of structurally deficient beams and other reinforced concrete members. The technique can extend the functional service life and enhance the durability of aging infrastructure by increasing the load-carrying capacity, stiffness and serviceability of existing structures. This is especially true in Nigeria where the rehabilitation of dilapidated bridges, buildings and other reinforced concrete infrastructure is becoming increasingly important in the maintenance of safe and reliable infrastructure networks.

From a sustainability perspective the improvement of existing structures reduces the need for new construction materials, demolition activities and associated construction waste, and retains the embodied energy already invested in existing structures. The results of this study thus contribute to sustainable structural rehabilitation and infrastructure transformation by providing numerical and experimental evidence that can support the use of steel-plate strengthening as a viable rehabilitation technique. The approach is consistent with the conference themes on sustainability, Nigerian infrastructure development and industrial transformation by promoting resource-efficient rehabilitation, extending the service life of infrastructure and reducing the environmental and economic impact associated with premature demolition and reconstruction.

4.0 CONCLUSIONS

From the finite element analysis, validation with experimental results, and load–deflection behaviour analysis of the externally steel-plated reinforced concrete beams, the following conclusions are drawn:

1. The developed finite element model was found to be a good predictor of the structural response of externally steel-plated reinforced concrete beams. The numerical results were closely corresponded with the experimental results reported by John (2023), as the Pearson correlation coefficient (0.961) with p value < 0.001, the developed model was reliable
2. The finite element model was always able to predict loads slightly higher than the experimental loads, but the differences were small and acceptable in engineering terms. This shows that the model can accurately predict the load carrying capacity of strengthened reinforced concrete beams.

3. Statistical analysis showed that the thickness of the adhesive significantly affected the ultimate load of the strengthened beams ($F = 5.12$, $p = 0.043$); however, the thickness of the steel plates in the range examined did not have a statistically significant effect on the ultimate load of the strengthened beams ($F = 2.12$, $p = 0.201$). This means that the impact of strengthening system is more related to the glue layer than to the thickness of the steel plate.
4. It was concluded that the structural performance of the reinforced concrete beams was significantly improved in terms of the stiffness, energy absorption potential and ductility by the exterior bonding of steel plates with the unstrengthened control beam. The enhanced beams performed better with respect to load resistance, post yield performance and failure gradient.
5. The overall performance of all the adhesive thicknesses tested was optimum for 4-6 mm.4-6 mm was found to be the optimum thickness of the adhesive for optimum performance in terms of stiffness, energy absorbed and ductility.
6. Results showed that the thickness of 8 mm adhesive layer had no advantage for the structurally steel-plated reinforced concrete beam because of less interface stiffness and less effective stress transferring.

ABSTRACT

More than a decade after the 2013 restructuring and privatization of Nigeria's electricity sector, the Nigerian Electricity Supply Industry (NESI) continues to face interacting technical, commercial, financial, and institutional constraints. Rather than treating recurrent failures as isolated generation, transmission, distribution, metering, or regulatory problems, this paper develops NESI-X as a systemic hybrid-leapfrogging architecture for coordinated transformation. It distinguishes what can be leapfrogged from what cannot: distributed generation, mini-grids, storage, advanced metering, and data-driven operations can bypass selected technological pathways in generation, distribution, metering, monitoring, and maintenance, whereas transmission infrastructure and the institutions that sustain it must be progressively reinforced. Hybrid electricity-sector leapfrogging (HESL) is formally defined as this selective-bypass-plus-reinforcement logic, and the functions it treats as indispensable are named non-bypassable system dependencies (NSDs). NESI-X organizes this distinction into two tiers, transformation capabilities and enabling conditions, coupled through a qualitative causal-loop model and a directed conceptual dependency matrix expressed as expert-informed propositions rather than statistically estimated dependencies. The architecture draws on Nigerian primary regulatory and institutional sources, including the Electricity Act 2023, the National Integrated Electricity Policy, the 2026 Mini-Grid Regulations, FoNER, NISO, and NEMSA's statutory technical-assurance mandate, alongside recent literature on smart metering, mini-grids, digital twins, and cyber-physical security. A gated roadmap and layer-level KPIs are proposed alongside financing, institutional capacity, skills, interoperability, cybersecurity, and political-economy risks as adoption conditions. The contribution is a testable architecture, not a claim of validation.

Keywords: *Nigeria Electricity Supply Industry; hybrid leapfrogging; non-bypassable system dependencies; distributed energy resources; regulatory governance*

1. INTRODUCTION

More than a decade after Nigeria's 2013 power-sector privatization, the sector has undergone substantial institutional restructuring, yet persistent weaknesses in electricity reliability, metering, revenue recovery, infrastructure condition, and system coordination continue to constrain sector performance (Adeku et al., 2026). Responsibilities are now divided among generation companies (GenCos), the Transmission Company of Nigeria (TCN), distribution companies (DisCos), the Nigerian Electricity Regulatory Commission (NERC), and a growing set of state-level institutions. Evidence from selected distribution companies indicates that institutional and ownership restructuring has not, by

itself, guaranteed sustained improvements in service quality, billing, metering, or customer response (Akunne et al., 2023). The Electricity Act 2023 and the subsequent transition of market regulation to participating states have expanded the reform agenda, creating opportunities for sub-national innovation while increasing the need for coordination across federal and state jurisdictions (Federal Republic of Nigeria, 2023).

Existing studies on Nigeria's electricity sector examine individual dimensions of this problem - privatization outcomes, technical and commercial losses, smart-metering strategies, mini-grid deployment, digitalization, and regulatory reform - largely in isolation. Three gaps motivate NESI-X. First, Nigerian electricity research treats reliability, losses, distributed generation, metering, regulatory reform, and digitalization as partially independent problems rather than a coupled system. Second, the leapfrogging literature offers limited guidance on how bypassable technological pathways should coexist, within a single architecture, with infrastructure and institutions that remain physically or legally indispensable. Third, few conceptual approaches translate these interacting dimensions into an institutionally grounded architecture with explicit inter-layer dependencies, implementation gates, and measurable transition conditions. NESI-X is accordingly defined here as a proposed adaptive architecture for coordinating decentralized energy resources, digital intelligence, technical assurance, regulatory governance, and market liquidity within a progressively reinforced national electricity system, addressing these three gaps together rather than in isolation.

The paper's contribution has three parts, developed in Section 2 and applied in Section 3: hybrid leapfrogging - selective technological bypass, formally defined, coupled with progressive reinforcement of non-bypassable dependencies; an assurance-integrated architecture, in which NEMSA is treated not as peripheral compliance but as a cross-cutting technical-assurance spine running through every operational layer; and testability, since the architecture generates an explicit causal-loop model, a directed dependency matrix, implementation gates, layer-level KPIs, and five empirical propositions (P1–P5) for future testing against Nigerian data.

These contributions support four linked claims. Conceptually, the paper formalizes hybrid electricity-sector leapfrogging and reframes NESI dysfunction as a coupled-system problem, distinguishing evidence-supported feedback mechanisms from hypotheses requiring empirical testing. Architecturally, it proposes the NESI-X architecture across two conceptual tiers with an explicit dependency matrix, so that "integration" is a specified dependency rather than a general aspiration. Institutionally, it integrates NERC, state regulators, FoNER, NISO, and NEMSA's technical assurance mandate into a single architecture. For implementation, it converts the architecture into a gated roadmap with measurable entry/exit conditions and layer-level KPIs, naming financing, skills, technical assurance, cybersecurity, and political economy as implementation constraints rather than afterthoughts.

Three research questions guide the paper. RQ1: Which components of Nigeria's electricity supply system can be leapfrogged, and which infrastructure and assurance functions remain non-bypassable? RQ2: How can distributed generation, digital intelligence, governance, technical assurance, and market liquidity be configured as an interdependent transformation architecture? RQ3: What institutional, technical, financial, and cybersecurity conditions should govern progression between transformation stages? Section 2 develops the conceptual apparatus for RQ1, Section 3 addresses RQ2, and Section 4's roadmap together with Section 5's discussion takes up RQ3.

Diagnosing NESI's dysfunction must precede any proposed architecture, since a system's coupling can only be modeled once its failure dimensions are known. The sector's problem is not merely insufficient installed generation capacity: a power system can possess substantial generation assets and still fail to deliver reliable electricity if transmission observability, distribution capacity, metering, revenue collection, gas availability, technical assurance, or regulatory coordination is inadequate. Table 1 identifies five interacting diagnostic dimensions. NESI-X responds through four operational layers - two transformation-capability layers and two enabling-condition layers - supported by a cross-cutting technical-assurance spine represented by NEMSA, as Section 3 develops.

Table 1: NESI 1.0 as a Coupled System: Diagnosis Matrix

Dimension	**Observed** Problem	**Systemic consequence**	**NESI-X response**
Technical resilience	Limited real-time visibility, aging and strained assets, and weak predictive capability.	Faults propagate through the network; maintenance remains reactive rather than planned; reliability deteriorates over time.	Digital intelligence, Wide Area Measurement Systems (WAMS), Phasor Measurement Units (PMU), digital twins, and predictive analytics are all part of Layer 2.
Distributed energy architecture	Centralized topology remains vulnerable to system-wide disturbance and access gaps.	Local loads are exposed to national-grid failures or protracted transmission/distribution extension cycles.	This layer includes Distributed Energy Resources (DER), mini-grids, energy storage, and intentional islanding.
Technical assurance and safety	Continuous need for standards enforcement, inspection, testing, certification, and meter/equipment assurance as physical and digital infrastructure expands.	Unsafe or non-compliant installations, equipment failure, degraded interoperability, and reliability risk that outpaces oversight capacity.	The NEMSA technical-assurance spine: inspection, testing, certification, and compliance with standards, operating alongside the Standards Organization of Nigeria (SON).
Governance coordination	Federal and state regulatory roles are still evolving under the Electricity Act 2023.	Divergent state-level rules raise coordination risk and transaction costs.	Harmonized standards, regulatory sandboxing, and FoNER coordination (Layer 3).
Market liquidity	High Aggregate Technical, Commercial and Collection (ATC&C) losses, and weak collection efficiency.	Reduced capacity to finance metering, operations and maintenance, and network reinforcement.	The focus areas include AMI, revenue assurance, loss analytics, and targeted investment (Layer 4).

The financial dimension is the most thoroughly documented in current Nigerian regulatory evidence. NERC's 2025/Q4 Quarterly Report states that the weighted average ATC&C loss across all DisCos in 2025/Q4 was 34.90%, comprising 17.97 percentage points of technical/commercial loss and 20.64 points of collection loss (NERC, 2026a, §2.3.5). These components combine multiplicatively rather than additively, following the standard ATC&C convention:

$$ATC\&C = 1 - [(1 - \text{Technical/Commercial Loss}) \times (1 - \text{Collection Loss})] \qquad Eq.1$$

$$ATC\&C = 1 - [(1 - 0.1797) \times (1 - 0.2064)] = 1 - (0.8203)(0.7936) = 34.90\%$$

This reconciles exactly with NERC's reported aggregate figure, sits 14.36 percentage points above the 20.54% efficient-loss target used in MYTO 2025 tariffs, and translates to a cumulative revenue loss of ₦139.19 billion for DisCos in that quarter alone; only Eko outperformed its ATC&C target, by 2.68 percentage points (NERC, 2026a, §2.3.5). This situation is not a marginal inefficiency but nearly fifteen percentage points of avoidable revenue loss recurring quarterly, sustained by the same structural weaknesses documented across the post-privatization literature. Smart-metering strategies have been directly linked to ATC&C loss mitigation in Nigerian distribution systems (Odje et al., 2021), so metering functions as a liquidity and data-quality intervention with system-wide consequences, not merely a customer-service improvement.

Nigeria is simultaneously moving toward a more decentralized electricity architecture, formalized in the National Integrated Electricity Policy and Strategic Implementation Plan (NIEP-SIP) mandated under Section 3 of the Electricity Act 2023 (Federal Ministry of Power, 2025). NERC's 2026

Mini-Grid Regulations recognize both isolated and interconnected mini-grids, the latter permitted up to 10 MW (NERC, 2026b), and the World Bank's Nigeria Electrification Project has already supported 125 mini-grids and more than a million solar home systems, helping over 5.5 million Nigerians gain electricity access (World Bank, 2024). Nigeria, therefore, need not replicate every historical stage of conventional electricity system development, particularly where distributed energy and digital technologies offer alternative pathways to access and modernization. The concept of energy leapfrogging is directly relevant here but must be applied carefully rather than treated as a slogan: its developmental effect depends on economic, institutional, and behavioral conditions being in place to sustain it, not merely on acquiring newer technology (van Benthem, 2015). Section 2 formalizes this idea as hybrid electricity-sector leapfrogging.

NESI 1.0 is used throughout this paper as analytical shorthand for the current fragmented configuration; the designation does not imply Nigeria has ever formally operated a versioned electricity-industry architecture, nor is it an official government classification.

2. CONCEPTUAL AND METHODOLOGICAL FOUNDATION

This section formalizes the paper's central construct - hybrid electricity-sector leapfrogging - names the dependencies it treats as non-bypassable, sets out the evidence-synthesis method, and develops the causal-loop model coupling Table 1's five dimensions into a single system.

2.1 Hybrid Electricity-Sector Leapfrogging (HESL)

HESL is defined here as a transformation pathway in which selected technological development stages are bypassed where alternative technologies provide functionally equivalent or superior outcomes, while physically indispensable infrastructure and institutionally non-bypassable functions are progressively reinforced rather than circumvented. What can be leapfrogged includes conventional generation-expansion sequencing; distribution-extension pathways; manual meter reading; and reactive maintenance - selected pathways in generation, distribution, metering, monitoring, and maintenance, not a wholesale bypass of any single sector-wide stage. Digital intelligence is best understood as the enabling capability that makes this leapfrogging possible, rather than a leapfroggable stage itself: Nigeria can leapfrog the sequence in which metering, monitoring, and generation technologies are adopted, but it deploys digital intelligence as the observability layer that lets the rest of the leapfrogging happen safely, rather than "leapfrogging" it.

The construct can be expressed compactly as:

Hybrid Leapfrogging = Selective Bypass + Progressive Reinforcement + Institutional Assurance

Nigeria can leapfrog selected stages of electricity-sector development; it cannot leapfrog the physical and institutional dependencies that make an electricity system work. That proposition, developed architecturally in Section 3 and tested through explicit propositions in Section 5, is the paper's core contribution.

2.2 Non-Bypassable System Dependencies (NSDs)

The functions HESL does not permit to be bypassed are named here as non-bypassable system dependencies (NSDs): the transmission backbone; protection coordination; equipment and interconnection technical standards; NEMSA inspection, testing, and certification; cybersecurity; competent technical personnel; regulatory coordination across federal and state jurisdictions; and financial liquidity. These are precisely the functions NEMSA's statutory mandate covers, which is why Section 3 treats technical assurance as a distinct, cross-cutting element rather than folding it into "governance." NESI-X can, therefore, be summarized as:

NESI-X = Leapfroggable Pathways + Non-Bypassable System Dependencies

NESI-X does not treat technical assurance as another sectoral silo; it treats assurance as the cross-cutting condition that makes leapfrogging safe, interoperable, measurable, and scalable.

2.3 Evidence Synthesis and Conceptual Modeling

This is a conceptual, policy-architecture paper rather than a calibrated econometric or simulation study, and its methodology is a transparent conceptual-synthesis protocol rather than a

formal systematic review. The synthesis combines four elements: primary Nigerian regulatory documents, including NERC quarterly reports; the Electricity Act 2023; the NIEP-SIP; the 2026 Mini-Grid Regulations, NERC's orders establishing FoNER and NISO, and NEMSA's establishing instrument and current mandate (NEMSA, 2023); peer-reviewed literature on smart metering, mini-grids, digital twins, AI in power systems, and cyber-physical security, focused predominantly on 2020–2026 studies and supplemented by one classical leapfrogging reference (van Benthem, 2015); qualitative causal-loop modeling formalizing Table 1's coupling; and architecture and roadmap design informed by the preceding elements. Table 2 maps each evidence stream to its primary sources and purpose within the architecture.

Table 2: Methodological Source Mapping

Evidence stream	Primary sources	Purpose in architecture
Sector performance	NERC quarterly reports	ATC&C, reliability, and collection-efficiency evidence (Table 1, Section 1)
Legal/institutional structure	Electricity Act 2023; NERC orders establishing FoNER and NISO	Institutional allocation of governance and system-operation roles (Sections 3.3, 3.6)
Technical assurance	NEMSA establishing Act, her installation guidelines and current mandate under the Electricity Act 2023 (NEMSA, 2023)	Standards enforcement, inspection, and certification spine (Section 3.5)
Decentralization	2026 Mini-Grid Regulations; World Bank project data	DER/mini-grid pathway feasibility (Section 3.1)
Digitalization	Peer-reviewed literature on digital twins, AI, and cyber-physical security	Layer 2 design and cybersecurity risk framing (Section 3.2)
Leapfrogging theory	Energy-leapfrogging literature	Conceptual foundation for HESL (Section 2.1)

Evidence was organized into Table 1's five analytical domains, with Nigerian institutional claims restricted to primary regulatory and government sources rather than secondary commentary and Table 3's ratings assigned analytically from system-function logic rather than statistical estimation. The objective is a logically coherent, evidence-grounded architecture testable against multi-year Nigerian data - a testable architecture, not one whose validity is merely asserted. Validating Table 3's ratings through structured elicitation methods such as Delphi, DEMATEL, Interpretive Structural Modeling, or AHP/ANP is a natural next step this paper does not itself undertake.

2.4 Causal-Loop Logic

Only once NESI's dysfunction is established as multi-dimensional does it make sense to ask how the dimensions interact; the causal-loop analysis below uses reinforcing-loop logic to formalize Table 1's dimensions as a coupled system, rather than leaving them as parallel, independently addressable lists.

R1, the technical-financial feedback loop, is assembled from observable sector relationships: technical losses and poor service reduce effective revenue; weak revenue constrains maintenance and investment; inadequate investment further deteriorates performance, reinforcing the losses that began the cycle. Each link is independently plausible and consistent with Section 1's evidence, but the complete closed loop and each link's magnitude have not been empirically estimated for Nigeria - direction and strength require future empirical estimation. As a reinforcing loop, R1 is directionally symmetric: the same chain that produces decline would, under sustained investment, run in reverse as a virtuous cycle, so R1 is a lever available in both directions, not solely a description of failure.

R2, the regulatory-fragmentation loop, is treated more cautiously: fragmentation across a growing number of state jurisdictions plausibly raises transaction costs, creates inconsistent rules, and

increases investor uncertainty, but its strength and direction in the Nigerian context should be empirically estimated as the state-transition process matures, not presented as fact.

R3, the technical-assurance-data-revenue loop, formalizes the NEMSA function developed in Section 3 as a third reinforcing mechanism: NEMSA assurance activity improves measurement and equipment-condition integrity; more trustworthy data improves digital-intelligence outputs and billing accuracy; more accurate billing improves collectible revenue and investment capacity; and greater investment capacity, including in assurance itself, reinforces measurement integrity again. NEMSA's inspection and testing activities already generate equipment-condition, compliance, and certification records as a normal byproduct of its statutory function; NESI-X proposes that these verified records could, subject to appropriate data-governance arrangements, become a technical-data stream feeding the same asset-information systems that support digital-twin and predictive-maintenance applications. That integration is NESI-X's proposed architecture, not established Nigerian practice, and is labeled accordingly below.

A further loop describing regulatory fragmentation as self-correcting through harmonization pressure was considered but is not represented separately: it is a variant of R2 rather than functionally distinct, and a fourth loop would add diagram complexity without a materially new claim beyond R2 and Section 3.3's FoNER discussion. Figure 1 represents R1, R2, and R3 together, distinguishing R1's evidence-supported status from R2's and R3's hypothesized status through explicit labeling.

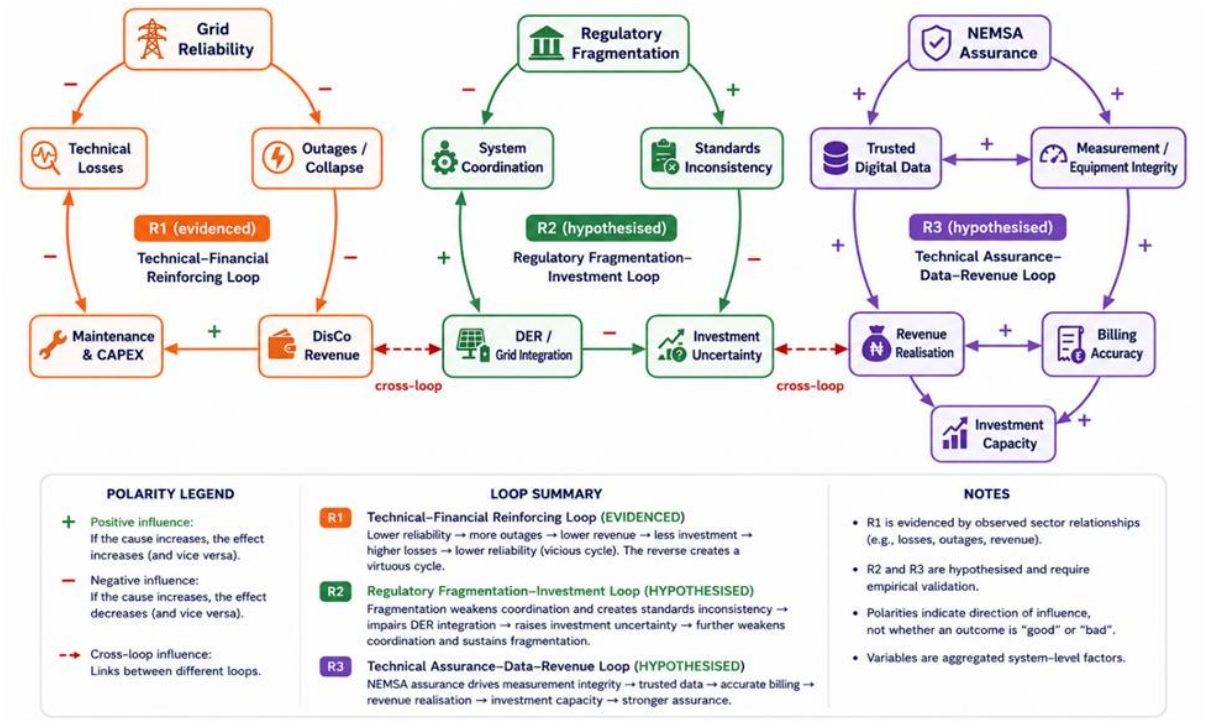

Figure 1: Qualitative causal-loop representation of NESI systemic coupling.

Distinguishing evidence-supported relationships from hypothesized ones strengthens the architecture, since a framework asserting every relationship with equal confidence is less useful to a reader - and less credible to a technical reviewer - than one that offers a path to test the difference. Concretely, R2's hypothesized strength and direction are the object of P3, which compares investment cycle times and DER interconnection approval times across states before and after FoNER-coordinated standard adoption; a null or reversed effect there would falsify R2 as specified. R3's hypothesized data-integrity channel is the object of P5, which compares an operational-data-only asset-condition model against an operational-plus-NEMSA-data model on the same asset population; no measurable improvement from the added NEMSA data stream would falsify R3's proposed mechanism. This gives each hypothesized loop a specific empirical test rather than leaving falsifiability implicit, and Section 5 converts this distinction into five explicit, individually testable research propositions.

3. NESI-X ARCHITECTURE

The causal coupling in Figure 1 motivates a structural response, but the response should treat the five diagnostic dimensions asymmetrically. Transformation capabilities are technological and infrastructural capabilities that directly alter NESI's physical or informational operating configuration: Layers 1 and 2. Enabling conditions are institutional and financial capabilities determining whether those technologies can be deployed, coordinated, financed, certified, and scaled sustainably: Layers 3 and 4, which, like the transmission backbone itself, cannot be bypassed and must be progressively built alongside the transformation-capability technologies. NESI-X is the overarching architecture: Figure 1 provides its causal logic; Figure 2 illustrates its structural configuration; Table 3 outlines its interdependencies; Table 4 details its implementation gates; Table 5 presents its performance indicators; and P1–P5 (Section 5) specify its empirical propositions. This tiering, shown in Figure 2, makes the paper's core proposition structurally explicit: Nigeria can leapfrog selected stages of electricity-sector development, but not the non-bypassable dependencies that make an electricity system work.

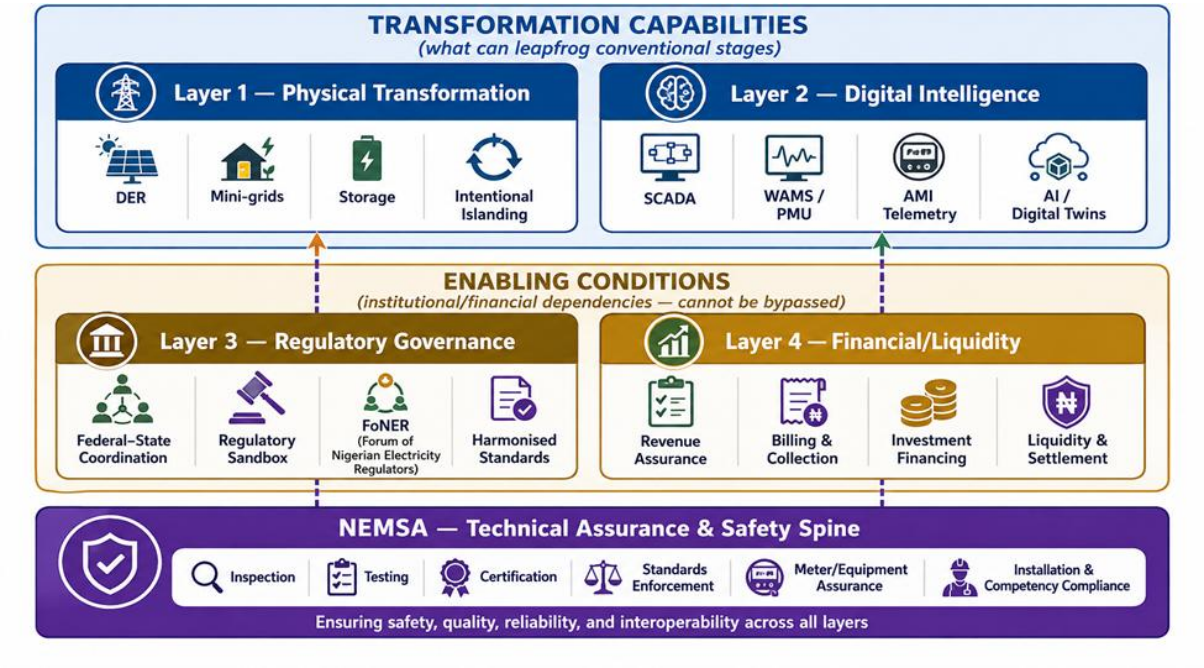

Figure 2: NESI-X architecture: transformation capabilities and enabling conditions.

NESI-X does not interpret decentralization as a substitute for transmission reinforcement. DER and mini-grids provide complementary resilience and access pathways while transmission capacity, protection, observability, and stability are progressively strengthened - decentralization is additive to the transmission backbone, not a replacement for it.

3.1 Layer 1 - Physical Transformation

This layer treats distributed energy resources, mini-grids, battery storage, and controllable local generation as strategic components of national resilience, not merely a rural-electrification substitute deployed where the conventional grid has not yet reached. NERC's 2026 Mini-Grid Regulations recognize both isolated and interconnected mini-grids (NERC, 2026b), and World Bank experience shows decentralized electricity is no longer a purely experimental pathway at scale (World Bank, 2024). The leapfrogging logic is architectural: an underserved community need not wait for a conventional transmission or distribution extension before receiving reliable electricity. But decentralization without interoperability and technical assurance can produce new fragmentation and a new category of safety risk rather than resolve the old one. Intentional islanding is not simply disconnection followed by continued local supply: it requires protection coordination, anti-islanding arrangements, synchronization on reconnection, frequency/voltage control, and, where relevant, black-start capability and DER inverter controls - none self-certifying. NESI-X therefore requires DER assets to comply with common protection, metering, telemetry, earthing, equipment, and interconnection requirements,

incorporated into the pre-commissioning and interconnection assurance pathway administered through the technical-assurance spine (Section 3.5). This gives Layer 1 a concrete engineering safeguard rather than an aspirational interoperability requirement: physical assets enter the system only once compliance has been independently verified, not merely declared by the deploying party.

3.2 Layer 2 - Digital Intelligence

This layer combines SCADA modernization, WAMS/PMU deployment, AMI telemetry, asset-condition monitoring, artificial intelligence, and digital-twin models to provide the observability that a more distributed system requires. A digital twin and an AI capability are not synonymous: the twin is the system-representation layer - a dynamic digital model of physical assets, topology, and state - while AI is an analytical capability operating on that representation and the validated data feeding it for forecasting, anomaly detection, or predictive maintenance. Digital-twin research shows a grid twin can support real-time analysis by linking physical-system measurements to a dynamic digital representation (Zhou et al., 2019). Recent work applies AI and reinforcement learning directly to cloud-based grid digital twins (Pei et al., 2024), while broader reviews identify combined digital-twin/AI use as an emerging pathway toward resilient grid management internationally (Ranawaka et al., 2024). The guiding principle for NESI-X in Nigeria should be "data before sophistication": a digital twin built on incomplete topology or unreliable measurements may appear visually impressive but will be operationally weak regardless of AI sophistication. NESI-X therefore prioritizes data governance, telemetry quality, and cybersecurity before deploying high-complexity AI.

Layer 2's data foundation need not come only from SCADA and AMI. NESI-X proposes that NEMSA-generated inspection, testing, and certification records could become a verified technical-data stream feeding the same asset-information systems supporting digital-twin and predictive-maintenance applications, illustrated in Figure 3 as a pathway from physical inspection through verified data, digital representation, and AI-based analytics to predictive maintenance and improved reliability and safety. This inspection-to-intelligence pipeline is one of the paper's more original operational contributions: it repositions a conventional statutory inspection function as a proposed active data source for a digitally intelligent grid, rather than a parallel, disconnected compliance process.

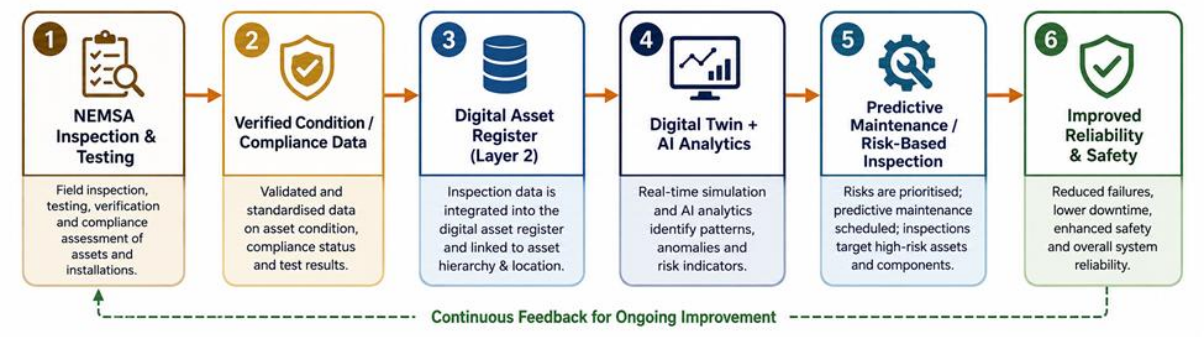

Figure 3: NEMSA inspection-to-intelligence pipeline within the NESI-X.

3.3 Layer 3 - Regulatory Governance

This layer does not transform the system directly; it determines whether Layers 1 and 2 can scale coherently across Nigeria's thirty-six states and the FCT. The Electricity Act 2023's decentralization can encourage valuable state-specific innovation but also creates a coordination challenge absent under the previous, purely federal structure. FoNER's 2026 inauguration - whose objectives include harmonized tariff-setting, market operations, consumer protection, and capacity-building among NERC and state regulators (NERC, 2026c) - provides an institutional basis for an adaptive regulatory layer. NESI-X proposes that FoNER could serve as a coordination platform for a regulatory sandbox operated against a national interoperability floor: states retain room to innovate in tariffs and DER business models - through data-informed, adaptive tariff-setting subject to regulatory approval - while core technical requirements (protection coordination, data exchange, cybersecurity

baselines, and metering interfaces) are harmonized, preventing state-level experimentation from producing incompatible electricity islands. This governance function is deliberately distinguished from technical assurance (Section 3.5), since economic/market regulation and technical standards enforcement are different institutional activities frequently, and inaccurately, conflated in general discussions of Nigeria's regulatory landscape.

3.4 Layer 4 - Financial/Liquidity

This layer likewise enables rather than transforms directly: reliable electricity must produce collectible revenue if the sector is to finance the maintenance Layers 1 and 2 depend on. Feeder-level energy accounting, automated billing, and transparent settlement form a data-to-cash chain in which AMI telemetry from Layer 2 feeds billing and revenue assurance directly (Odje et al., 2021). This chain is only as trustworthy as its measurements: meter testing, calibration, and certification are part of the technical-assurance spine below, so Layer 4's revenue-assurance function depends on Section 3.5 as much as on Layer 2's telemetry - an uncertified meter produces inaccurate billing regardless of digital sophistication. NESI-X treats this as a single, shared data infrastructure serving technical and commercial functions simultaneously, reducing the risk that separately commissioned digitalization projects create duplicated costs and incompatible databases - a failure mode that has characterized parts of Nigeria's metering rollout.

3.5 NEMSA: A Cross-Cutting Technical-Assurance Spine

Independent technical assurance of electrical infrastructure, before and during system integration, is a distinct institutional function from both the tariff/market regulation performed by Layer 3 and the technology deployed in Layers 1 and 2. It is deliberately represented as something other than a fifth layer because it is fundamentally different from the other four: it verifies safety and conformity to standards rather than transforming the system or regulating its economics. NESI-X therefore represents technical assurance as a cross-cutting spine beneath all four operational layers (Figure 2).

The Nigerian Electricity Management Services Agency (NEMSA) provides this spine's institutional interface. Under the Electricity Act 2023, NEMSA carries out electrical inspectorate services for NESI and enforces statutory technical standards and regulations, including inspection, testing, and certification of electrical installations, equipment, meters, and instruments (Nigerian Electricity Management Services Agency, 2023). NEMSA was established under the NEMSA Act 2015 (Act No. 6) and now operates under the Electricity Act 2023 framework, with the stated purpose of ensuring safe, reliable, sustainable electricity while guaranteeing the safety of lives and property (NEMSA, 2015). Its technical-assurance role operates within a wider standards ecosystem involving NERC, the Standards Organization of Nigeria (SON), utilities, manufacturers, and other technical institutions (Nigerian Electricity Management Services Agency, n.d.-b), rather than existing in isolation. This is materially different from NERC's function: NERC regulates market structure, tariffs, licensing, and economic conduct, while NEMSA enforces technical standards, safety, and equipment conformity - complementary rather than overlapping institutions.

Within NESI-X, NEMSA's spine connects to all four operational layers: to Layer 1 by verifying DER, mini-grid, and storage installations against protection, earthing, and interconnection requirements before integration (Section 3.1); to Layer 2 through the inspection-to-intelligence pipeline (Figure 3), where certification records become a data source for digital-twin applications rather than a parallel compliance archive; to Layer 4 through meter testing and certification, determining whether billing measurements can be trusted; and to Layer 3 by providing technical-assurance evidence and compliance requirements that inform the interoperability floor and technical conditions applied within regulatory experimentation, rather than by setting regulatory policy itself. This role is particularly important under a hybrid leapfrogging strategy, since accelerated deployment must not translate into accelerated technical risk; Section 2.4's causal-loop model formalizes this as R3, linking NEMSA assurance to measurement integrity, billing accuracy, and investment capacity.

3.6 NISO and TCN: Operational Coordination

The Electricity Act 2023 also provided for unbundling system and market operations from the Transmission Company of Nigeria (TCN). Under NERC Order No. NERC/2024/45, TCN's market- and system-operation functions transferred to a newly incorporated entity, the Nigerian Independent System Operator (NISO), while TCN retains responsibility for transmission infrastructure as a Transmission Service Provider (NERC, 2024). NISO functions as a critical operational coordination actor within Layer 2, particularly for system observability, balancing, dispatch coordination, and integration of distributed resources: as decentralization and digitalization proceed under Layers 1 and 2, NISO's system- and market-operation role and TCN's transmission-infrastructure role become the operational counterpart to the interconnection and technical-assurance requirements set out in Sections 3.1 and 3.5.

3.7 Conceptual Dependency Matrix

Table 3 makes the layers' dependence on one another explicit, rather than leaving cross-layer "integration" as a general aspiration. Rows represent the dependent/target component; columns represent the enabling/source component. Each cell reports the degree to which the row component's function is constrained without the column component functioning adequately:

Score	Meaning
0	No material dependency
1	Low / indirect dependency
2	Moderate dependency
3	Critical dependency

These scores are conceptual, expert-informed judgments assigned from system-function logic rather than statistical estimation - architectural hypotheses for future empirical testing (Delphi elicitation, DEMATEL, or Interpretive Structural Modelling), not statistical findings. Unlike a symmetrical matrix, the structure below is deliberately directional: governance and the NEMSA spine constrain the transformation-capability layers and Layer 4 at high strength, while dependencies among the transformation-capability layers themselves, and Layer 3's dependence on the layers it constrains, are lower.

Table 3: NESI-X Conceptual Dependency Matrix

Target (row) \ Enabling source (column)	L1 Physical	L2 Intelligence	L3 Governance	NEMSA Spine	L4 Financial
L1 Physical transformation	-	2	3	3	2
L2 Digital intelligence	2	-	2	3	1
L3 Regulatory governance	0	1	-	1	1
NEMSA spine	1	1	1	-	2
L4 Financial/liquidity	1	2	2	3	-

A few illustrations clarify these scores. Layer 1 depends critically (3) on Layer 3 and the NEMSA spine because DER cannot scale safely without interconnection standards and NEMSA-verified compliance. Layer 2 depends critically on the NEMSA spine (3), since digital intelligence cannot support dependable decisions without reliable field or inspection data and moderately on Layer 1 and Layer 3. Layer 4 depends critically on the NEMSA spine (3), since meter certification determines whether billing data can be trusted, and moderately on Layers 2 and 3. By contrast, Layer 3 is scored as having low dependency on the layers it constrains (0–1): governance shapes what Layers 1, 2, and 4 can do, but its own function is not materially constrained by their technological maturity - correcting a symmetrical-dependency reading that would otherwise overstate governance's reliance on the layers it regulates. Conversely, better revenue data finances reinforcement, and better reliability improves willingness to pay: the architecture is designed to create reinforcing improvement across layers, not a sequence of isolated projects.

Nigeria already offers partial evidence supporting each transformation-capability layer's feasibility, though this should not be overstated as proof that NESI-X as a whole is validated. The World Bank's Nigeria Electrification Project supported 125 mini-grids and over a million solar home systems, giving over 5.5 million Nigerians electricity access (World Bank, 2024), now backed by NERC's 2026 Mini-Grid Regulations (NERC, 2026b) - meaningful support for Layer 1's feasibility, though not itself demonstrating the interoperability and technical-assurance requirements NESI-X adds. FoNER provides a concrete institutional development aligned with Layer 3, with objectives including harmonized regulatory approaches and joint capacity-building between NERC and state regulators (NERC, 2026c); NESI-X does not claim FoNER has already resolved regulatory fragmentation. Digital twins are technically mature enough internationally to be a plausible Layer 2 pathway, but Nigerian evidence should not be overstated: cybersecurity research highlights that increasing digital connectivity widens the cyber-physical attack surface (Pei et al., 2024; Nemade et al., 2024), so NESI-X treats digital twins as requiring Nigerian validation through pilot substations and feeders rather than as an already proven national solution. Nigerian-specific evidence at this intersection remains limited: no digital-twin grid study using Nigerian utility data was identified in the sources reviewed. The closest available Nigerian evidence is an IoT-and-neural-network fault-detection system for smart-grid components tested on a modified IEEE 30-bus network, reporting roughly 95% detection accuracy across several fault types (Omowaye et al., 2025) - a predictive-monitoring result adjacent to, but not itself, a digital-twin implementation. This gap is consistent with the caution above: NESI-X's digital-twin proposition should be read as requiring Nigerian pilot validation, not as resting on existing Nigerian digital-twin evidence. NEMSA's inspection, monitoring, investigation, and certification function, by contrast, is not a pathway requiring validation in the same sense - it is an existing, operating capability whose integration with digital asset management and revenue assurance, rather than its existence, is the genuinely novel element NESI-X proposes.

4. IMPLEMENTATION ARCHITECTURE: PHASED ROADMAP, KPIS, AND RISK CONTROLS

NESI-X deliberately uses gates rather than calendar milestones to sequence its implementation. A state, utility, plant, or network should not advance merely because a calendar date has arrived; advancement should require evidence that the necessary data, skills, cybersecurity controls, regulatory rules, technical-assurance capacity, and financing are genuinely in place. This is the architecture's primary safeguard against reproducing the historical pattern of installing technology faster than the institutions required to operate, finance, and certify it safely. Table 4 sets out the four phases in indicative terms, and Figure 4 presents the same roadmap as a gated timeline.

Table 4: NESI-X Phased Transformation Roadmap (Gated)

Phase	Indicative period	Primary actions	Gate / success condition
0 - Stabilize	2026-2027	Establish a common asset/data taxonomy, including NEMSA inspection and certification data; prioritize critical grid observability; baseline ATC&C, reliability, and outage metrics; and map regulatory responsibilities across federal and state levels.	Baseline dataset and governance ownership have been approved.
1 - Foundation	2027-2029	Pilot DER interoperability; expand AMI/feeder energy accounting; deploy PMU/WAMS at strategically important nodes; establish regulatory sandbox procedures; pilot integration of NEMSA inspection/testing records with utility asset-management systems.	Pilots demonstrate data integrity, safety, and measurable operational value.
2 - Integration	2029-2032	Scale digital twins, predictive analytics, and DER coordination; harmonize technical standards across participating states; incorporate verified NEMSA inspection data into digital twin and predictive maintenance systems.	Cross-layer KPIs improve simultaneously; no major interoperability or cybersecurity failure.
3 - Adaptive maturity	2032 onward	Continuous optimization, automated decision support, data-informed adaptive tariff-setting subject to regulatory approval, coordinated DER participation, risk-informed technical assurance, and resilience planning.	The system demonstrates sustained reliability, liquidity, interoperability, and learning capacity.

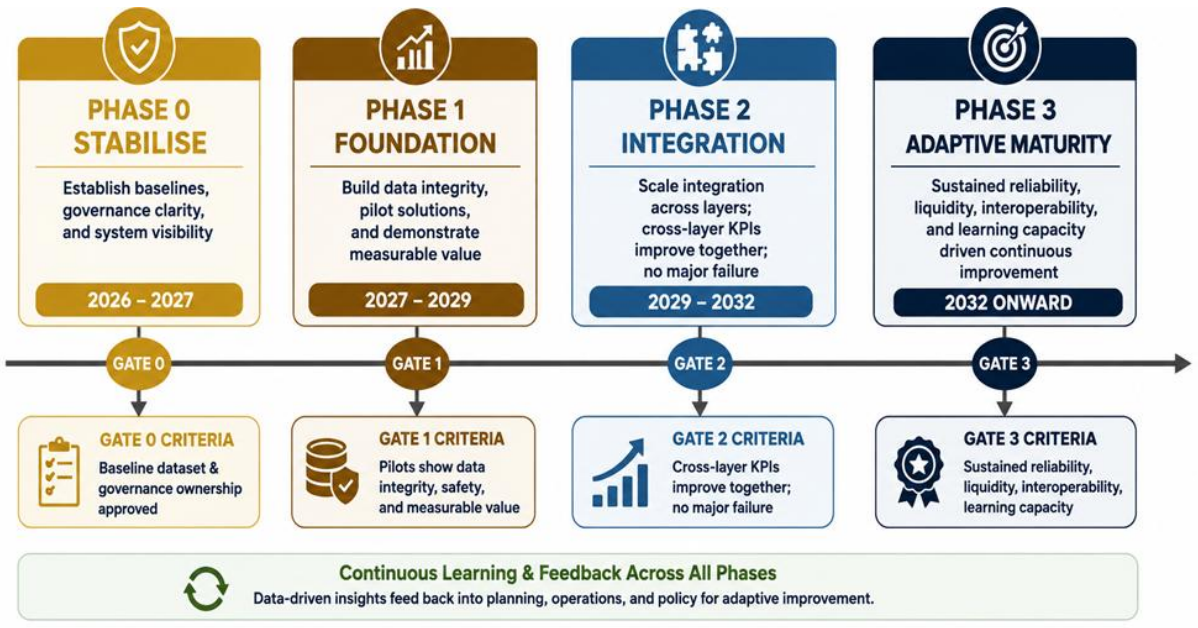

Figure 4: NESI-X gated transformation roadmap.

Table 5 converts each layer and the system as a whole into measurable indicators so that "progress" under NESI-X is something a regulator, utility, or independent researcher can actually check against data rather than assess only qualitatively. Baseline values are deliberately left unspecified here rather than invented: Phase 0 of the roadmap exists precisely to establish them from primary Nigerian data before Phase 1 targets are set. KPIs are divided into a core set likely measurable from currently available Nigerian data and an advanced set dependent on data infrastructure the roadmap itself is designed to build.

Table 5: Key Performance Indicators by Layer

Layer	KPI	Operational definition	Data source	Tier	Roadmap Phase
L1 Physical	Islanding readiness	Share of critical loads capable of intentional islanding within a defined response time.	DisCo/NERC outage records; utility asset registers	Core	Phase 1
L1 Physical	DER hosting capacity	Additional DER capacity a feeder can accommodate before violating protection or voltage limits.	DisCo/NISO network studies	Advanced	Phase 2
L2 Intelligence	Telemetry completeness	Valid data points received / expected data points x 100.	TCN, DisCo SCADA/telemetry logs	Core	Phase 1
L2 Intelligence	Digital-twin model fidelity	Agreement between predicted and observed system states under predefined validation scenarios.	Pilot digital-twin validation records	Advanced	Phase 2
L3 Governance	Regulatory sandbox cycle time	Elapsed time from sandbox application to regulatory decision.	NERC, state regulator, FoNER records	Core	Phase 1
NEMSA spine	Inspection closure rate	The formula for calculating the inspection closure rate is: (Corrective actions closed / Corrective actions issued) x 100.	NEMSA inspection and certification records	Core	Phase 0
NEMSA spine	AMI/meter certification coverage	Active, NEMSA-certified meters / total customer meters x 100.	NEMSA, DisCo meter registers	Core	Phase 1
L4 Financial	ATC&C loss	As defined in Section 1: 1 - [(1 - Technical/Commercial Loss) x (1 - Collection Loss)].	NERC quarterly reports	Core	Phase 0
System-level	SAIDI / SAIFI	Standard reliability indices, where applicable.	NERC, TCN, DisCo aggregated reporting	Core	Phase 1–2
System-level	LOLE / EENS	Loss of load expectation / expected energy not served, where data permit.	TCN, NISO system-operation data	Advanced	Phase 2–3

Four risks condition whether the roadmap's gates are actually cleared rather than remaining aspirational. Financing is the first and most immediate constraint: digitalization, DER deployment,

storage, metering, and network reinforcement all require capital while the sector works through historical liquidity weaknesses documented in Section 1. NESI-X responds by prioritizing projects that create measurable technical and commercial value simultaneously - for example, feeder digitalization that improves both outage visibility and revenue assurance from the same investment. Skills are the second constraint: digital-grid transformation requires engineers, technicians, data scientists, protection specialists, cybersecurity professionals, and regulators capable of working across disciplinary boundaries historically kept separate in Nigerian institutional training, built through joint university-NAPTIN-utility-regulator competency pathways around digital substations, DER control, AMI analytics, and cyber-physical security.

Interoperability and cybersecurity are the third constraint, growing more serious precisely as the other layers succeed. Smart-grid expansion under Layers 1-2 creates substantially more communication interfaces, and therefore, more attack surface than NESI 1.0's largely analog configuration presents today. Recent research emphasizes holistic cyber defense for smart grid environments - proactive threat detection, secure integration, and continuous monitoring rather than perimeter security alone (Nemade et al., 2024). NESI-X treats cybersecurity as a design requirement embedded within every layer, including the NEMSA spine's data flows into Layer 2, rather than as a separate IT project bolted on afterward. Political economy is the fourth constraint and the one most likely underestimated by a purely technical reading: reform touches tariffs, subsidies, investment rights, and the distribution of authority between federal and state governments, and a technically coherent architecture can still fail if stakeholders perceive it as redistributing costs or authority without credible accountability. The architecture therefore requires transparent KPIs, public reporting, meaningful stakeholder participation, and independent evaluation, rather than self-reported progress.

5. EMPIRICAL PROPOSITIONS AND DISCUSSION

NESI-X is not a prediction that Nigeria will automatically achieve a resilient electricity system simply by adopting four technologies or institutional mechanisms; it is a systems architecture and a set of testable propositions. Its core claim, made structurally explicit by Section 3's tiering, is that Nigeria can leapfrog *selected stages* of electricity-sector development but cannot leapfrog the institutional, technical-assurance, and financial dependencies that make an electricity system work; those enabling conditions and the NEMSA spine that verifies them must be progressively built, not bypassed, regardless of how quickly transformation-capability technologies can be deployed.

Three distinctions follow directly from this claim. First, distributed generation can meaningfully reduce dependence on a single, centralized national grid pathway, but it cannot eliminate the underlying need for transmission and distribution coordination, protection coordination, and independent technical assurance of the assets being connected (Section 3.5). Second, digital twins and artificial intelligence can greatly enhance our ability to see and make decisions about systems, but they cannot resolve underlying issues such as missing sensors, poor data management, inadequate maintenance, or weak cybersecurity; if a complex digital system is built on a poorly maintained physical system, it will only create confident predictions about a system whose actual condition is not accurately known. Third, state-level regulatory autonomy under the Electricity Act 2023 can genuinely stimulate valuable local innovation, but without the interoperability floor proposed in Layer 3, it can just as easily fragment the national market further rather than resolving NESI 1.0's existing fragmentation. Each of these distinctions creates a clear expectation about what should be observable if the architecture's account of NESI's problems is accurate, which is what makes the architecture testable rather than merely plausible.

The architecture accordingly yields five propositions that future empirical work - ideally conducted with the primary Nigerian regulatory and utility data referenced throughout this paper - can test directly.

P1. ATC&C loss reduction correlates with feeder-level metering penetration, consistent with existing Nigerian evidence at the DisCo level (Odje et al., 2021), but the marginal effect of additional metering should diminish measurably where Layer 3 governance capacity or NEMSA spine meter-certification capacity is weak, since metering alone cannot correct misaligned tariffs, weak enforcement, or uncertified meters.

P2. DER and mini-grid deployments interconnected under common technical standards and NEMSA-verified compliance should show measurably lower post-disturbance restoration times and fewer safety-related incidents than isolated deployments lacking equivalent verification, holding local generation capacity constant.

P3. The strength and direction of R2, the hypothesized regulatory-fragmentation loop, are empirically testable by comparing investment cycle times and DER interconnection approval times across Nigerian states before and after FoNER-coordinated standard adoption, once a sufficient number of states have transitioned and a baseline period is available for comparison.

P4. Transformation-capability KPIs (Table 5, Layers 1-2) should stagnate wherever governance, technical assurance, or liquidity indicators fall below an identifiable threshold, largely independent of Layer 1/2 technological maturity - enabling-condition maturity should constrain observed outcomes in practice, not merely in Table 3's conceptual ratings.

P5. Integration of verified NEMSA inspection, testing, and certification data with utility asset-management datasets will improve asset-condition classification and predictive-maintenance performance relative to models using operational data alone - testable by comparing an operational-data-only model against an operational-plus-NEMSA-data model on the same asset population.

None of these five propositions is claimed to have already been demonstrated in Nigeria; each is offered as a testable proposition consistent with the methodological discipline established in Section 2.4, where R1 was distinguished from R2 and R3 precisely along these lines. This maintains the paper's evidence-first posture through to its final analytical section, rather than relaxing it once the architecture itself has been presented.

6. LIMITATIONS, INTERNATIONAL TRANSFERABILITY, AND CONCLUSION

6.1 Limitations

This paper lacks an econometric estimation of the causal relationships it proposes and a calibrated system dynamics simulation of NESI as a whole. R1, R2, and R3 are causal-loop propositions rather than fitted models, and none has been empirically validated against Nigerian time-series data. Table 3's dependency scores are conceptual, derived from system-function logic rather than statistical estimation. Because these scores were assigned by the author team rather than through structured elicitation, they carry a risk of single-team framing bias. For example, the NEMSA core structure's uniformly high dependency scores reflect the authors' institutional familiarity with NEMSA's mandate but could plausibly be contested by DisCo or NERC-side reviewers with different operational perspectives or prior expectations. Independent expert elicitation (Delphi, DEMATEL, or AHP/ANP, as already flagged in Section 2.3) remains necessary before Table 3's scores can be treated as more than a starting hypothesis for empirical and expert scrutiny.

The paper also performs no cost-benefit optimization of the Table 4 roadmap, and Table 5's KPI baselines are deliberately left unspecified pending the Phase 0 baselining that the roadmap proposes, rather than being populated with placeholder numbers that might misrepresent current evidence. The architecture has not yet been field-validated as an integrated system; Section 3.7's evidence supports the feasibility of individual layers, not NESI-X's validated performance as a whole. Nigeria's regulatory conditions, particularly the state transition process and FoNER's evolving mandate, remain in flux, and data availability for empirical validation may itself be constrained by the same institutional immaturity the architecture seeks to address.

6.2 International Relevance and Transferability

NESI-X is specifically developed for Nigeria, and its evidence base is entirely Nigerian. However, the underlying architecture - distinguishing bypassable technological pathways from indispensable physical and institutional infrastructure and coupling transformation capabilities to enabling conditions through an explicit dependency structure - is not specific to Nigerian institutional detail in its logic, even though it is specific to Nigerian institutions in its evidence. The architecture is plausibly transferable, as a conceptual template rather than a ready-made solution, to electricity systems sharing a similar combination of conditions: weak grid reliability alongside rapid DER growth,

regulatory authority fragmented across sub-national jurisdictions, high technical and commercial losses, limited digital grid infrastructure, and an active energy-access agenda. Nigeria serves as the primary application context for this paper, but it does not limit its theoretical relevance; testing the transferability of these findings to other national contexts with similar conditions - for example, elsewhere in Sub-Saharan Africa and South Asia - is a natural extension of the empirical agenda above, although this paper does not pursue that comparison directly.

6.3 Conclusion

NESI's persistent electricity problems are better understood as a coupled system than as a collection of isolated technical defects to be addressed one at a time. Verified regulatory evidence shows substantial ATC&C losses and quarterly revenue leakage exceeding ₦139 billion across DisCos, while current Nigerian policy is simultaneously opening genuine pathways for decentralized generation, digital grid intelligence, and multi-level governance. NESI-X's central proposition is that Nigeria can leapfrog selected technological pathways in generation, distribution, metering, monitoring, and maintenance but cannot leapfrog the non-bypassable system dependencies - governance, technical assurance, and liquidity, alongside the transmission backbone itself - that make an electricity system work.

Technical assurance, positioned in Section 3.5 as a cross-cutting spine rather than a fifth layer, is a further institutional requirement in its own right: as NESI decentralizes and digitalizes, infrastructure expansion must be matched by effective inspection, testing, certification, and safety assurance, or deployment will simply outrun the system's ability to verify that what has been built is safe and fit for purpose. NESI-X positions NEMSA as a technical-assurance spine connecting physical infrastructure, digital asset intelligence, regulatory governance, and revenue assurance, with a proposed contribution extending beyond conventional compliance toward integrating verified technical-condition data into asset management and risk-informed planning. As Section 6.2 argues, this coupling of bypassable technology to non-bypassable assurance is plausibly relevant wherever rapid DER growth meets fragmented governance and weak technical oversight, with Nigeria as this paper's primary evidence base rather than its outer boundary.

The roadmap in Section 4 is gated rather than calendar-driven because institutional readiness, skills, technical-assurance capacity, cybersecurity, interoperability, and financing determine whether investment actually translates into reliable and safe electricity, not the simple passage of time. The immediate research agenda is the empirical validation of P1-P5: quantifying the causal loops introduced in Section 2.4 against multi-year NERC, TCN, NISO, DisCo, NEMSA, and market data as it becomes available; evaluating pilot DER and digital-twin deployments as they are commissioned; and testing directly whether enabling-condition maturity constrains transformation-capability outcomes in the way the architecture predicts. NESI-X should ultimately be judged not by the elegance of its architecture but by whether these measurable outcomes improve as it is applied and tested against Nigerian evidence.

ABSTRACT
Groundwater is the principal source of freshwater for domestic, agricultural and livestock activities in the semi-arid Sokoto Basin of northwestern Nigeria, yet increasing water demand, climate variability and uncertainty in aquifer replenishment pose growing challenges to its sustainable management. This study developed an integrated Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) and Improved Soil Moisture Balance (SMB) framework for estimating groundwater recharge using long-term hydro-meteorological records from 1990 to 2025, observed streamflow, measured soil hydraulic properties and topographic information. HEC-HMS was used to simulate rainfall–runoff processes, while the Improved SMB model incorporated dynamic root-zone soil moisture accounting, spatially variable soil hydraulic properties, moisture-dependent evapotranspiration, separate treatment of lateral runoff and threshold-controlled deep percolation. Model calibration produced a Nash–Sutcliffe Efficiency (NSE) of 0.84, coefficient of determination (R^2) of 0.86, Root Mean Square Error (RMSE) of 42.6 m^3/s and Percent Bias (PBIAS) of +3.7%. Independent validation yielded NSE = 0.77, R^2 = 0.79, RMSE = 49.8 m^3/s and PBIAS = −4.2%, demonstrating satisfactory predictive performance. Long-term recharge analysis showed pronounced interannual variability, with a mean annual recharge of 126 mm/year, a minimum of 62 mm/year in 1991 and a maximum of 205 mm/year in 2009. Rainfall and recharge were positively correlated ($r = 0.72$; $R^2 = 0.52$), with a regression slope of 0.115 mm recharge per millimetre of rainfall and an intercept of −34.3 mm, indicating threshold-controlled recharge under semi-arid conditions. Spatial analysis further identified distinct recharge zones controlled by rainfall, soil hydraulic characteristics and terrain conditions. The integrated framework provides a reproducible decision-support approach for groundwater planning, managed aquifer recharge, watershed conservation and climate-resilient water-resource management in semi-arid regions.

1. INTRODUCTION

Groundwater is a critical component of global freshwater resources and supports domestic water supply, irrigated agriculture, industrial production and ecosystem functioning. Its importance is particularly pronounced in regions where surface-water availability is strongly seasonal or unreliable. Unlike surface reservoirs and rivers, groundwater is less directly exposed to evaporation and can provide an important buffer against short-term rainfall variability and drought (Freeze & Cherry, 1979; de Vries & Simmers, 2002). Consequently, sustainable groundwater development has become increasingly important as population growth, urbanisation, agricultural expansion and industrial development increase freshwater demand worldwide (Scanlon et al., 2006).

Recent global assessments further demonstrate the importance of groundwater within an increasingly variable hydrological system. The World Meteorological Organization (WMO, 2023) reported substantial regional anomalies in river discharge, reservoir inflows, soil moisture and groundwater conditions during 2022, reflecting increasing hydrological variability across many regions. Similarly, the United Nations World Water Development Report emphasises that water security is closely connected to economic development, food production, social stability and resilience to climatic extremes (UNESCO, 2024). These assessments highlight the need for improved quantitative understanding of groundwater replenishment, particularly in regions where groundwater constitutes a major component of freshwater supply.

Despite its importance, groundwater is under increasing pressure from abstraction, land-use change, climatic variability and changes in natural recharge. Excessive groundwater withdrawal relative to aquifer replenishment can result in declining groundwater levels, reduced baseflow, increasing pumping costs and deterioration of groundwater-dependent ecosystems (Taylor et al., 2013). The sustainability of groundwater development therefore depends not only on the volume of groundwater stored within an aquifer but also on the rate and variability of groundwater recharge.

Groundwater recharge is the downward movement of infiltrated water through the unsaturated zone to the saturated aquifer. It is among the most difficult components of the hydrological cycle to quantify because it depends on interacting climatic, hydrological, soil, geological, vegetation and topographic controls (Healy, 2010). Recharge can vary considerably over both space and time, and the magnitude of this variability becomes particularly important when groundwater-development decisions are based on long-term average estimates (Scanlon et al., 2006). Reliable estimation of recharge is therefore essential for groundwater-resource assessment, sustainable abstraction planning, aquifer protection and climate-resilient water management.

The difficulty of recharge estimation is particularly pronounced in semi-arid environments. Rainfall in such regions is strongly seasonal and frequently occurs as short-duration, high-intensity storms, while potential evapotranspiration remains high for much of the year. Consequently, a large proportion of precipitation may be lost through evapotranspiration and surface runoff before sufficient soil moisture is accumulated to generate deep percolation (Healy, 2010). Groundwater recharge therefore tends to be episodic and threshold-dependent rather than continuous. Scanlon et al. (2006) demonstrated that recharge in arid and semi-arid environments can vary substantially in response to rainfall magnitude, soil characteristics and land-surface conditions, while Taylor et al. (2013) showed that intense rainfall events can play a disproportionate role in groundwater replenishment across parts of Africa.

Northern Nigeria exhibits many of these characteristics. The Sokoto Basin forms the Nigerian sector of the larger transboundary Iullemmeden Basin shared principally between Nigeria and the Republic of Niger. Within Nigeria, the basin extends across Sokoto and Kebbi States and parts of Zamfara and Niger States. The broader hydrogeological system extends beyond the Nigerian boundary into Niger Republic; however, the hydrological modelling undertaken in this study is restricted to the delineated Nigerian model domain represented in Figure 1. This distinction is important because the hydrogeological basin is transboundary, whereas the quantitative recharge estimates presented in this study relate specifically to the modelled catchment.

Groundwater is extensively used within the Sokoto Basin for domestic water supply, irrigation, livestock production and rural livelihoods. However, recurrent drought, agricultural expansion, population growth and high rainfall variability place increasing pressure on available groundwater resources. Reliable information on recharge remains limited because of sparse hydrological observations, inadequate long-term groundwater monitoring and the complexity of rainfall–runoff–infiltration interactions. Consequently, groundwater-development decisions may be undertaken without sufficient quantitative information on the temporal and spatial variability of aquifer replenishment.

Numerous methods have been developed for estimating groundwater recharge, including empirical rainfall–recharge relationships, water-table fluctuation methods, chloride mass balance, lysimeter measurements, environmental tracers, water-balance techniques and physically based numerical models (Scanlon et al., 2002; Healy, 2010). Each method has advantages and limitations. Field-based approaches may provide detailed information at individual locations but can require extensive monitoring and may not adequately represent basin-scale spatial variability. Conversely, empirical approaches are comparatively simple to implement but may not adequately represent changing hydrological conditions. Sophocleous (2004) noted that recharge estimation remains a major source of uncertainty in groundwater assessment because no single technique can completely represent the complexity of natural recharge processes.

These limitations are especially important in African basins where observational networks may be sparse and long-term hydrogeological data are frequently incomplete. Xu and Beekman (2019) emphasised that groundwater-recharge assessment in Africa requires approaches capable of integrating available climatic, hydrological and hydrogeological information while explicitly recognising data limitations and spatial variability. An integrated modelling framework can therefore provide a useful

alternative by combining complementary techniques rather than depending on a single recharge-estimation method.

The Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) provides a widely applied framework for simulating rainfall–runoff processes at catchment scale. It allows precipitation losses, runoff transformation and channel routing to be represented using established hydrological methods. Soil Moisture Balance (SMB) modelling, in contrast, provides a physically interpretable framework for tracking rainfall inputs, evapotranspiration losses, runoff, soil-water storage and drainage below the root zone. Integration of the two approaches enables runoff estimated by a calibrated hydrological model to be incorporated directly into soil-water accounting, thereby reducing reliance on assumed runoff coefficients.

However, a conventional SMB formulation based solely on annual or monthly precipitation minus evapotranspiration and runoff can oversimplify recharge generation in semi-arid environments. Recharge generally occurs only after antecedent soil-water deficits have been replenished and soil storage exceeds a drainage threshold. Soil depth, field capacity, wilting point and saturated hydraulic conductivity also vary spatially, while evapotranspiration becomes constrained as soil moisture declines. These processes require a temporally explicit soil-water accounting framework rather than simple residual water-balance estimation.

Accordingly, the present study integrates HEC-HMS with an Improved SMB model incorporating dynamic root-zone moisture accounting, variable soil hydraulic properties, moisture-dependent evapotranspiration, explicit treatment of runoff and lateral losses, and threshold-controlled deep percolation. The integrated approach is consistent with the broader need for groundwater assessments that account for interactions among surface hydrology, soil-water processes and groundwater replenishment (Gleeson et al., 2020; Xu & Beekman, 2019).

The aim of this study is therefore to develop and apply an integrated HEC-HMS–Improved SMB framework for assessing the temporal and spatial variability of groundwater recharge in the semi-arid Sokoto Basin. Specifically, the study uses long-term hydro-meteorological observations from 1990 to 2025, observed streamflow, soil hydraulic measurements and topographic information to simulate rainfall–runoff processes, quantify groundwater recharge, examine the rainfall–recharge relationship and identify spatial variations in recharge potential.

Beyond its hydrological contribution, the framework is intended as an engineering decision-support tool. Quantitative recharge information can support the siting of managed aquifer recharge facilities, groundwater-development planning, watershed conservation, drought-risk management and prioritisation of areas for groundwater protection. The approach therefore connects hydrological modelling with practical engineering innovation and evidence-based water policy, supporting sustainable water-resource development and improved climate resilience in northern Nigeria and comparable semi-arid environments.

2. MATERIALS AND METHODS

The study was conducted in the Sokoto Basin in northwestern Nigeria, which forms the Nigerian sector of the larger transboundary Iullemmeden Basin extending into the Republic of Niger. Within Nigeria, the basin covers Sokoto and Kebbi States and parts of Zamfara and Niger States. Although the broader hydrogeological system is transboundary, the numerical modelling undertaken in this study was restricted to the Nigerian catchment delineated from the Digital Elevation Model (DEM) and represented in Figure 1. The delineated HEC-HMS model domain covers approximately **28,400 km²** and should therefore not be interpreted as the total geographical area of the entire Sokoto-Rima or transboundary Iullemmeden Basin.

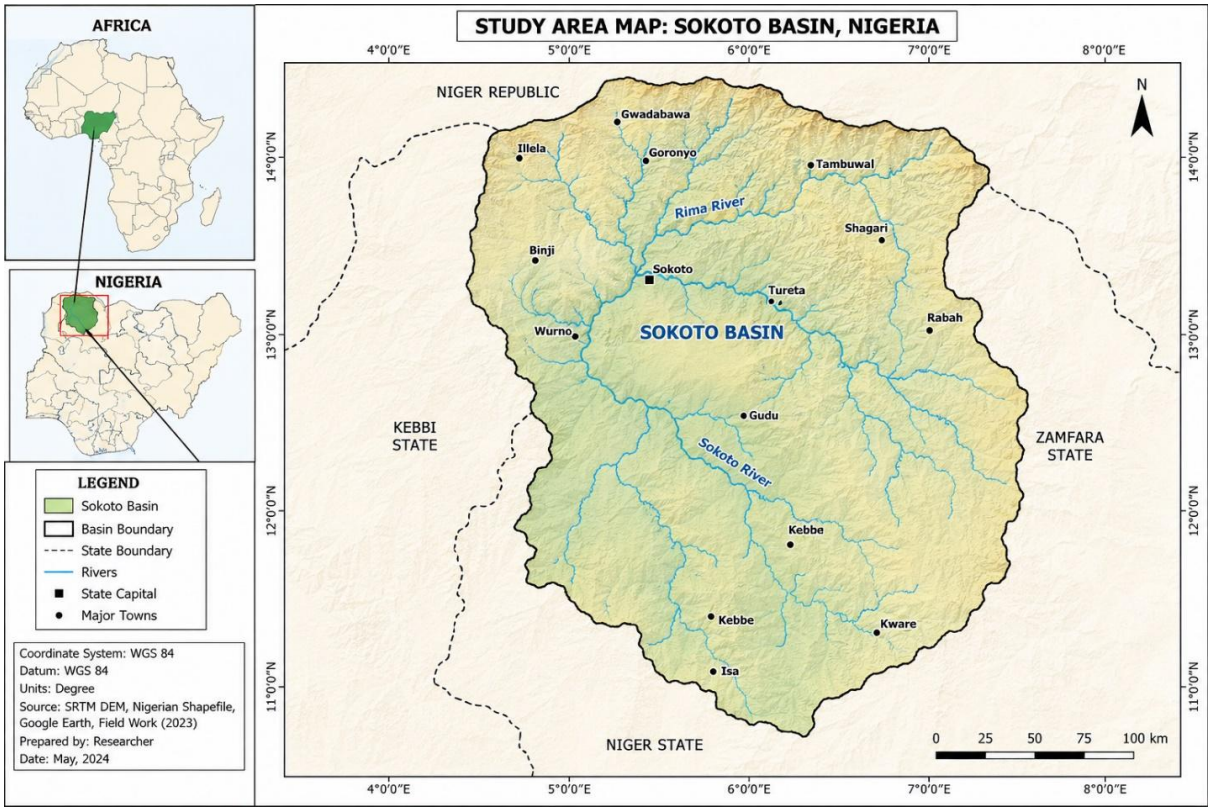

Figure 1: Study Area Map of the Sokoto Basin

Geologically, the basin consists predominantly of sedimentary formations, including the Gundumi, Rima, Sokoto and Gwandu Formations, which exhibit differences in lithology, aquifer properties and groundwater-storage characteristics. These formations constitute important groundwater-bearing units supporting domestic water supply, irrigation and livestock production within the region.

The climate is semi-arid and characterized by a distinct wet season extending approximately from May to October and a prolonged dry season from November to April. Annual rainfall generally ranges between 700 and 1,200 mm, with most precipitation occurring between June and September. Mean annual temperatures commonly exceed 30°C, resulting in substantial atmospheric water demand and high evapotranspiration losses. The drainage system is dominated by the Sokoto-Rima River network.

Soils within the modelled area are predominantly sandy loam and loamy sand, with localized sandy clay loam and finer-textured deposits. Variations in soil texture influence infiltration, soil-water retention, runoff generation and the amount of water available for deep percolation. Land use is dominated by rain-fed and irrigated agriculture, grazing land, riparian vegetation and settlements. The combined effects of climate, soils, terrain and land use produce considerable spatial and temporal variability in runoff and groundwater recharge.

2.2 Overall Modelling Framework

The methodological framework integrated HEC-HMS rainfall-runoff simulation with an Improved Soil Moisture Balance (SMB) model. The modelling procedure consisted of five principal stages: (1) hydro-meteorological, soil and spatial data preparation; (2) DEM-based watershed delineation and HEC-HMS model development; (3) calibration and validation of simulated runoff against observed streamflow; (4) daily root-zone soil-water accounting and estimation of deep percolation using the Improved SMB model; and (5) temporal and spatial analysis of groundwater recharge.

The principal rationale for coupling the two models was to avoid estimating runoff as an arbitrary residual or fixed fraction of rainfall within the SMB calculation. Instead, surface runoff was independently simulated using the calibrated HEC-HMS model and subsequently transferred to the

SMB framework. The SMB component then accounted for rainfall, evapotranspiration, soil-water storage, lateral losses and threshold-controlled drainage below the root zone.

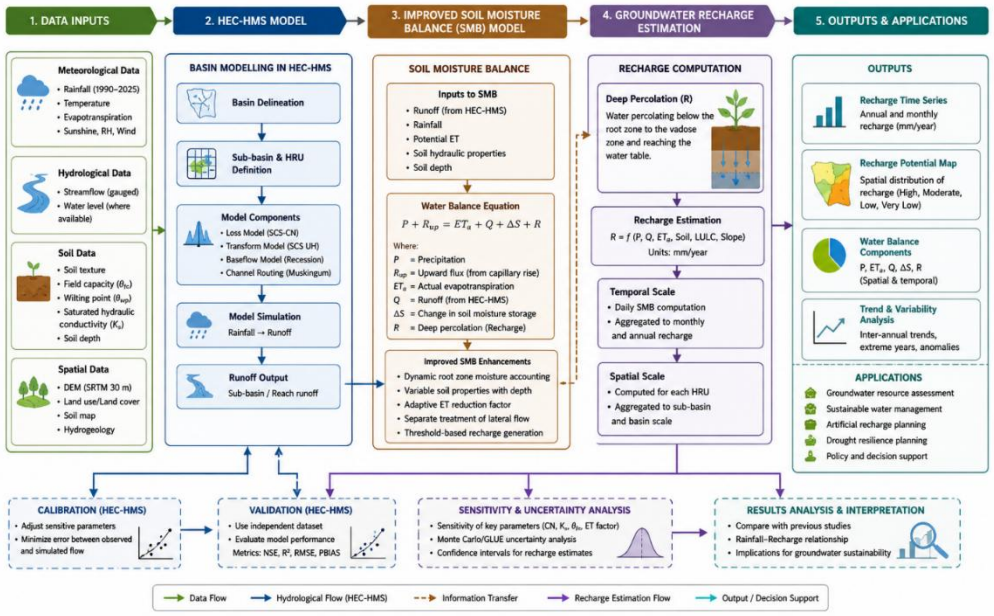

Figure 2: Integrated HEC-HMS–SMB Methodological Framework

2.3 Data Collection and Preparation

Meteorological, hydrological, soil and topographic datasets were assembled for development of the integrated framework. Daily rainfall and temperature records covering 1990–2025 were obtained from the Nigerian Meteorological Agency (NiMet). Relative humidity and wind-speed observations were also incorporated into the climatic dataset for evapotranspiration estimation.

Observed daily streamflow records from hydrological gauging stations within the modelled basin were used for HEC-HMS calibration and validation. The streamflow record used in the modelling was divided into 1990–2011 for calibration and 2012–2025 for validation, consistent with the periods represented in the observed-versus-simulated hydrograph.

Soil samples collected during the 2024 field investigation were analysed for soil texture, bulk density, field capacity, permanent wilting point and saturated hydraulic conductivity. These measurements were treated as static soil hydraulic parameters for the long-term simulation. This assumes that the principal soil hydraulic characteristics represented by the sampled locations remained sufficiently stable to characterize the corresponding soil units during the 1990–2025 simulation period. The assumption is necessary because equivalent historical measurements were unavailable and represents a limitation of the long-term reconstruction.

A 30-m Shuttle Radar Topography Mission (SRTM) DEM was used for catchment delineation, drainage-network extraction and terrain analysis. Land-use/land-cover information was obtained from Landsat imagery, while the FAO/Harmonized World Soil Database (HWSD) provided supplementary spatial soil information used to extend measured soil characteristics across the modelled area.

Table 1: Summary of Meteorological, Hydrological and Soil Datasets.

Dataset	Variable	Source	Temporal resolution	Spatial resolution	Period/status	Purpose
Meteorological	Rainfall	NiMet	Daily	Station	1990–2025	Hydrological forcing
Meteorological	Temperature	NiMet	Daily	Station	1990–2025	Evapotranspiration estimation
Meteorological	Relative humidity	NiMet	Daily	Station	1990–2025	Climate/ET analysis
Meteorological	Wind speed	NiMet	Daily	Station	1990–2025	Evapotranspiration estimation
Hydrological	Streamflow	NIHSA/River gauge stations	Daily	Gauge	1990–2025*	HEC-HMS calibration and validation
Soil	Texture	Field/laboratory analysis	Static	Sampling sites	Sampled 2024	Soil classification
Soil	Bulk density	Laboratory analysis	Static	Sampling sites	Sampled 2024	Soil-water parameterization
Soil	Field capacity	Laboratory analysis	Static	Sampling sites	Sampled 2024	Root-zone storage calculation
Soil	Permanent wilting point	Laboratory analysis	Static	Sampling sites	Sampled 2024	Available-water calculation
Soil	Saturated hydraulic conductivity	Laboratory analysis	Static	Sampling sites	Sampled 2024	Drainage/infiltration parameterization
Spatial	DEM	SRTM	Static	30 m	DEM product	Watershed and terrain delineation
Spatial	Land use/land cover	Landsat	Annual/periodic	30 m	2020–2025	Surface characteristics
Spatial	Soil map	FAO/HWSD	Static	250 m	Reference dataset	Spatial soil parameterization

The 1990–2025 streamflow period represents the record used to construct the calibration and validation datasets. Calibration covered 1990–2011 and validation covered 2012–2025.

Because the soil observations represent measurements made in 2024 rather than annual observations throughout the modelling period, the analysis assumes temporally invariant soil hydraulic properties. Consequently, long-term changes in soil structure arising from land management, erosion or other processes are not explicitly represented.

2.4 HEC-HMS Rainfall-Runoff Modelling

Rainfall-runoff simulation was undertaken using the Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS Version 4.12). Watershed boundaries, drainage networks and sub-basins were delineated from the SRTM DEM in a GIS environment and subsequently imported into HEC-HMS.

The Soil Conservation Service Curve Number (SCS-CN) method was used to represent rainfall losses because it provides a practical means of incorporating soil type, land use and antecedent moisture effects in data-limited catchments.

The potential maximum retention, (S) (mm), was computed from the Curve Number (CN) using Equation 1.

$$S = \frac{25400}{CN} - 254 \quad (1)$$

Where S is the maximum potential soil water retention (mm) and CN is the dimensionless Curve Number representing land use, soil type and antecedent moisture conditions.

Direct runoff depth, (Q) (mm), was then estimated using Equation 2.

$$Q = \frac{(P - I_a)^2}{P - I_a + S} \quad (2)$$

Where Q is direct runoff (mm), P is rainfall depth (mm), (I_a) is initial abstraction (mm), commonly taken as (0.2S), and S is potential maximum retention (mm).

Runoff transformation from rainfall excess to the catchment hydrograph was represented using the SCS Unit Hydrograph method. Channel flow was routed using the Muskingum method, with routing parameters (K) and (X) representing travel time and relative storage weighting, respectively.

The delineated watershed area used in HEC-HMS was approximately **28,400 km²**. This value represents the DEM-derived computational domain used for the present model and **not the total area of the complete Sokoto-Rima/Iullemmeden hydrological system**.

Table 2: Hydrological Model Parameters Used in HEC-HMS and Improved Soil Moisture Balance Simulation.

Component	Parameter	Symbol	Value	Unit
Basin	Watershed Area	A	28,400	km²
Basin	Curve Number	CN	68–84	–
Basin	Initial Abstraction	Ia	12.6	mm
Basin	Lag Time	Tlag	5.4	hr
Basin	Time of Concentration	Tc	8.2	hr
Channel	Manning Roughness	n	0.035	–
Channel	Muskingum K	K	4.0	hr
Channel	Muskingum X	X	0.20	–
Soil	Field Capacity	θFC	0.28	m³/m³
Soil	Wilting Point	θWP	0.14	m³/m³
Soil	Saturated Moisture	θS	0.43	m³/m³
Soil	Hydraulic Conductivity	Ks	18.5	mm h^{-1}
SMB	Root Zone Depth	Zr	1.20	m
SMB	Deep Percolation Threshold	R	Variable	mm

2.5 HEC-HMS Calibration and Validation

HEC-HMS calibration was undertaken by adjusting hydrologically sensitive parameters within physically reasonable ranges until the simulated hydrograph reproduced the timing and magnitude of observed discharge. Particular attention was given to the Curve Number, initial abstraction, lag time and routing parameters because these control runoff volume, peak discharge and hydrograph timing.

The available discharge record was separated temporally to maintain independence between model calibration and validation. The 1990–2011 period was used for calibration, while 2012–2025 was reserved for validation. No further parameter optimisation was undertaken using the validation dataset.

Calibration and validation performance were evaluated using NSE, R^2, RMSE and PBIAS as described in Section 2.8. The calibrated HEC-HMS runoff series was subsequently supplied to the Improved SMB model as the surface-runoff component of the daily water balance.

2.6 Improved Soil Moisture Balance Model

Groundwater recharge was estimated using a daily Improved Soil Moisture Balance model coupled with HEC-HMS runoff. Unlike a simple residual water-balance calculation, the Improved SMB framework explicitly tracked the state of root-zone soil-water storage and allowed recharge to occur only when sufficient water was available after evapotranspiration, runoff and soil-moisture requirements had been satisfied.

The general daily root-zone water balance was represented in Equation 3.

$$S_t = S_{t-1} + P_t - Q_t - ET_{a,t} - L_t - R_t \quad (3)$$

Where S_t is root-zone soil-water storage at the end of day t (mm), S_{t-1} is storage from the preceding day (mm), P_t is daily precipitation (mm), Q_t is HEC-HMS simulated surface runoff (mm), $ET_{a,t}$ is actual evapotranspiration (mm), L_t represents lateral or other explicitly represented drainage losses (mm), and R_t is groundwater recharge or deep percolation below the root zone (mm).

Equivalently, the daily change in storage can be expressed in Equation 4.

$$\Delta S_t = P_t - Q_t - ET_{a,t} - L_t - R_t \quad (4)$$

This formulation ensures that recharge is calculated as part of a closed daily water balance rather than simply as (P-ET-Q) at annual scale.

2.6.1 Dynamic Root-Zone Moisture Accounting

The maximum root-zone water storage associated with field capacity was determined using Equation 5.

$$S_{FC} = \theta_{FC} Z_r (1000) \quad (5)$$

While storage corresponding to permanent wilting point expressed in Equation 6.

$$S_{WP} = \theta_{WP} Z_r (1000) \quad (6)$$

Where S_{FC} and S_{WP} are root-zone water storage at field capacity and wilting point (mm), respectively; θ_{FC} and $\theta_{WP} Z_r$ are volumetric field capacity and wilting-point water contents (m^3/m^3); and Z_r is effective root-zone depth (m).

The model updated S_t sequentially at the daily time step, thereby retaining the influence of antecedent moisture conditions. This is particularly important under semi-arid conditions because two rainfall events of equal magnitude may generate different recharge depending on the initial soil-water deficit.

2.6.2 Spatially Variable Soil Hydraulic Properties

Measured field capacity, wilting point and saturated hydraulic conductivity differed among the sampled soil units. Rather than representing the entire basin with a single homogeneous soil condition, the Improved SMB framework used the corresponding hydraulic characteristics to parameterize soil-water storage and drainage behaviour within the represented soil zones.

This modification allows areas characterized by sandy and highly conductive soils to drain differently from areas with greater water-retention capacity. The spatial variability of soil properties therefore influences both the amount of water retained within the root zone and the potential for deep percolation.

2.6.3 Moisture-Dependent Actual Evapotranspiration

Actual evapotranspiration was constrained by the amount of water available within the root zone. Under sufficiently wet conditions, evapotranspiration could approach the atmospheric demand represented by potential evapotranspiration. As soil moisture declined toward the permanent wilting point, evapotranspiration was progressively reduced using a soil-water stress factor expressed in Equation 7.

$$ET_{a,t} = K_{s,t} ET_{p,t} \quad (7)$$

Where $ET_{a,t}$ is actual evapotranspiration (mm/day), $ET_{p,t}$ is potential evapotranspiration (mm/day), and $K_{s,t}$ is the dimensionless soil-water stress coefficient bounded between 0 and 1.

For the root-zone accounting framework, $K_{s,t}$ was represented as a function of available soil water:

$$\min\left[1, \max\left(0, \frac{S_t - S_{WP}}{S_{FC} - S_{WP}}\right)\right] \quad (8)$$

Thus, K_s approaches 1 under adequately moist conditions and declines toward zero as storage approaches the permanent wilting-point threshold.

2.7 Threshold-Based Recharge and Lateral-Flow Treatment

The central improvement to the recharge calculation was the use of a threshold condition for deep percolation. Rainfall remaining after HEC-HMS runoff and evapotranspiration was first used to replenish the root-zone soil-water deficit. Recharge was generated only when available soil water exceeded the field-capacity storage threshold.

Conceptually, subject to the drainage capacity of the soil, where S_t^* represents provisional soil-water storage after precipitation, runoff and evapotranspiration have been accounted for but before deep drainage (Equation 9).

$$R_t = \max[0, ; S_t^* - S_{FC} - L_t] \quad (9)$$

Where drainage was constrained by soil hydraulic conductivity, the daily recharge flux was limited expressed in Equation 10.

$$R_t = \min\left[\max(0, S_t^* - S_{FC} - L_t), K_{s,\text{hyd}}\Delta t\right] \quad (10)$$

Where $K_{s,\text{hyd}}$ is saturated hydraulic conductivity expressed in compatible units and Δt is the model time step.

Surface runoff and lateral flow were not treated as groundwater recharge. Surface runoff, Q_t, was supplied directly from HEC-HMS, while L_t represented water leaving the root-zone control volume laterally where applicable. This separation prevents surface and shallow lateral water losses from being incorrectly counted as deep aquifer recharge.

Accordingly, the annual water balance used for reporting results was obtained by summing the daily components expressed in Equation 11.

$$P = Q + ET_a + L + R + \Delta S \quad (11)$$

Where all terms represent annual totals in millimetres and ΔS is the net change in root-zone storage between the beginning and end of the reporting period.

This equation is important when interpreting annual recharge results because recharge cannot generally be calculated as (P-Q-ET) alone unless both lateral losses and net storage change are zero.

Recharge efficiency was defined explicitly as the proportion of annual rainfall converted to groundwater recharge expressed in Equation 12.

$$RE = \frac{R}{P} \times 100 \quad (12)$$

where RE is recharge efficiency (%), R is annual groundwater recharge (mm/year), and P is annual precipitation (mm/year).

2.8 Model Performance Evaluation

The performance of HEC-HMS was evaluated using four statistical measures: Nash-Sutcliffe Efficiency (NSE), coefficient of determination (R^2), Root Mean Square Error (RMSE) and Percent Bias (PBIAS).

The Nash-Sutcliffe Efficiency was calculated using Equation 13.

$$NSE = 1 - \frac{\sum_{i=1}^{n}\left(Q_{obs,i} - Q_{sim,i}\right)^2}{\sum_{i=1}^{n}\left(Q_{obs,i} - \overline{Q}_{obs}\right)^2} \quad (13)$$

Where (Q_{obs}) is observed discharge, (Q_{sim}) is simulated discharge, ($\overline{Q}_{obs}$) is the mean observed discharge and n is the number of observations (Nash & Sutcliffe, 1970.

The coefficient of determination was calculated using Equation 14.

$$R^2 = \left[\frac{\sum\left(Q_{obs} - \overline{Q}obs\right)\left(Qsim - \overline{Q}sim\right)}{\sqrt{\sum\left(Qobs - \overline{Q}obs\right)^2 \sum\left(Qsim - \overline{Q}_{sim}\right)^2}}\right]^2 \quad (14)$$

Where **(R^2)** indicates the strength of agreement between observed and simulated values.

RMSE was calculated using Equation 14.

$$RMSE = \sqrt{\frac{\sum(Q_{obs} - Q_{sim})^2}{n}} \quad (14)$$

Where RMSE measures the average magnitude of simulation error.

and PBIAS was calculated using Equation 15.

$$PBIAS = 100\frac{\sum(Q_{obs} - Q_{sim})}{\sum Q_{obs}} \quad (15)$$

Where PBIAS quantifies the tendency of the model to overestimate or underestimate observed values. With this sign convention, positive PBIAS indicates overall model underestimation and negative PBIAS indicates overestimation.

Following Moriasi et al. (2007, 2015), NSE values greater than approximately 0.50 were considered indicative of satisfactory model performance for streamflow simulation, with progressively higher values representing improved agreement. (R^2) was used as a complementary measure of correspondence between simulated and observed variability, while RMSE was interpreted relative to the magnitude and variability of observed discharge.

For PBIAS, values within ±10% were interpreted as very good, values between ±10% and ±15% as good, values between ±15% and ±25% as satisfactory, and values exceedingly approximately ±25% as unsatisfactory for streamflow simulation. These criteria were used together rather than independently because no single statistical measure fully describes hydrological model performance.

Kling-Gupta Efficiency (KGE) was excluded from the primary evaluation because it was not consistently reported in the calibration and validation outputs presented in Figure 4.

2.9 Temporal and Spatial Recharge Analysis

The validated HEC-HMS runoff series and Improved SMB model were applied over the 1990–2025 study period to estimate daily groundwater recharge. Daily values were aggregated to monthly and annual time scales to evaluate seasonal and interannual variability.

The rainfall-recharge relationship was assessed statistically to determine the degree to which variations in annual rainfall explained variations in recharge. Pearson correlation and linear regression were used to quantify association, while the physical interpretation considered the threshold behaviour inherent in the SMB formulation.

Spatial recharge potential was assessed by integrating estimated recharge with the spatial distribution of rainfall, soil hydraulic characteristics and terrain conditions. To avoid inconsistent interpretation between temporal and spatial results, recharge classes were harmonized using a common classification framework presented in Table 3.

Table 3: Recharge Classification

Recharge class	Annual recharge (mm/year)
Very low	<50
Low	50–100
Moderate	100–150
Moderate-high	150–200
High	200–250
Very high	>250

The classification was applied consistently to the spatial recharge map. Where temporal recharge values are discussed independently, the actual numerical values are reported rather than assigning a conflicting second set of class boundaries.

2.10 Methodological Assumptions and Limitations

Several assumptions were necessary because of the data limitations typical of long-term hydrological studies in semi-arid environments. First, soil hydraulic properties measured in 2024 were assumed to represent the dominant characteristics of the corresponding soil units during the 1990–2025

simulation period. The model therefore does not explicitly represent historical changes in soil structure arising from cultivation, erosion, compaction or land degradation.

Second, the 28,400 km² watershed area refers specifically to the DEM-delineated computational domain and should not be interpreted as the area of the complete transboundary Sokoto-Rima/Iullemmeden system. Third, groundwater recharge estimated by the SMB model represents potential diffuse recharge crossing the lower boundary of the modelled root zone. The approach does not explicitly simulate subsequent travel time through the deeper unsaturated zone or groundwater flow within individual aquifer formations.

Finally, uncertainty remains associated with rainfall observations, streamflow measurements, spatial interpolation, soil hydraulic parameters and model structure. The integrated framework reduces some uncertainty by constraining surface runoff using calibrated HEC-HMS simulations, but it does not eliminate uncertainty inherent in basin-scale groundwater recharge estimation.

3. RESULTS AND DISCUSSION

3.1 Rainfall Characteristics and Seasonal Hydrological Regime

The long-term rainfall record for 1990–2025 demonstrated a strongly seasonal precipitation regime across the Sokoto Basin. Rainfall was concentrated primarily between May and October, whereas precipitation during the November–April dry season was generally limited. August represented the principal rainfall month, with July and September also contributing substantially to wet-season precipitation. This concentration of rainfall within a relatively short period is characteristic of the semi-arid climatic conditions of northwestern Nigeria and has important implications for both runoff generation and groundwater recharge.

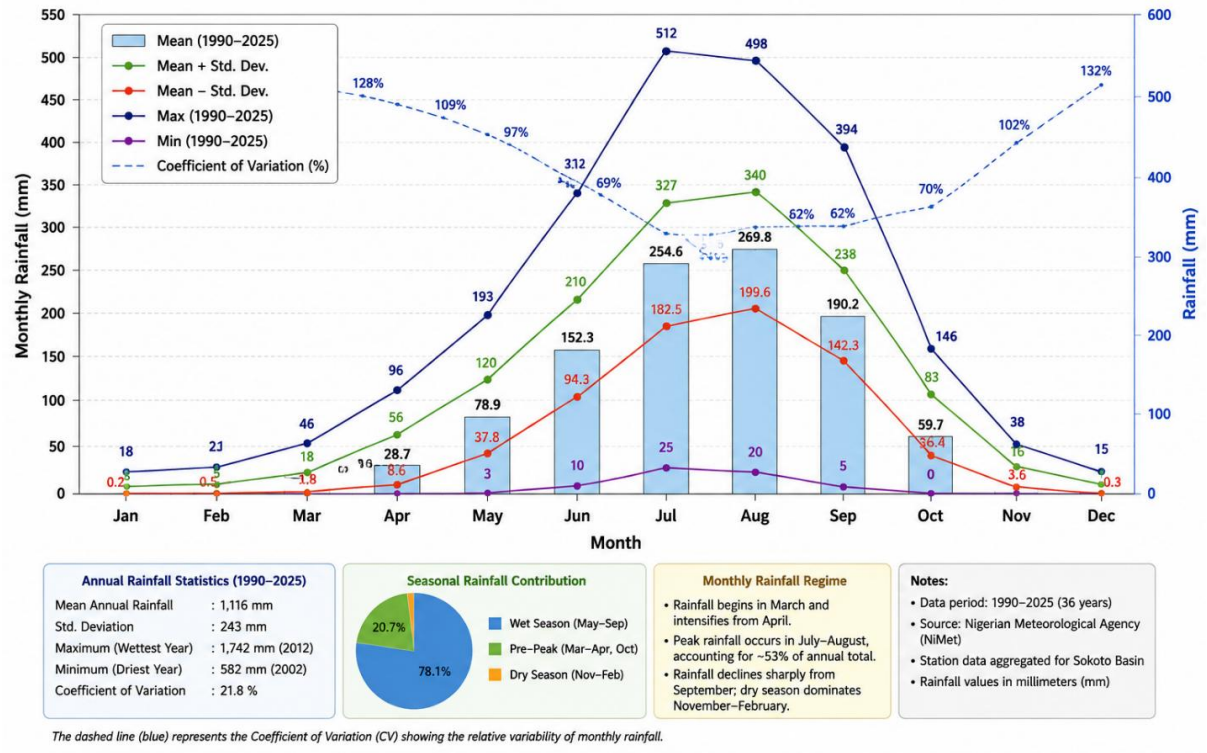

Figure 3: Monthly Rainfall Distribution (1990–2025)

Considerable interannual variability was also evident during the 36-year study period. Wetter years were characterized by greater rainfall totals and more sustained wet-season conditions, whereas lower-rainfall years experienced larger soil-water deficits and reduced opportunities for deep drainage. Consequently, annual rainfall alone does not determine recharge; the timing and sequence of rainfall relative to antecedent soil-water conditions are also important.

This behaviour is consistent with the conceptual basis of the Improved Soil Moisture Balance model developed in this study. At the beginning of the rainy season, a substantial proportion of

incoming rainfall is required to replenish root-zone soil-water deficits and satisfy evapotranspiration demand. Groundwater recharge becomes more likely as soil-water storage approaches field capacity and subsequent rainfall produces drainage below the effective root zone. Recharge is therefore concentrated within the wettest portion of the rainy season rather than being distributed uniformly throughout the year.

The observed pattern is consistent with the broader understanding of groundwater recharge in semi-arid environments. Scanlon et al. (2006) showed that recharge in arid and semi-arid regions is highly variable and sensitive to rainfall characteristics, while Taylor et al. (2013) demonstrated the importance of episodic intense rainfall for groundwater replenishment in African aquifers. The strong seasonality observed in the Sokoto Basin therefore reinforces the importance of considering both intra-annual and interannual rainfall variability when evaluating groundwater sustainability.

3.2 Spatial Variability of Soil Hydraulic Characteristics

The measured soil hydraulic properties presented in Table 4 varied considerably among the five sampling locations, indicating that the modelled basin cannot be adequately represented using a single uniform soil condition. Field capacity ranged from 23.5% at Bunza to 29.4% at Gwadabawa, while permanent wilting point varied from 10.8% to 15.6%. Hydraulic conductivity ranged from 13.9 mm/h at Gwadabawa to 24.8 mm/h at Bunza.

Table 4: Soil Hydraulic Characteristics of the Study Locations.

Location	Soil Texture	Bulk Density (g/cm^3)	Field Capacity (%)	Wilting Point (%)	Available Water (%)	Hydraulic Conductivity (mm/h)
Argungu	Sandy Loam	1.47	28.0	14.0	14.0	15.2
Bunza	Loamy Sand	1.56	23.5	10.8	12.7	24.8
Gwadabawa	Sandy Clay Loam	1.43	29.4	15.6	13.8	13.9
Tambuwal	Sandy Loam	1.50	26.8	13.5	13.3	17.5
Wurno	Sandy Loam	1.46	27.2	13.7	13.5	16.8

Gwadabawa exhibited the highest field capacity (29.4%), rather than Argungu as stated in the original manuscript. Its sandy clay loam texture and comparatively low hydraulic conductivity of 13.9 mm/h indicate greater water-retention capacity and slower drainage. Argungu also exhibited relatively high field capacity at 28.0%, but it was not the maximum among the sampled locations.

In contrast, Bunza recorded the lowest field capacity (23.5%) and the highest hydraulic conductivity (24.8 mm/h). The loamy sand at this location therefore permits comparatively rapid infiltration and drainage but retains less water within the root zone. These contrasting properties illustrate an important feature of recharge generation: high infiltration capacity does not necessarily correspond directly to high root-zone water storage.

Available water content was greatest at Argungu (14.0%), followed closely by Gwadabawa (13.8%), Wurno (13.5%), Tambuwal (13.3%) and Bunza (12.7%). These relatively modest differences nevertheless influence the amount of rainfall required to replenish antecedent soil-water deficits before threshold-controlled drainage can occur.

The spatial variation in field capacity, wilting point and hydraulic conductivity provides an important justification for incorporating variable soil hydraulic properties into the Improved SMB model. Healy (2010) similarly identified soil-water storage and hydraulic characteristics as fundamental controls on recharge, while Li et al. (2019) demonstrated that soil characteristics and land-surface conditions can substantially alter soil-moisture dynamics and deep drainage in arid and semi-arid environments.

3.3 HEC-HMS Calibration and Validation Performance

The corrected calibration and validation results demonstrate that HEC-HMS reproduced the observed streamflow dynamics with satisfactory agreement during both modelling periods. The hydrograph shown in Figure 4 indicates that the model generally reproduced the timing and magnitude of observed discharge, although differences between simulated and observed flows remained during individual high-flow events.

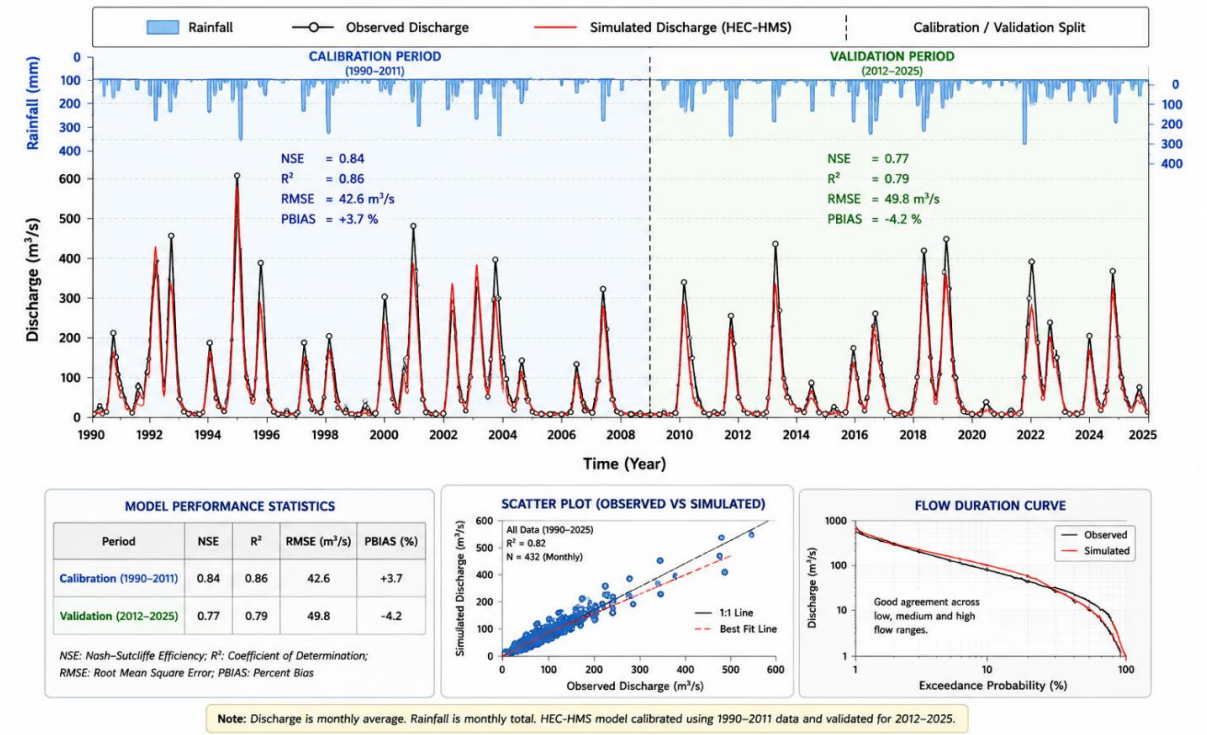

Figure 4: Observed and simulated streamflow during HEC-HMS calibration (1990–2011) and validation (2012–2025).

During calibration, the model presented in Table 5 achieved NSE = 0.84, R^2 = 0.86, RMSE = 42.6 m³/s and PBIAS = +3.7%. During validation, the corresponding statistics were NSE = 0.77, R^2 = 0.79, RMSE = 49.8 m³/s and PBIAS = −4.2%.

Table 5: Corrected HEC-HMS calibration and validation statistics

Performance index	Calibration	Validation	Adopted interpretation
NSE	0.84	0.77	Good to very good
R^2	0.86	0.79	Strong agreement
RMSE (m³/s)	42.6	49.8	Evaluated relative to observed discharge
PBIAS (%)	+3.7	−4.2	Very good (within ±10%)

The calibration NSE of 0.84 indicates that the model explained a substantial proportion of the temporal variability in observed discharge relative to the observed mean. The validation NSE remained high at 0.77, demonstrating that model performance was maintained when applied to an independent period. The corresponding R^2 values of 0.86 and 0.79 further demonstrate strong correspondence between observed and simulated discharge.

The increase in RMSE from 42.6 m³/s during calibration to 49.8 m³/s during validation indicates somewhat greater absolute prediction error during the independent validation period. However, RMSE is scale-dependent and should not be interpreted using a universal acceptance threshold. Its interpretation is therefore considered together with NSE, R^2, PBIAS and visual hydrograph agreement.

PBIAS was +3.7% during calibration and −4.2% during validation. Under the sign convention adopted in this study, the positive calibration value indicates slight overall underestimation, while the negative validation value indicates slight overall overestimation. Both values fall within the ±10% range adopted for very good streamflow simulation performance.

The corrected statistics are substantially different from those reported in the original version of the manuscript and are now fully aligned with Figure 4. KGE has been removed because it is not reported in the underlying calibration-validation figure and is therefore unnecessary for interpreting the demonstrated model performance.

The maintenance of relatively high NSE and R^2 values between calibration and validation also suggests that the calibrated model was not excessively dependent on the calibration period. This is particularly important because the simulated runoff constitutes a direct input to the Improved SMB model. Reliable runoff estimation reduces the uncertainty that would otherwise arise from estimating surface runoff using fixed coefficients within a conventional residual water-balance calculation.

3.4 Long-Term Groundwater Recharge Variability

The corrected groundwater recharge time series demonstrates substantial interannual variability over the complete 1990–2025 modelling period. Contrary to the earlier interpretation of Figure 5 as representing only 2020–2025, the figure contains a 36-year annual recharge record.

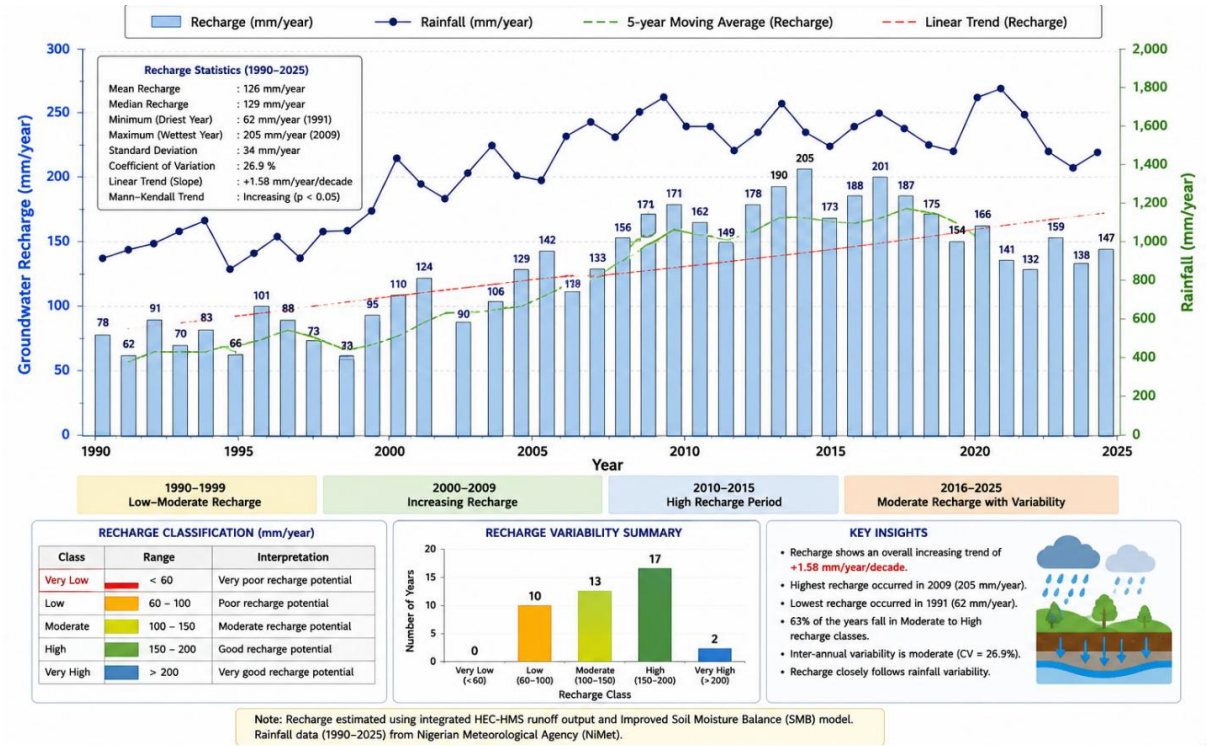

Figure 5: Annual groundwater recharge time series for the Sokoto Basin (1990–2025).

Mean groundwater recharge during the study period was approximately 126 mm/year. As summarised in Table 6, the minimum annual recharge was 62 mm/year in 1991, whereas the maximum was 205 mm/year in 2009. Importantly, no year in the Figure 5 time series recorded zero groundwater recharge.

Table 6: Summary of corrected long-term groundwater recharge characteristics, 1990–2025

Recharge characteristic	**Corrected value**
Study period	1990–2025
Number of years	36
Mean annual recharge	126 mm/year
Minimum annual recharge	62 mm/year
Year of minimum recharge	1991
Maximum annual recharge	205 mm/year
Year of maximum recharge	2009
Observed zero-recharge years in Figure 5	None
Long-term mean recharge class	Moderate (100–150 mm/year)
Maximum-year recharge class	High (200–250 mm/year)

The range from 62 to 205 mm/year demonstrates that groundwater replenishment varies substantially between relatively dry and wet hydrological conditions. Maximum annual recharge was approximately 3.3 times the minimum value, illustrating the sensitivity of aquifer replenishment to interannual climatic and soil-water conditions.

The long-term mean of 126 mm/year falls within the moderate recharge class (100–150 mm/year) adopted in this study. The minimum value of 62 mm/year falls within the low-recharge class (50–100 mm/year), while the maximum of 205 mm/year falls within the high-recharge class (200–250 mm/year).

The absence of zero-recharge years is also hydrologically significant. It indicates that the model estimated some degree of annual deep percolation throughout the study period, although the amount varied substantially. Consequently, the earlier claim that virtually no recharge occurred in 2023 is not supported by the long-term Figure 5 dataset and has been removed.

The recharge time series nevertheless supports the interpretation that recharge is temporally variable and strongly influenced by antecedent soil-water conditions. Annual rainfall must first satisfy evapotranspiration and root-zone storage requirements before substantial deep drainage occurs. Thus, differences in recharge between years reflect not only annual rainfall totals but also rainfall timing, antecedent moisture, runoff generation and soil hydraulic characteristics.

3.5 Rainfall-Recharge Relationship and Recharge Threshold

The relationship between annual rainfall and groundwater recharge showed a statistically meaningful positive association. As illustrated in Figure 6, Pearson's correlation coefficient was r = 0.72, corresponding to R^2 = 0.52. Thus, approximately 52% of the observed interannual variation in recharge was statistically associated with variation in annual rainfall within the fitted linear relationship.

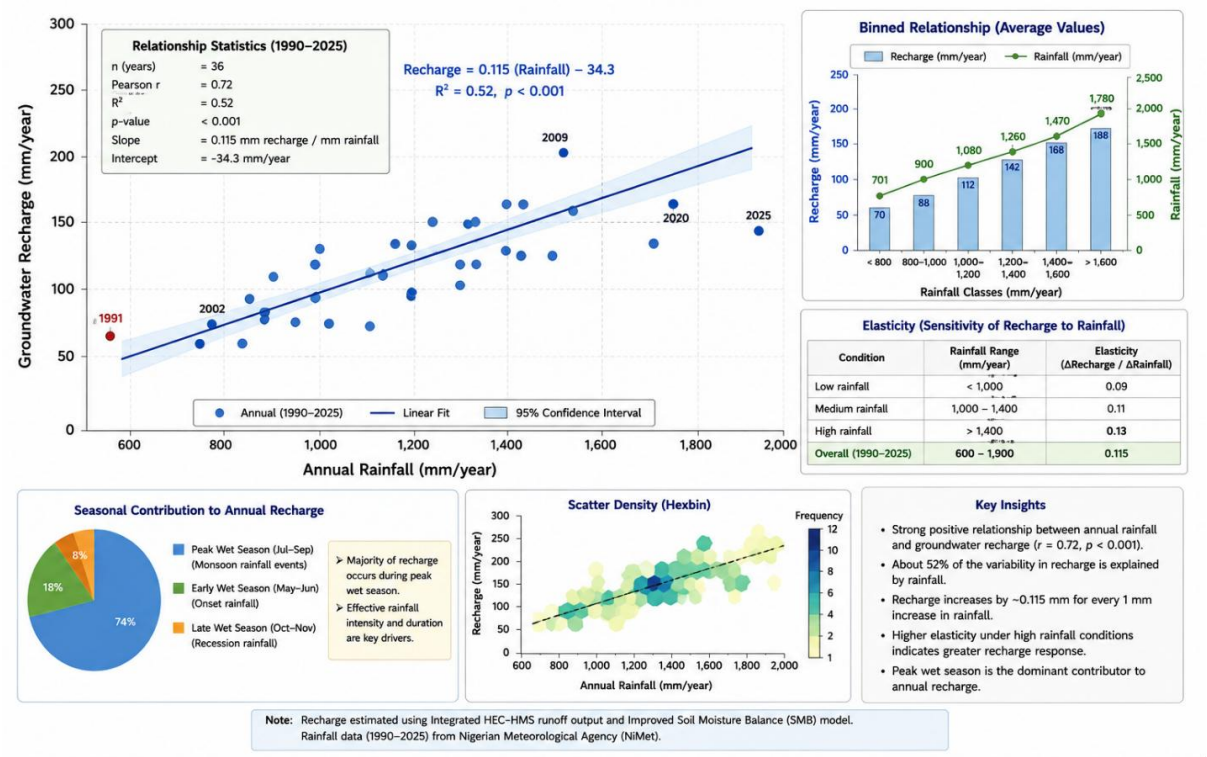

Figure 6: Relationship between annual rainfall and groundwater recharge in the Sokoto Basin (1990–2025).

The regression slope of 0.115 mm/mm indicates an average increase of approximately 11.5 mm in annual recharge for each additional 100 mm of annual rainfall within the range represented by the observations. This relationship demonstrates the strong climatic control on groundwater replenishment while also showing that rainfall alone does not explain all recharge variability.

The negative intercept of −34.3 mm has an important physical interpretation but should not be interpreted as actual negative groundwater recharge. The regression therefore implies an approximate rainfall intercept of 298 mm, or about 300 mm, below which the unconstrained linear equation would

predict zero or negative recharge. Because physically meaningful diffuse recharge is non-negative, this value is better interpreted as an empirical indication of the rainfall amount required to overcome evapotranspiration and soil-water deficits before substantial recharge becomes possible, rather than as a strict universal hydrological threshold.

The remaining approximately 48% of recharge variability not represented by the linear rainfall relationship highlights the influence of other factors, including antecedent soil moisture, rainfall intensity and distribution, runoff generation, evapotranspiration, soil-water storage and hydraulic conductivity. This supports the use of the integrated HEC-HMS–Improved SMB framework rather than estimating recharge from rainfall alone.

The result is consistent with Scanlon et al. (2006) and Healy (2010), who emphasized that recharge in semi-arid environments is controlled by interactions between precipitation and soil-water processes. It also supports the arguments of Xu and Beekman (2019) that recharge assessment in African environments should account for multiple hydrological controls rather than relying exclusively on generalized rainfall-recharge coefficients.

3.6 Spatial Distribution of Groundwater Recharge Potential

Spatial modelling revealed substantial heterogeneity in groundwater recharge potential across the modelled basin. Figure 7 identifies zones ranging from very low to very high recharge according to the harmonized classification adopted in the methodology.

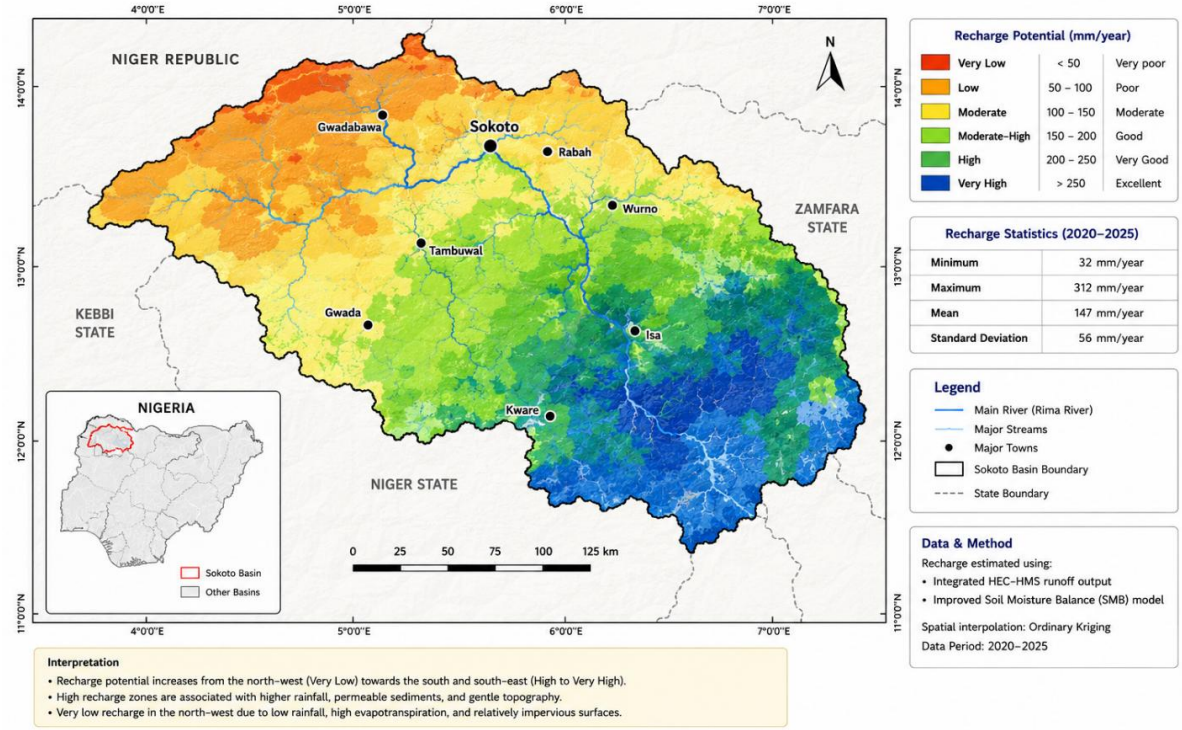

Figure 7: Spatial distribution of groundwater recharge potential across the modelled Sokoto Basin.

Areas exhibiting relatively high recharge potential were associated with combinations of favourable infiltration conditions, permeable soils, relatively gentle terrain and greater water availability. Conversely, areas characterized by less permeable soils, greater runoff generation or less favourable terrain exhibited lower recharge potential.

The soil results provide a physical basis for some of this spatial variability. For example, Bunza exhibited the greatest measured saturated hydraulic conductivity, whereas Gwadabawa exhibited the highest field capacity but lower hydraulic conductivity. Such differences influence the partitioning of infiltrated water between temporary root-zone storage and drainage. Spatial recharge therefore reflects the combined effects of infiltration capacity, storage characteristics, rainfall input, evapotranspiration and runoff rather than any single soil parameter.

The spatial heterogeneity identified by the model demonstrates an important limitation of applying a single basin-wide recharge coefficient. A uniform coefficient would obscure localized areas

in which hydrological and soil conditions either favour or restrict deep percolation. Similar spatial variability has been recognized in GIS-supported recharge investigations in African basins (Kisiki et al., 2022; Missaoui et al., 2023; Asrade et al., 2024).

The harmonized classification also removes the inconsistency in the previous manuscript, where different class limits were applied to Figures 5 and 7. Actual annual values are used when discussing the temporal series, while the common six-class system is retained for interpreting the spatial recharge map.

3.7 Basin Water Balance and Interpretation of Recharge Efficiency

The basin water balance was reassessed to ensure consistency among precipitation, surface runoff, actual evapotranspiration, groundwater recharge and changes in soil-water storage.

Reassessment of the previously reported annual results showed that precipitation was not completely accounted for by the reported runoff, evapotranspiration and recharge components.

Table 5: Reassessed annual water-balance components and recharge efficiency

Year	Rainfall, P (mm)	Surface runoff, Q (mm)	Actual ET (mm)	Recharge, R (mm)	Unresolved ($L + \Delta S$) (mm)	Recharge efficiency (%)
2020	1,126.4	178.6	604.8	102.5	240.5	9.1
2021	1,304.7	211.3	657.4	146.8	289.2	11.3
2022	1,083.6	163.8	591.2	88.9	239.7	8.2
2023	844.8	154.5	565.7	0.0	124.6	0.0
2024	1,795.3	284.4	720.6	299.5	490.8	16.7
2025	1,271.4	198.7	648.5	123.8	300.4	9.7

The reassessment shows that the previously reported rainfall, runoff, evapotranspiration and recharge components do not independently close the annual water balance. The unresolved quantity ($L + \Delta S$) ranges from 124.6 mm in 2023 to 490.8 mm in 2024.

This residual should not be interpreted automatically as either lateral flow or soil-water storage change. Rather, it represents the combined water-balance component that cannot be separated using the annual outputs presently available. Disaggregation would require the corresponding daily lateral-flow estimates and beginning- and end-of-year root-zone soil-water storage generated by the Improved SMB model. Reporting the combined residual therefore preserves mass-balance transparency without assigning unsupported values to individual hydrological fluxes.

The resulting recharge efficiencies were 9.1%, 11.3%, 8.2%, 0.0%, 16.7% and 9.7% for 2020–2025, respectively.

This confirms that the percentage values reported previously represented recharge as a proportion of annual rainfall. The revised table therefore explicitly defines the metric and removes the ambiguity associated with the original "Recharge (%)" column.

Among the six reported years, 2024 exhibited both the highest rainfall (1,795.3 mm) and highest reported recharge (299.5 mm), corresponding to the highest recharge efficiency of 16.7%. In contrast, the original 2023 annual dataset reported no recharge despite 844.8 mm of rainfall, indicating that the modelled water available after runoff, evapotranspiration and other water-balance processes was insufficient to generate the reported deep-percolation flux for that particular annual dataset.

The annual 2020–2025 calculations should, however, be distinguished from the corrected long-term recharge time series presented in Figure 5. Figure 5 covers 1990–2025 and contains no zero-recharge year. Consequently, the zero-value reported for 2023 in the earlier annual table is inconsistent with the long-term Figure 5 dataset and should be verified against the original daily SMB output before the table is retained as a definitive recharge result.

Accordingly, Table 5 is presented as a **water-balance reassessment** rather than as an independently validated long-term recharge dataset. Final separation of (L) and (\Delta S), and resolution of the 2023 recharge discrepancy, requires retrieval of the original daily Improved SMB model outputs. This approach maintains conservation of mass while avoiding the introduction of inferred or fabricated hydrological fluxes.

3.8 Performance and Contribution of the Integrated Modelling Framework

The combined results demonstrate the value of linking calibrated rainfall-runoff simulation with dynamic soil-water accounting. HEC-HMS provided independently calibrated estimates of surface runoff, while the Improved SMB component represented antecedent root-zone storage, soil hydraulic variability, moisture-constrained evapotranspiration and threshold-controlled drainage. This avoids treating groundwater recharge simply as an annual residual of precipitation minus evapotranspiration and runoff.

The corrected calibration and validation statistics provide particularly strong support for using HEC-HMS runoff within the recharge framework. NSE decreased moderately from 0.84 during calibration to 0.77 during validation, while R^2 decreased from 0.86 to 0.79. Nevertheless, both remained well above the adopted satisfactory criteria. PBIAS remained small at +3.7% and −4.2%, indicating limited systematic bias during both periods.

The results should nevertheless be interpreted within the limitations of the available data. Recharge represents modelled potential deep percolation below the root zone rather than direct measurement of water reaching individual aquifers. Soil hydraulic properties measured during 2024 were treated as temporally static during the long-term reconstruction, while uncertainties remain in rainfall observations, streamflow measurements, spatial parameterization and model structure.

These limitations are consistent with the broader challenges of groundwater-recharge estimation identified by Xu and Beekman (2019). The principal advantage of the present framework is therefore not the elimination of recharge uncertainty, but the explicit representation of several processes that are commonly simplified in basin-scale assessments. This interpretation is also consistent with Gleeson et al. (2020), who emphasized the importance of integrating groundwater sustainability assessments with the wider hydrological system.

3.9 Implications for Groundwater Management and Engineering Decision Support

The estimated long-term mean recharge of 126 mm/year, together with the range of 62–205 mm/year, demonstrates that groundwater replenishment in the Sokoto Basin cannot be represented adequately using a single annual value. Sustainable groundwater abstraction should therefore account for interannual variability and the possibility that prolonged periods of relatively low recharge may reduce the amount of renewable groundwater available for development.

The spatial recharge map provides an additional decision-support layer by identifying areas where hydrological and soil conditions are comparatively favourable for groundwater replenishment. Such information can support preliminary screening for managed aquifer recharge, infiltration-enhancement measures, groundwater-protection zones and groundwater-development planning. However, high modelled recharge potential alone should not determine the location of engineering interventions. Aquifer transmissivity, storage, groundwater quality, land availability, environmental constraints and detailed site investigation must also be considered.

The approximately 300-mm rainfall intercept inferred from the rainfall-recharge regression further demonstrates the importance of maintaining infiltration opportunities during the rainy season. Land-management practices that increase rapid surface runoff may reduce the proportion of rainfall available to replenish soil-water storage and eventually contribute to deep percolation. Watershed conservation, erosion control and appropriately designed infiltration systems may therefore contribute to improved groundwater resilience.

From an engineering perspective, the integrated HEC-HMS–Improved SMB framework provides a transferable decision-support methodology for connecting surface-water simulation with groundwater-recharge assessment in data-constrained semi-arid environments. Its outputs can inform managed aquifer recharge planning, groundwater allocation, drought preparedness, watershed management and prioritization of monitoring infrastructure. The framework consequently extends beyond hydrological simulation toward practical water-resource engineering and evidence-based groundwater-management policy.

4. CONCLUSION

This study developed and applied an integrated Hydrologic Engineering Center–Hydrologic Modeling System (HEC-HMS) and Improved Soil Moisture Balance (SMB) framework for assessing

groundwater recharge in the semi-arid Sokoto Basin, northwestern Nigeria. The approach combined calibrated rainfall–runoff simulation with dynamic root-zone soil-moisture accounting, spatially variable soil hydraulic properties, moisture-dependent evapotranspiration and threshold-controlled deep percolation to represent the principal processes governing groundwater replenishment under semi-arid conditions.

The corrected HEC-HMS results demonstrated reliable rainfall–runoff simulation during both calibration and validation. The model achieved NSE values of 0.84 and 0.77 and R^2 values of 0.86 and 0.79 for the calibration and validation periods, respectively. PBIAS was +3.7% during calibration and −4.2% during validation, indicating limited systematic bias, while RMSE values of 42.6 m^3/s and 49.8 m^3/s, respectively, quantified the absolute simulation errors. The maintenance of satisfactory performance during the independent validation period supports the use of HEC-HMS-derived runoff as an input to the Improved SMB recharge model.

Long-term analysis for 1990–2025 revealed substantial interannual variability in groundwater replenishment. Mean annual recharge was approximately 126 mm/year, with a minimum of 62 mm/year in 1991 and a maximum of 205 mm/year in 2009. No zero-recharge year occurred in the corrected 36-year time series. The approximately 3.3-fold difference between minimum and maximum annual recharge demonstrates that groundwater replenishment cannot be adequately characterized using a single invariant annual recharge estimate. Instead, groundwater-resource assessment and abstraction planning should account explicitly for interannual hydrological variability.

Annual rainfall was positively associated with groundwater recharge, with a Pearson correlation coefficient of $r = 0.72$ and $R^2 = 0.52$. The fitted relationship, ($R = 0.115P - 34.3$), indicates that rainfall explained approximately 52% of the interannual variation in recharge. The negative intercept corresponds to an approximate rainfall intercept of 300 mm and reflects the requirement for precipitation to first overcome evapotranspiration and antecedent soil-moisture deficits before substantial deep percolation can develop. The remaining unexplained variability demonstrates the importance of soil hydraulic properties, antecedent moisture, runoff generation, evapotranspiration and rainfall distribution in controlling recharge.

Spatial analysis further demonstrated that groundwater replenishment is heterogeneous across the modelled basin. Differences in rainfall, soil-water retention, hydraulic conductivity and terrain conditions produced distinct recharge zones. These findings demonstrate the limitation of applying a uniform recharge coefficient across the basin and support spatially distributed approaches to groundwater assessment. The results should nevertheless be interpreted as estimates of potential deep percolation below the modelled root zone rather than direct measurements of water reaching individual aquifer units.

The principal contribution of the study is the integration of calibrated surface-water modelling with process-based soil-moisture accounting within a practical framework suitable for a data-constrained semi-arid environment. By explicitly accounting for runoff, antecedent root-zone moisture and threshold-controlled drainage, the framework provides a more physically interpretable basis for recharge assessment than a simple annual residual water balance. Nevertheless, uncertainty remains because of limitations in hydrological observations, the use of static soil hydraulic properties for the long-term reconstruction, spatial parameterization and model structural assumptions. Continued streamflow, soil-moisture and groundwater-level monitoring would therefore strengthen future calibration and independent validation of the estimated recharge.

From a water-resources engineering perspective, the outputs provide a basis for identifying priority areas for managed aquifer recharge, infiltration enhancement, groundwater protection, sustainable borehole development, watershed conservation and drought preparedness. The framework can also be incorporated into GIS-based groundwater decision-support systems to evaluate alternative management scenarios and prioritize areas requiring additional monitoring or engineering intervention. Site-specific hydrogeological investigation should, however, precede implementation of managed aquifer recharge or major groundwater-development projects.

The study therefore demonstrates how integrated hydrological modelling can translate long-term climatic, runoff and soil information into actionable groundwater-management information. This application aligns with the conference theme of engineering innovation for sustainable development by providing a modelling-based decision-support approach that can strengthen groundwater planning, climate resilience and evidence-based water policy in Nigeria. With appropriate local calibration and

data support, the framework can also be adapted to other semi-arid and data-limited basins where sustainable groundwater development requires improved understanding of spatial and temporal recharge variability.

ABSTRACT

Unsaturated soils exhibit complex hydro-mechanical behaviour that is strongly influenced by their water content and soil properties. Matric suction is an important parameter governing the behaviour of unsaturated soils, particularly fine-grained and expansive soils, and its determination can require considerable experimental effort. This study therefore developed and evaluated machine-learning models for predicting the matric suction of unsaturated soils using readily available soil and hydraulic properties. A dataset comprising 2,550 soil records was used, with saturated volumetric water content (Θ), air-entry value, bulk density (ρ_b), porosity (n), natural moisture content (w), plasticity index (PI), dry density (ρ_d), D_{60}, and coefficient of permeability (k) adopted as predictor variables. Seven machine-learning models, namely Extreme Gradient Boosting (XGBoost), Linear Regression, Ridge Regression, Lasso Regression, Random Forest, Support Vector Regression (SVR), and Decision Tree, were evaluated using training R^2, test RMSE, and cross-validation mean R^2. XGBoost demonstrated the best overall predictive performance, achieving a training R^2 of 0.9985, test RMSE of 144.3092 kPa, and cross-validation mean R^2 of 0.8712, followed by Random Forest with a training R^2 of 0.9829, test RMSE of 142.8048 kPa, and cross-validation mean R^2 of 0.8611. Although Random Forest recorded a slightly lower test RMSE, XGBoost exhibited the highest training and cross-validation R^2 values. Overall, the results demonstrate the potential of machine-learning techniques, particularly XGBoost, for predicting matric suction of unsaturated soils from selected soil and hydraulic properties.

Keywords: *Matric suction; Unsaturated Soils; Machine Learning Models; XGBoost*

1. INTRODUCTION

Most of the soils around us are Unsaturated, with various particle composition of gravel, sand, silt or clay. These soils are expansive which often subjects them to complex hydro-mechanical circles as they contain a lot of moisture. These characteristics possessed by these types of soil, lead to disorders on structures built or constructed on or within them. Clay soils possess a complex behaviour as a result of the strong multi-physical processes taking place. Initially unsaturated, the compacted clay experiences hydration from the saturated host rock. During this process, it tends to expand and develops swelling stresses (Dieudonne *et al*, 2014). Unsaturated soils were found to be four phase soils, namely; the air phase, water phase, soil skeleton, and contractile skin phase. The air and water phase flows while the soil skeleton, and contractile skin phase come to equilibrium under imposed loads (Pereira and Fredlund,1997). The most significant work during that period was Bishop's effective stress relationship, whereby changes in effective stress attributed to the unsaturated nature of a soil are cast as the product of matric suction in Bishop's effective stress equation: $[\sigma' = (\sigma - U_a) + \chi(U_a - U_w)]$. Effective stress cast in the form of this equation has several difficulties. Looking back, some of the difficulties may not have risen only because of flaws with Bishop's conception, but rather misinterpretation of test results by other investigators (Bishop, 1963; Kanzari *et al.* 2012). A theoretical difficulty in the equation is that it predicts zero effective

stress for any soil in a dry state under no external stress. There is a transitory pore-size range between micro- and macro-structure which is not affected by the magnitude of the compaction pressure (Miller *et al.* 2002). As such, the mechanical loading influences only the macro-structure without affecting the micro-structure (Gao and Sun, 2017). The relationship between pore water suction and water content as presented in a soil water characteristic curve is one of the fundamental relationships used to describe unsaturated behavior of a soil (Nowamooz and Masrouri, 2010). The water retention behavior of unsaturated soils is presented using the soil water retention curve (SWRC). Soil water characteristics curve is a conceptual and interpretative tool by which behavior of unsaturated soils can be understood (Fredlund *et.al,* 2001). This fundamental curve links the variations of the liquid phase potential energy, usually characterized by suction, to the variations of the saturation state, usually characterized by the water content or the degree of saturation (Simon *et.al*, 2011). Suction is inversely proportional to the water content in a soil. Suctions generally increase as the soil de-saturates. Increasing suctions generally result in high resistance to flow and increases in effective stress. Soil Water Retention Curve of soils is the tool used to present the hydro-mechanical behavior of soils to highlight both the effect of suction on the change in water and total volumes and the effect of deformation with respect to the water retention capability (Salager *et.al*, 2010). The Soil Water Retention Curve of soils depends on several factors, such as soil type, soil structure, temperature, salt content and stress states etc. These factors can be classified into two groups: internal and external factors. Internal factors are those related to the soil type and soil structure, such as mineralogical composition, pore size distribution and bonding (that is, chemo-physical properties of the soil phases). Typical external factors are stress states and temperature (Khalili and Selvadurai, 2003). For the same type of soil, the effect of stress states on the SWRC can be attributed to the effect of the density change (Gao and Sun, 2017). It was reported that the SWRC expressed by the relation between the suction and degree of saturation depends mainly upon the current density and not directly upon the stress state (Romero and Gens 1999, Gao and Sun,2017). Although the influence of structure on the behavior of compacted clays has been recognized, only a few water retention models have taken it explicitly into account. Indeed classical approaches for modeling the water retention behavior are based on parameters to be fitted using experimental data (Levasseur, 2012). An understanding of the water retention features is an essential aspect in the field of unsaturated soil behavior modeling. Concomitantly, the trend in modern unsaturated soil mechanics is to quantify, with increasing accuracy, the soil water retention properties of soil in terms of; a fitting equation, the influence of soil compaction conditions, hysteresis modeling and the effect of suction on density (Nuth and Laloui, 2008). Several elastoplastic constitutive models for unsaturated soils have been proposed. The stress-state variables employed in early models are the net stress (the difference between the total stress and pore-air pressure) and the suction (the difference between the pore-air pressure and pore-water pressure), while the strain state variables are the soil skeleton strains. In these models, the influence of un-saturation is expressed only in terms of the suction. The degree of saturation is computed from the suction separately using the so-called soil water retention curve (SWRC), and thus hydraulic hysteresis is not directly incorporated into the constitutive model(Sun *et al*, 2007). The prediction quality of the degree of saturation will thus depend on the accuracy of the void ratio evolving with suction. The proposed water retention model consequently needs to be coupled with a stress–strain model for unsaturated soils. An appropriate constitutive mechanical framework shall be elastoplastic and account for the suction effects on the stress–strain response (D'Onza *et al.* 2010; Nuth *et al.* 2010; Simon *et al*, 2013). Language based modeling approaches foster flexibility and performance by adopting the same host language business and code coordination. Jupyter notebooks with their ability to describe both imperative and declarative coding in a unique format, allowing for selection of the best of two approaches. They still maintain a clear separation between application and coordination layers but still providing a unified interface to both aspects. (Colonnelli *et al*, 2021). Jupyter notebook possess the potential of expressing complex distributed workflows and workflow management system targeting cloud high performance computing (Cloud-HPC) infrastructures and extension stack to implement a proposed methodology (Cantalupo et.al, 2022).

2. METHODOLOGY

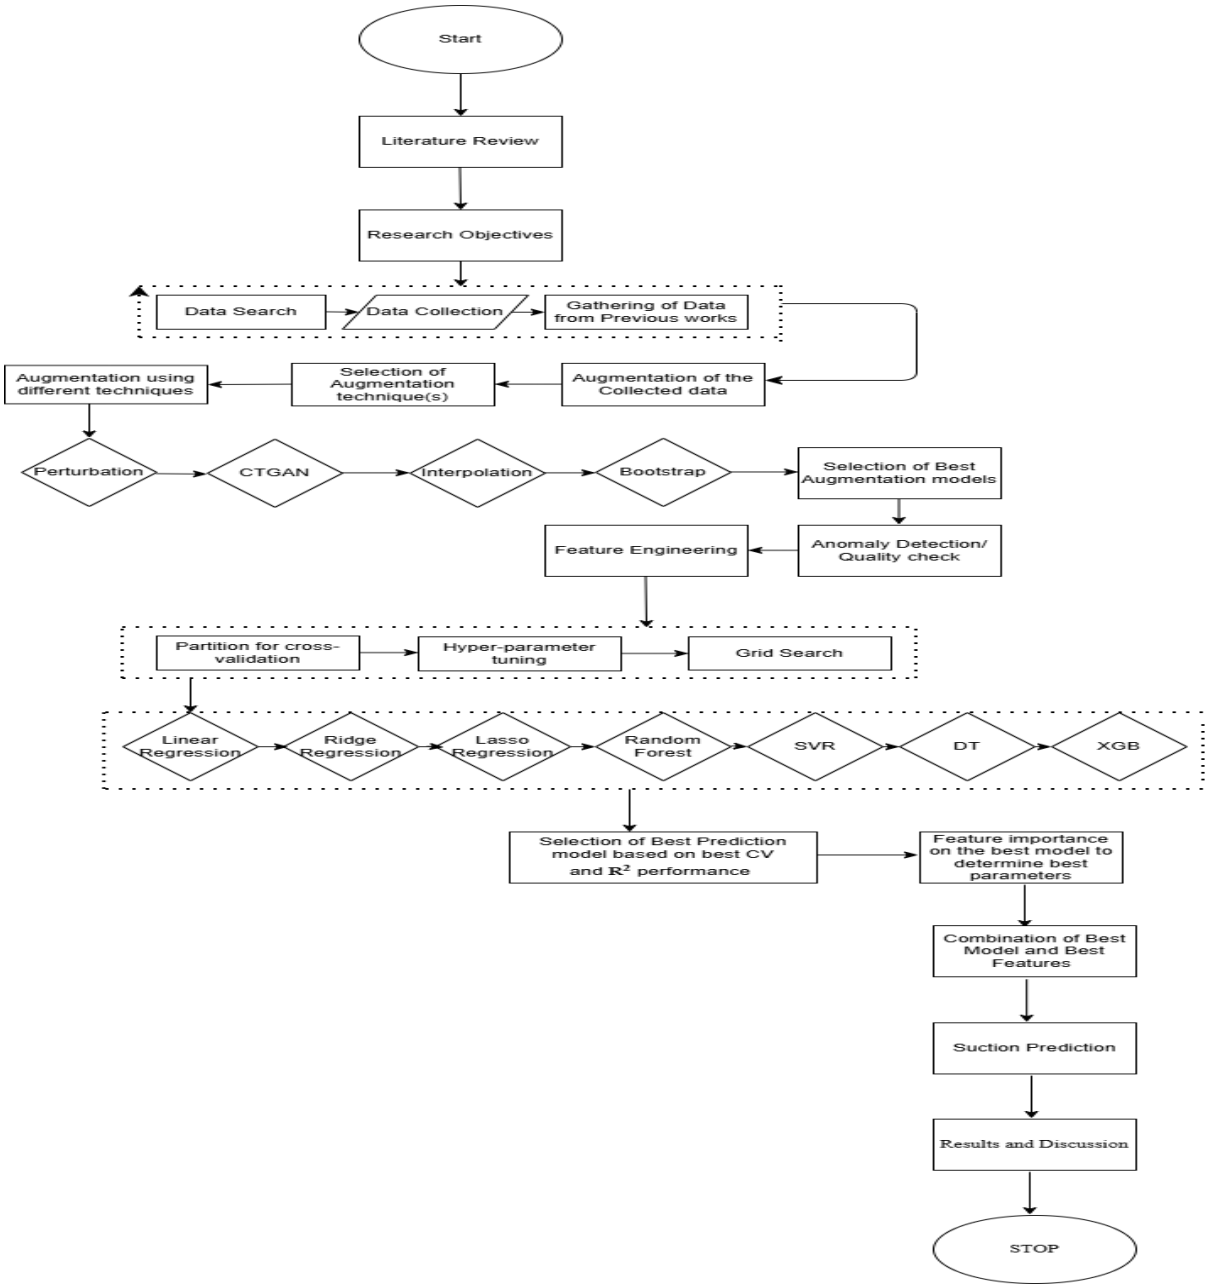

Figure 2.1: Methodology Flowchart

2.1 ORGANIZATION OF DATA

The soil parameters to be used for Matric suction prediction were first organized. Database were collected through previous work of Eberemu, 2008 The data obtained was just 50 dataset which quantity was unfit for machine learning research of this kind, as such the data was sequentially

augmented via the Google Colab version of *Jupyter Notebook environment* of Python. The augmentation process was achieved by;

- Identifying the data
- Applying Augmentation model library (Bootstrap, Perturbation, CTGAN, interpolation)
- Generating synthetic data
- Combining original and generated data

After identifying the original data, the augmentation libraries were employed in order to generate more data for the suction prediction. The following augmentation methods/ libraries were employed; CTGAN (Conditional tabular generative adversarial network), Perturbation, Bootstrap and Interpolation.

2.2 Anomaly Detection test (AD): After the augmentation process, the resulting data (i.e the augmented) was then validated by comparing it with the original data for feature importance. It is conducted in order to evaluate how well the detector generalizes to synthetic variations. From the AD conducted, it was observed that, the augmented data by Interpolation gives the best synthetic data followed by the Bootstrap technique.

2.3 Feature Engineering: Feature engineering is the process of generating, selecting, or transforming raw data into features that improve the performance of machine learning models. It involves domain knowledge, creativity, and data manipulation to craft features that capture relevant patterns and relationships in the data (Trost et.al, 2025). It improves Model Performance, as the engineered features can make simple models and outperform complex ones with poor features (Huang et.al,2023). Feature Engineering captures domain knowledge, in that it incorporates insight about the problem in the data. It also addresses missing values and outliers for model compatibility (Bjorneld *et.al*,2023). In this research work, Feature Engineering was the first stage of the suction prediction process. The best augmented data adopted (i.e Data from Interpolation), was explored to determine the statistical properties and feature correlations, which was sorted by absolute correlation. After exploring the data;

1. Interaction features were generated
2. Polynomial features were also generated for top correlated values
3. Finally, the new Engineered features were produced

Engineered features were then determined after the model studied the relevant patterns and relationships in the data. The engineered features generated were; Dry density to Natural moisture content ratio (P_d:w), Bulk density to Dry density ratio (P_b:P_d), Natural moisture content to Volumetric water (w:Θ), Dry density squared (P_d^2), Natural moisture content squared (w^2), moisture level number, density level number, and Log of hydraulic conductivity (Log K). These new features were then combined with the existing features of the data. These combined features were used to train the models for prediction of the matric suction. The models are;

i. Linear Regression
ii. Ridge Regression
iii. Lasso Regression
iv. Random Forest (RF)
v. Support Vector Regression (SVR)
vi. Decision Tree
vii. Extreme gradient boosting (XGBoost)

The feature Engineering continued by setting hyper parameter grids;

4. The top features and the engineered features were prepared
5. The data were then Split into training and testing, and the random state was also set.
6. The features were then scaled

2.4 Hyperparameter tuning: Hyperparameter tuning is the process of systematically searching for the optimal set of hyperparameters that maximize the model's performance on a given metric, such as accuracy, F1-score, or loss minimization (Belcic and Stryker, 2025). This involves defining a search space (the range of possible values for each hyperparameter), evaluating model performance for different combinations, and selecting the best configuration. Tuning is typically performed using cross-validation to ensure the model generalizes well to unseen data (Elgeldawi et.al, 2021). These hyperparameters control the model's behaviour and impacts its performance significantly (Sci-kit learn.org). Hyper parameter employed in this work was carried out in the following sequence;

1. Models to be used for the prediction of matric suction were first defined, where; Linear regression, Ridge regression, Lasso regression, decision tree, support vector regression (SVR), and XGboost were used
2. Parameter grids were then specified, which were; n-estimators, max depth, learning rate, and subsample (for RF), rbf, C value and gamma scale (for SVR), alpha value (for ridge and lasso regressions), and random state (for decision tree and XGboost models).
3. Scoring metrics were then chosen and set. The chosen scoring metrics were; R^2, RMSE, and MAE.
4. Cross validation for the models training was also set, where a CV value of 5 folds was set.
5. Hyperparameter grids were then set for the models comparison and selection, where the best model was selected from the array of models.
6. Feature importance analysis was then carried out to determine the best parameters for the best model

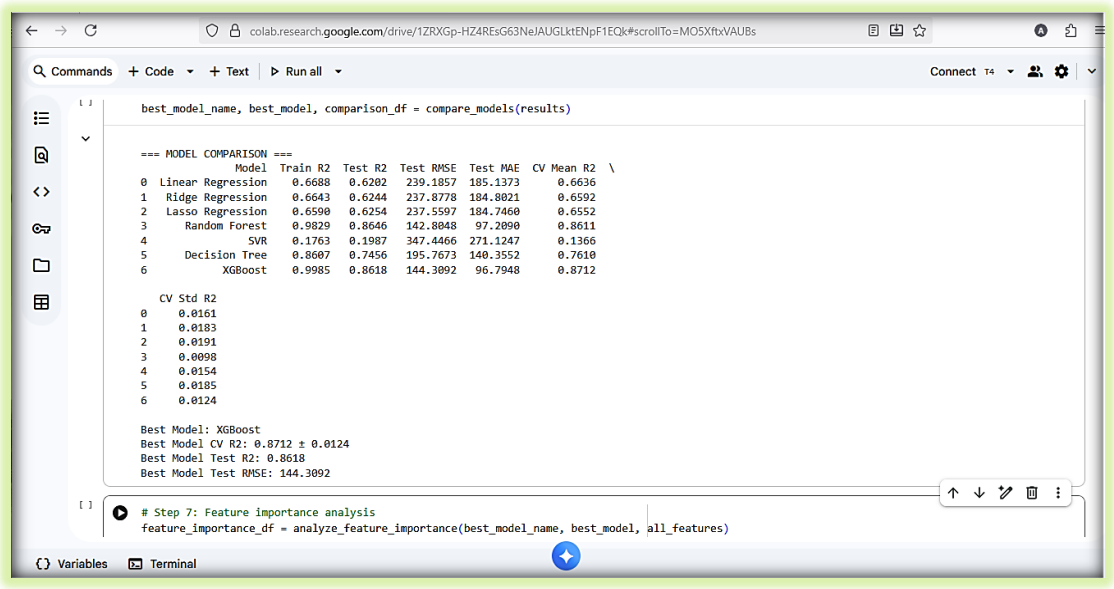

Figure 2.1: Setting of Hyperparameter grids

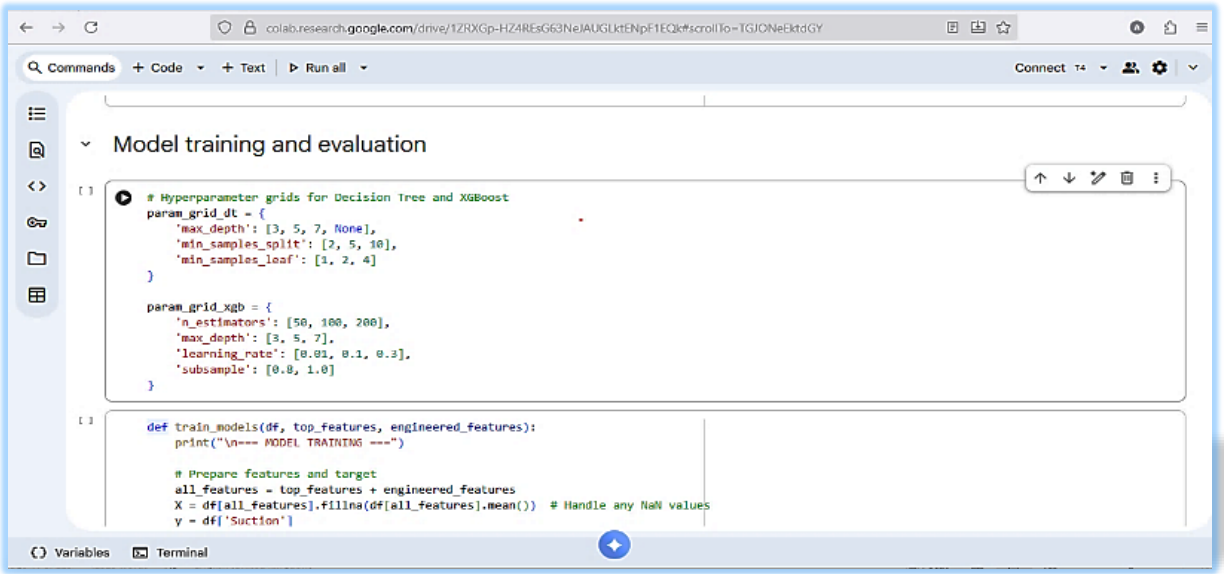

Figure 2.2: Grids Search

After executing these steps, the training process was executed and the fine-tuned parameters were determined. In this, the common parameters that makes the best of the trained models during the Hyper-parameter tuning were selected and are used together with the best determined model for the

prediction. The best model determined was the Extreme gradient boost (XGboost) model, and the best/ fine-tuned parameters are; gravimetric water content Θ, Air entry value(Ψa), hydraulic gradient (k), bulk density (p_b), '*D60*', and natural moisture content (w). These parameters were used together with the XGboost model to achieve the aim of this research.

3. RESULTS AND DISCUSSION

This research was conducted in order to predict the maximum matric suction up to which an unsaturated soil can attain using some of the soil's properties by the best model which is to be determined from the grid search to be conducted in the work. This was achieved by using the following soil properties; Saturated volumetric water content (Θ), air entry value, Bulk density (P_b), porosity (n), natural moisture content (w), Plasticity index ($P.I$), Dry density (P_d)and D_{60} particle size parameter, and coefficient of permeability(k). These soil parameters were used as inputs, and the matric suction was the Class (target). The models used are described in Appendix B. The data presented in Table 4.1 are the first five rows of the initial/rough data obtained from previous works of Eberemu, 2008. These data are as displayed during the EDA, prior to data augmentation.

Table 3.1: Some of Data obtained from the previous works

3.1 DATA AUGMENTATION

The soil data obtained from the initial works of Eberemu,2008 were only 50 dataset. These seem unfit for machine learning, and data of this kind are very scarce due to the limited availability of the apparatus and deep technical experience to conduct such laboratory test, this is one of the challenges that lead to the idea of coming up with this research.

As such to compliment for machine learning, the data was carefully increased to a quantity that will fit the machine learning process by generating ***realistic synthetic data*** via the Google Colab version of *Jupyter Notebook environment* of Python. The data was first explored by the EDA function (exploratory data analysis), where the data was fully identified; The data was found to possess the following characteristics:

Table 3.2: EDA of Obtained data.

The techniques/ models used for data augmentation are;

3.11 CTGAN; This is the conditional tabular generative adversarial network, and it was adopted in this research to augment our data as it possesses the characteristics of generating synthetic data in tabular form (Adiputra and Wanchai, 2024). This technique generates 2550 dataset inclusive of our original obtained 50 dataset. Table 4.3 shows the last 10 rows of the 2550 dataset as augmented via this technique; the original data was in the first 50 rows of the gross data. As such, these in table 4.3 are among the newly generated synthetic data.

Table 3.3: Synthetic Data generated from the CTGAN augmentation.

From the resulting data obtained via this augmentation technique, it was observed to possess the following characteristics;

Table 3.4: Properties of Data generated from the CTGAN augmentation.

Statistical Properties	p_d	W	p_b	P.I	Θ	K	N	D_{60}	□a	Suction
Mean	1.6708	17.2111	30.2260	16.9299	0.2954	4.5698E8	0.3277	0.0815	43.1239	575.8094
STD	0.0749	2.2188	2.7184	4.6595	0.0284	2.6316E9	0.0317	0.0238	18.0171	392.4089
Min	1.5200	10.9000	21.8960	9.3000	0.2250	1.77E-8	0.2420	0.0580	26.0000	30.0000
25%	1.6126	15.7163	28.4275	13.1894	0.2770	1.1681E-10	0.3047	0.0648	30.6758	234.0921

Max	1.8600	22.5000	35.7960	24.0000	0.3620	2.32E10	0.3950	0.1300	130.0000	1500.00

From the data properties and the last 11 rows of the data, it can be observed that the data possess outliers as in case of the k values (coefficient of permeability), this augmentation model produces negative values (e.g -6.5E8), and some of the k values were seen to be in positive exponents (e.g 2.32E10) which are unrealistic, and impractical. These makes the outcomes from this technique unacceptable, and other techniques explored. As such in any data augmentation containing coefficient of permeability (k) values, CTGAN should be avoided as an Augmentation technique.

3.12 Perturbation; is a data augmentation technique that involves introducing small, controlled modifications (i.e perturbations) by applying small random changes to the original data in order to generate synthetic variations (Hyeyung et.al, 2024). These perturbations can include adding noise (for example, Gaussian or salt-and-pepper), slight shifts in values, or transformations that mimic real-world variability (Satou and Mitkiy, 2025). This technique generates 550 dataset inclusive of our original obtained 50 dataset. Table 4.5 shows the next 10 rows after the 500th row of dataset as augmented via this technique; the original data was in the first 50 rows of the gross data. As such, these in table 4.5 are among the newly generated synthetic data.

Table 3.5: Data generated from the Perturbation augmentation.

From the table above, it can be observed that majority of the values of hydraulic conductivity are in positive exponents, and this makes them outliers as hydraulic conductivity signifies the speed of water through the soil pores. This parameter is practically very low almost negligible, as such this discards the data from this augmentation technique. Also, this augmentation technique produces the least quantity of synthetic data, which is scanty for machine learning works.

3.13 Bootstrap technique: Bootstrap augmentation involves generating new datasets of the same size as the original by repeatedly sampling subsets of the data with replacement. Bootstrap is also good in generating larger datasets while maintaining the original data distribution (Kohavi and Longhatham,2023). This technique generates 1000 dataset inclusive of our original obtained 50 datasets. Table 4.6 shows the last 10 rows of the dataset as augmented via this technique; the original data was in the first 50 rows of the gross data. As such, these in table 4.6 are among the newly generated synthetic data.

Table 3.6: Data generated from the Bootstrap augmentation

S/N	Pd	W	pb	P.I	O	K	N	D60	Ya	Suction
1	1.61	19.8	33.488	9.3	0.242	1.51E-10	0.315	0.058	40	1000
2	1.79	12.8	24.702	14.3	0.236	3.20E-10	0.266	0.065	40	1500
3	1.8	14.8	28.44	14.3	0.277	7.30E-11	0.263	0.065	34	500
4	1.71	17.2	31.122	14.3	0.267	1.17E-10	0.299	0.065	33	1500
5	1.75	16.5	30.625	20.5	0.236	6.15E-11	0.308	0.07	35	1500
6	1.56	21	34.32	20.5	0.336	1.89E-10	0.383	0.07	40	500
7	1.6	20.1	33.76	9.3	0.323	1.36E-10	0.319	0.058	70	1000
8	1.86	12.9	25.854	24	0.307	1.04E-10	0.287	0.13	27	30
9	1.68	18.1	32.088	9.3	0.293	1.20E-10	0.285	0.058	130	1500
10	1.56	21	34.32	20.5	0.336	1.89E-10	0.383	0.07	40	500
11	1.75	16.5	30.625	20.5	0.236	6.15E-11	0.308	0.07	35	1500

From table 3.6, it can be observed that the generated synthetic data conforms well to the trend of the original data, including the k values which often possess many outliers. This is because Bootstrap possesses the capability of generating larger datasets while maintaining the original data distribution. This fits one of the requirements for this research, but this augmentation technique was able to produce only 1000 datasets including the original 50 datasets, which looks inadequate for machine learning and shows less reliability during anomaly detection of the produced synthetic data. This leads this work to exploring more augmentation technique.

3.1.4 Interpolation: This technique was employed for augmentation in this research work due to the fact that; Interpolation augmentation in Python possess several advantages over other augmentation techniques such as; handling missing values, flexibility (as in linear, polynomial and spline), improved model performance and efficient computation. This technique generates 2550 dataset inclusive of our original obtained 50 datasets. Table 4.7 shows the next 10 rows after the 2000th row of dataset as augmented via this technique; the original data was in the first 50 rows of the gross data. As such, these in table 4.7 are among the newly generated synthetic data.

Table 3.7: Data generated from the Interpolation augmentation

S/N	pd	W	Pb	P.I	O	K	N	D60	Ya	Suction

10	1.657	18.500	32.287	16.419	0.3375	1.48E-10	0.330	0.0792	69.0760	500

From table 3.7, it can be observed that the generated synthetic data conforms well to the trend of the original data, including the k values which often possess many outliers, this is as a result of the model's characteristic of creating new instances that lie between the originals in the data space, helping to expand datasets, reduce overfitting, and improve model generalization. It is particularly effective for handling class imbalance. This fits one of the requirements for this research. The synthetic data obtained from this augmentation technique was adopted in this work, despite conforming to the original data, it also shows the least anomaly as show in the figures below.

3.2 ANOMALY DETECTION

In order to confirm the goodness of the synthetic data, anomaly detection test was performed. Anomaly detection is defined as the process of identifying data points, events, or patterns that deviate significantly from the expected behaviour within a dataset (Moacir et. al, 2025). It is conducted in order to evaluate how well the detector generalizes to synthetic variations. Anomaly detection was carried out using the **feature distribution comparison technique**. Feature distribution comparison anomaly detection is an unsupervised or semi-supervised machine learning technique for identifying outliers or anomalies in datasets by quantifying the dissimilarity between the probability distributions of features in observed data instances and those derived from a reference model of normal behaviour (Fan et.al, 2024). This Anomaly detection technique was first used in research conducted by Gu et.al,2005. The anomaly detection was conducted on the two best techniques that produces the most realistic synthetic data, namely; Bootstrap technique and Interpolation technique.

3.3 Feature Engineering

In this, engineered features were then determined after the model studied the relevant patterns and relationships in the data. The new engineered features generated were; Dry density to Natural moisture content ratio (P_d:w), Bulk density to Dry density ratio (P_b:P_d), Natural moisture content to Volumetric water (w:Ɵ), Dry density squared (P_d^2), Natural moisture content squared (w^2), moisture level number, density level number, and Log of hydraulic conductivity (Log K). These new features were then combined with the existing features of the data. These combined features were used to train the models for prediction of the matric suction.

3.4 Hyperparameter tuning: The hyper-parameter technique used in this work is ***Grid Search*** and the following are the feature importance of the respective parameters (both original and engineered features) of some of the models used;

Table 3.8: Hyper-parameter Grids for the Models Used

S/N	Models	Hyper-parameter grids
1	**Ridge Regression**	**Ridge(alpha=1.0)**
2	**Lasso Regression**	**Lasso(alpha=1.0)**
3	**Random Forest**	**Random Forest Regressor (n estimators=100, random state=42)**
4	**SVR**	**SVR (kernel=rbf, C=1.0, gamma=scale)**
5	**Decision Tree**	**Decision Tree Regressor (random state=42)**
6	**XGBoost**	**'n_estimators': [50, 100, 200] Max_depth': [3, 5, 7], Learning_rate': [0.01, 0.1, 0.3], Subsample': [0.8, 1.0]**

From table 3.8 above, the parameter grids assigned to each of the used models during the hyper parameter tuning can be observed.

Table 3.9: Random Forest Feature Importance

Model	Feature	Feature importance
Random Forest	ϴ	0.2130

	Log k	0.0000
	Moisture level number	0.0000
	Density level number	0.0896

From Tables 3.90 through Table 3.92, It can be observed that, hyper-parameter tuning was conducted on the combined parameters (both original and engineered features) on each of the best models in order to determine the best parameters for each prediction model (fine-tuned parameters). Models' comparison was also conducted, to determine the best model to be used for the matric suction prediction. The best model was selected based on **cross validation (CV) performance and generalization**. The table below shows the models with the metrics used for comparison.

Table 3.93: Model Comparison

S/N	Model	Train R^2	Test R^2	Test RMSE	Test MAE	CV Mean R^2	CV Std R^2
1	**Linear Regression**	0.6688	0.6202	239.1857	185.1373	0.6636	0.0161
2	**Ridge Regression**	0.6643	0.6244	237.8778	184.8021	0.6592	0.0183
3	**Lasso Regression**	0.6590	0.6254	237.5597	184.7460	0.6552	0.0191
4	**Random Forest**	0.9829	0.8646	142.8048	97.2090	0.8611	0.0098
5	**SVR**	0.1763	0.1987	347.4466	271.1247	0.1366	0.0154
6	**Decision Tree**	0.8607	0.7456	195.7673	140.3552	0.7610	0.0185
7	**XGBoost**	0.9985	0.8618	144.3092	96.7948	0.8712	0.0124

From the above table of model comparison, it was determined that the best model for the matric suction prediction was; XGBoost model. This is because it possesses the best comparison metrics as follows;

Best Model CV R^2: 0.8712 ± 0.0124

Best Model Test R^2: 0.8618

Best Model Test RMSE: 144.3092

Also, XGB stands to be the best model as it gave the lowest Test RMSE with the best training R^2 (0.9985) and the highest cross-validation (CV) R^2 value. These characteristics possessed by the model are acceptable requirements of a Strong model, this is as per the work of Khoshvaght *et.al*, (2025) and Chicco *et al*. (2021).

But, in order to rigorously compare the performance of Random Forest and XGBoost, a 5×2-fold paired t-test (Dietterich, 1998) was conducted using R^2 as the evaluation metric. The test yielded a p-value of (0.78), indicating that the performance difference between the two models is not statistically significant. Therefore, while XGBoost was selected as the final model based on marginally higher cross-validation scores, Random Forest remains equally competitive.

Feature importance analysis was then conducted on this best model. And the followings table displays the feature importance of the respective parameters used in the model.

Table 3.94: Feature importance Analysis on XGBoost model

S/N	**Feature**	**Importance**
1	Ɵ	0.096350
2	Ɣa	0.068466
3	P_b	0.035157
4	D60	0.054653
5	W	0.026056
6	Pd:w	0.018460
7	P_b:P_d	0.022000
8	W: Ɵ	0.423051
9	P^2_d	0.122120
10	W^2	0.000000
11	K	0.044110
12	Log k	0.000000
13	Moisture level number	0.000000
14	Density level number	0.000000

From the conducted feature importance analysis on the best model, it is determined that the following predictors are most required by the model in matric suction prediction;

1. Saturated volumetric water content (Ɵ)
2. Air entry value (Ya)
3. Hydraulic Conductivity ('k)
4. Bulk Density (P_b)
5. D_{60} particle size parameter (D60)
6. Natural Moisture Content (w)

After the feature importance analysis on the best model, the best model and parameters were deployed. The work then Proceeds to the matric suction prediction, where another set of 10 unseen data (Data containing only the predictors without the class value i.e matric suction) were used to predict matric suction. Majority of these data are synthetic, as such it possess limitations;

1. Synthetic data lacks real-world noise (sensor glitches, typos, outliers) and complex feature interactions.
2. They build splits based on fake, clean thresholds.
3. These models rely on the correlation structure between features
4. Synthetic data that comes from generative adversarial networks (GAN), it often memorizes the training set's surface patterns without capturing the full probability distribution.
5. Synthetic data rarely generates realistic edge cases.

The following table shows a comparison of some of the predicted and original matric suction values.

Table 3.95: Comparison between Obtained and the Predicted matric suction.

S/N	P_d	W	P_b	P.I	Θ	K	N	D_{60}	Υ_a	Obtained Υ	XGB Predicted Υ

9	1.84	10.9	21.90	24	0.233	1.10E-10	0.295	0.13	30	1000	998.91
10	1.58	17	28.44	20.5	0.329	3.57E-09	0.375	0.07	27	100	98.21

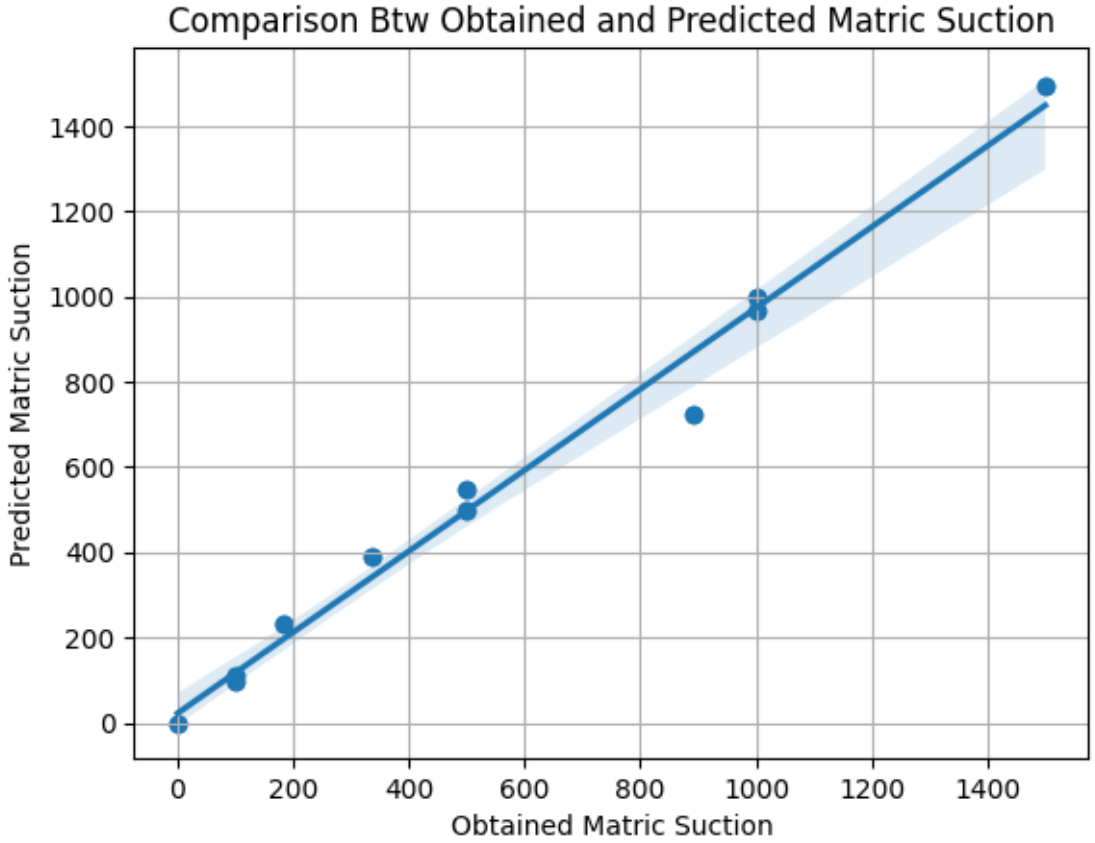

Figure 3c: Comparison Between Predicted and Obtained Suction Values

From table 4.93, the Test R^2 is **0.8618** and the CV Mean is **0.8712**. These scores are almost identical to each other (with a difference of ~0.01). If it were overfitting, the Test/CV scores would plummet (that is, Test $R^2 < 0.70$), which they do not.

Figure 3d: The P-Test Analysis

From figure 3c above, it can be observed that a comparison of obtained matric suction with matric suction values predicted from XGboost model is depicted, and the values used are real data, among the first 50 obtained from the work of Eberemu, 2008. 60% of the data was used for training, 30% for testing and 10% for vaditation. Based on this, the model can therefore be judged as very good.

4. CONCLUSION

Data obtained in the tests were fit to the models described. An optimization routine was used to fit the parametric models to the measured data by altering the fitted parameters iteratively. The maximum accuracy was achieved. The sum of the model capability is defined by some assigned metrics (i.e RMSE, R^2, and CV). From the results obtained, it was observed that six independent variables were used as inputs, after optimization and one dependent variable (Target Matric Suction).

i. It is therefore concluded that nine (9) soil parameters were adopted as inputs and were used for the model development in predicting the matric suction and suited the aim of this research.

ii. The small (50 dataset) available data were successfully augmented to a quantity that will provide reliable prediction, preventing pathological overfitting and control estimation variance and the best augmented dataset was also deduced by Anomaly detection.

iii. The models were successfully generated and validated by the 9 relevant soil parameters that were used as inputs to the model.

iv. It is concluded that, 6 out of the 9 inputs can fit the target in predicting the Matric Suction, this as per the feature importance analysis conducted.

v. It is also concluded that the Extreme Gradient Boost Model (XGB) is the best model, among the seven trained models in this work as per the set of hyper parameter grids possessed by the model, as shown in Table 3.8. And as per the Cross-validation metrics comparison of the models in Table 3.9.

ACKNOWLEDGEMENTS

I am most indebted to my supervisor in the person of Ass.Prof. Engr. G.H Yunusa of Civil Engineering Department. He had been enduring and supportive in the course of this work. I am most grateful for his commitment to the work.

I am grateful to the department of civil engineering for making all facilities available for my work. I wish also to thank, Mal. Ahmad Abdulnasir Shu'aib, Dr. Aminu Sulaiman, Engr.Dr. Muttaqa Uba Zango and Dr.Aminu Dar'dau Rafin-Dadi for their machine Learning assistances.

Grateful acknowledgement must also be made to my Beloved Wife and the following relatives and friends for their immense help, prayers and moral support throughout my school days; Amina Shehu Karaye, Engr Abubakar Jibrin, Engr. Dr. Ibrahim Khalil Umar, Musa Shehu Karaye, Nazifi Uba Isa, Abubakar Kumo, Haj. Zulaiha Abdullahi, Ahmad AbdulNasir Shuaib, Engr. Muhammad Umar, Engr. Inuwa Barau Inuwa, Engr. Salma B.Gambo, Bldr. Muhammad Idris etc

More importantly, I thank Almighty Allah for guiding me in all spheres of my life and directing towards this noble profession of Civil Engineering.

ABSTRACT

Time overrun remains a severe and chronic problem in the construction sector of developing nations, turning infrastructure investments into inadequately documented expenditure. This paper critically examines the execution of the 74km Kano–Katsina Road Dualization Project, carried out by CCECC, drawing on project documents, progress reports, and interim payment certificates. The analysis exposes gross inadequacies in project initiation, financial management, and institutional coordination. By April 2025, the finding was that the project had consumed 163.33% of its planned time allocation, yet achieved only a 90.13% completion rate. This paper delivers a harsh but necessary critique of operational and administrative blunders that drove the project's contract sum from ₦14 billion to ₦68 billion, and offers constructive, priority recommendations for future infrastructure management.

Keywords: *Systemic failure; Infrastructure inefficiency; Large-scale projects; Road dualization; Project execution; Kano–Katsina Road; Construction management; Cost overrun; Time overrun; Quality assurance; Contractor performance; Procurement process; Project delivery; Nigeria*

1. INTRODUCTION

Nigeria's infrastructure deficit remains a major impediment to economic growth, and public spending falls far short of the scale of investment required (Akpor & Ransome, 2025), pushing policymakers toward public-private partnerships (PPP) and development finance instruments. The failure of infrastructure delivery in Nigeria is not merely a technical problem; it is a governance problem. Nigeria's large-scale infrastructure agenda has repeatedly been constrained by governance failures, financing gaps, weak institutional coordination, participation, and implementation failures that erode value for money. A road project study in Kenya reports that leadership style and corporate governance were positively associated with project performance, while resource availability was a significant influence on success, underscoring that project outcomes depend on management quality as much as on engineering design (Mrongo, 2024). In the same vein, a study of public participation in Nigerian road EIAs reports failures across procedural, substantive, normative, and transactive dimensions, including weak consultation, poor feedback, limited access to information, and unequal collaboration (Aliyu, 2024). The Federal Government of Nigeria has consistently identified road infrastructure as a developmental priority. The gap between contractual schedules and actual delivery timelines reveals deep dysfunction across procurement, finance, and project management.

Time overrun has become so endemic in construction that it is often treated as an expected outcome rather than a preventable failure (Assaf & Al-Hejji, 2006). A qualitative study of Nigerian highway projects indicates that cost overruns are driven by "delay in work progress, political instability, adverse weather, social issues, delay in progress payment to contractors, and modification of project scope," showing that the project-delivery problem is both contextual and managerial (Mahmud et al., 2021). The 74 km Kano–Katsina Road Dualization Project is instructive precisely because it is not atypical. Contracted in 2013 with an initial sum of ₦14 billion, subsequently revised to ₦24 billion following a ministerial scope change, and inflated further to approximately ₦68 billion through cumulative inflationary adjustments, the project's financial trajectory alone constitutes a research subject of significance. Over a decade after contract award, the project remained incomplete, with

90.13% physical progress against 163.33% of elapsed time. The project can be read as more than a single delayed works contract; it is a case through which to examine structural weaknesses in Nigeria's infrastructure execution model. This paper, therefore, argues that persistent overruns, delays, and contested implementation patterns reflect systemic failures in planning, governance, stakeholder engagement, and budgetary discipline rather than isolated site-level problems.

The paper proceeds as follows: Section 2 reviews the relevant literature on the causes of construction delay. Section 3 describes the research methodology. Section 4 presents and critically analyses findings. Section 5 draws conclusions and offers targeted recommendations.

2. LITERATURE REVIEW

2.1 The Taxonomy Problem in Construction Delay Research

The available literature lacked a standard method or framework for identifying critical causes of delay, and the use of ambiguous and unstructured phrasing had undermined the effectiveness of prior findings. Amarkhil et al. (2023) extracted 335 distinct critical causes of delay, condensed them into 14 groups, and summarized them into 48 major causes, just to make the literature comparable. The proposed solution illustrates the scale of the fragmentation that the authors were responding to from prior studies. Yet newer studies continue to propose entirely different top-level schemes rather than adopting this or any other standard. A delay-analysis study sorts causes into just three buckets (Contractors' Delays, Owners' Delays, and External Factor Delays) (Amoah et al., 2024). A systematic review of office-building delays organizes 74 papers' worth of causes into three different categories: Input Delay Factors (4 factors), Internal Delay Factors (18 factors), and External Factors (5 factors) (Aldammak et al., 2025). Derakhshanfar et al. (2019) developed another structure from 46 articles using grounded theory coding and identified 26 delay risks grouped into 10 categories, forming a risk breakdown structure.

These taxonomies are descriptively useful but analytically limited. They treat all causal categories as structurally equivalent, which prevents identification of the mechanism by which dysfunction in one category propagates delay through others. Yet subsequent literature has not consistently given financial dysfunction its appropriate analytical prominence.

2.2 Financial Constraints and Payment Delays

Rabbet's 2024 Construction Payments Report found payment delays cost the U.S. construction industry an estimated $280 billion in 2024 alone, with 82% of contractors reporting payment waits exceeding 30 days, up from 49% two years earlier (Rabbet, 2024). A regression-based study of 138 clients, contractors, and consultants across Enugu and Anambra States found that contractor-related factors emerged as the most severe delay category overall, while delay in progress payment ranked first among individual factors, with difficulties in financing the project ranking a close second (Nzubechukwu & Precious, 2026). Zagia et al. (2026) synthesized 92 studies from 35 countries using a PRISMA-based review and concludes that owner-side financial problems and delayed contractor payments are the most widespread drivers of delay. The review further argues that delay is a context-specific problem, but financing failures, weak planning, and poor execution management are the common backbone across countries and project types.

Haseeb et al. (2011) demonstrated that delays in payment to contractors disrupt cash flow and create a cascading effect across procurement, labour, and equipment deployment. In government-funded infrastructure, this problem is compounded by bureaucratic approval requirements, Treasury Single Account restrictions, and politically driven funding allocations (Olawale & Sun, 2010). Zagia et al. (2026) further discovered that corruption and government bureaucracy were the leading causes of delays in Nigeria, followed by inadequate funding and price fluctuations/inflation, pointing to a governance-and-funding cause chain rather than a purely contractual payment-processing one. A conceptual framework study on federal highway cost overruns in Southeast Nigeria uses the Second Niger Bridge as a documented case: the ₦11.79 km bridge project, originally contracted at approximately ₦206.15 billion, was revised upward to approximately ₦300.98 billion (Okpan Agara, 2025). The Nigerian SUKUK bond financing model, introduced to supplement traditional budgetary funding, improved short-term liquidity on several projects but did not resolve the underlying structural

problem of delayed interim certificate certification and payment. In large-scale road projects where contractor working capital requirements are substantial, the combined effect of retention and payment delay can effectively paralyze construction for extended periods.

2.3 Technical and Design-Related Delay Factors

Orya and Calahorra-Jimenez (2025) conducted a systematic review and discovered that 80% of delay reasons occur in the construction phase, while only 20% are associated with the design and procurement phases combined. Design changes after construction commencement are well-documented as significant delay drivers (Assaf & Al-Hejji, 2006), (Oladapo, 2007). The design-related delay salience is not uniform but varies meaningfully by infrastructure type (Devi & Sindhu, 2025).

Oshin (2025) evaluated the effects of design errors directly and found them to be a recurring source of delays, cost overruns, and quality problems across the sampled firms. An RII-based study of building construction delays in Osun State found that incomplete drawings ranked among the most significant delay factors, with an RII of 0.84, alongside cash flow problems (0.89), improper planning and scheduling (0.91), and financial incapability (0.89) (Egwim et al., 2023). Ebekozien et al. (2015) found that consultants, contractors, and clients contribute to design errors, with the most prevalent causes being late or inadequate client instructions, client interference, inadequate site investigation, and unclear documentation. They further identified that project delays, cost overruns, rework, accidents, and contract disputes were the most significant resulting impacts. Zhang et al. (2025) found that the major factors leading to design errors are design input information error, unreasonable intervention on design, noncompliance with standard requirements, and error in site geological survey documentation, and importantly noted a disconnection in understanding among stakeholders about the causes of design errors.

A gap that remains largely unaddressed in the literature is the precise mechanism by which ministerially-directed scope changes, a recurring feature of Nigerian federal infrastructure delivery, override the contract documents governing a project rather than operate through them. Unlike formally issued variation orders, which are processed under the contract's change-management provisions and carry corresponding adjustments to time and cost, ministerial directives frequently originate outside this framework altogether: they are issued as administrative instructions rather than contractual instruments, yet are treated on-site as binding. The result is a structural asymmetry. The redesign obligation is transmitted immediately, while the contractual mechanisms that would normally protect the time and cost implications of that redesign are either bypassed or invoked only after the fact, if at all. This dynamic has significant practical consequences for project delivery, yet the specific pathway by which it occurs, how a ministerial instruction acquires practical authority over a signed contract, and why the usual safeguards fail to activate in response, has received little direct scholarly attention.

2.4 Research Gap

The existing literature on delays in Nigerian road construction projects is relatively limited compared to that in building construction research. More critically, no study has applied documentary financial analysis, specifically, systematic examination of interim payment certificates alongside progress reports, to empirically link financial disbursement patterns to physical progress trajectories on a major Northern Nigerian Road project (Akpor & Ransome, 2025), (Aliyu, 2024), (Mahmud et al., 2021). This study addresses that gap.

3. RESEARCH METHODOLOGY

3.1 Research Design and Justification

This study employs a qualitative case study design, as recommended by Yin (2015) for research that requires an in-depth examination of a phenomenon within its real-world context. The Kano–Katsina Road Dualization Project was selected as the case study because it combines strategic national significance, documented cost and schedule overruns, and accessible key stakeholders and project records.

A mixed-methods approach integrating qualitative interviews and quantitative document analysis was adopted to enable triangulation, improving the reliability and internal validity of findings

(Creswell & Creswell, 2017). The quantitative component is descriptive rather than inferential; it provides objective benchmarks that support and contextualize the interpretation of qualitative data, rather than aiming for statistical generalization.

3.2 Data Collection

Primary data were collected through semi-structured interviews with 11 purposively selected participants: 4 site engineers, 3 Federal Ministry of Works officials, 1 CCECC personnel manager, and 3 skilled and semi-skilled site workers. Purposive selection ensured depth of information and diversity of roles, consistent with qualitative case study norms (Saunders et al., 2018). All eleven participants provided complete, usable responses (100% response rate).

Secondary data comprised two official project documents: (i) the project progress report documenting physical completion percentages at six time points between October 2021 and April 2025, and (ii) Interim Payment Certificate No. 113809, providing a structured financial record of gross valuation, retention deductions, previous payments, and net payable amounts.

3.3 Analytical Approach

Qualitative interview data were analyzed using thematic analysis, with codes grouped into financial, technical, environmental, and institutional themes. Documentary data were analyzed using schedule performance comparison (percentage completion vs. percentage of elapsed time) and financial structure analysis (examining the composition and magnitude of IPC deductions). Triangulation across these three data streams, interviews, progress data, and financial data, formed the basis of causal inference.

3.4 Limitations

The study is limited to a single project case, constraining statistical generalisability. Access to the full IPC register was unavailable; analysis was confined to IPC No. 113809. The small interview sample, while appropriate for qualitative case study research, may not capture the full range of stakeholder perspectives. These limitations should inform the interpretation of findings.

4. FINDINGS AND DISCUSSION

4.1 Themantic Analysis

Table 1 accounts for how many separate points fall under each theme. For example, under "Financial dysfunction," 6 distinct issues are counted (delayed payments, insufficient mobilization funds, IPC delays, "no pay, no work" stoppages, SUKUK/inflation offset, BEME cost escalation). The sentences in the last column are paraphrased and combined by the interviewers, not verbatim.

Table 1: Thematic Summary

Theme	**Distinct sub-issues raised in the narrative**	**Illustrative characterization (paraphrased from findings, not verbatim)**
Financial dysfunction	6 (delayed payments; insufficient mobilization funds; IPC processing delays; "no pay, no work" stoppages; SUKUK financing offset by inflation/accumulated delay; BEME revision cost escalation)	Respondents linked payment delay directly to work stoppages, describing a "no pay, no work" posture by the contractor during funding gaps. All 11 interviewers confirmed.
Technical/design inadequacy	6 (cost-driven original design; FMW directive for full dual-carriageway reconstruction; design creep/redesign; groundwater-induced settlement near Bichi; inadequate EIA; extended remedial works)	Respondents attributed the redesign disruption to a late directive requiring full reconstruction of both carriageways, including sub-base replacement, rather than the originally scoped partial rehabilitation. Confirmed by the 7 interviewers.
Environmental factors	4 (rainfall; continued earthworks against advice; washouts/rework from carriageway height mismatch; unanticipated seasonal hydrology)	Respondents noted that earthworks continued through peak rainy periods despite recommendations to suspend, resulting in washouts and repeated compaction rework. Confirmed by the 5 interviewers.
Institutional/administrative factors	4 (bureaucratic/approval delays; overlapping client-consultant-contractor responsibilities; "protected works only" payment restriction; late-discovered 7 km measurement discrepancy)	Respondents described payment certification limited to "protected works" (e.g., asphalt, drainage), excluding subgrade and pavement layers, as a disincentive to continuous progress. Confirmed by the 6 interviewers.

4.2 Extent and Trajectory of Schedule Overrun

The progress report data, presented in **Table 2**, provide the clearest quantitative evidence of the project's performance failure. At every recorded time point, the percentage of project time elapsed materially exceeded the percentage of physical work completed. Critically, this disparity was not the result of a single acute disruption; it reflects a progressive, cumulative deterioration in schedule performance spanning more than 3 years of documented data.

Several features of this trajectory warrant particular attention. First, the project had already exceeded its planned duration by the time the earliest recorded data point was reached (October 2021, 104.44% time elapsed). This is not a project that started well and collapsed; it was in arrears before the observation window even opened, indicating that delays were systemic from the outset. Second, the period from January to June 2022 shows complete stagnation: physical progress did not advance by a single percentage point over five months, while time continued to accumulate. This is not a slowdown; it is a construction halt. Third, between June 2022 and March 2025, a gap of nearly three years in the

recorded data, physical progress advanced by only 5.49 percentage points (from 82.97% to 88.46%), while time elapsed increased by 48.89 percentage points. Whatever happened in this interval, the project was producing work at a rate catastrophically below what time and resources should have permitted.

Table 2: Schedule Performance Comparison (October 2021 – April 2025)

Date	Physical Completion (%)	Time Elapsed (%)	Schedule Gap (pp)
October 2021	81.70	104.44	22.74
January 2022	82.97	107.78	24.81
May 2022	82.97	112.22	29.25
June 2022	82.97	113.33	30.36
March 2025	88.46	162.22	73.76
April 2025	90.13	163.33	73.20

Note: No progress reports were available to the authors for the period June 2022 to February 2025; this gap reflects a documentation limitation in the project records accessed, not a pause in construction activity

4.3 Financial Dysfunction: The Interim Certificate as Evidence

Analysis of IPC No. 113809 reveals the financial structure underlying this schedule failure. The certificate demonstrates that the contractor's effective working capital was substantially constrained by three compounding mechanisms: (i) gross valuation falling below actual work value due to 'protected works only' certification policies; (ii) retention deductions reducing the certified amount; and (iii) previous payment adjustments further reducing net disbursements. These findings should be read as indicative of a documented instance rather than as a representative average across the project's full payment history, given the single-certificate limitation acknowledged in Section 3.4.

The 'protected works only' policy whereby the Ministry certified payment only for completed, weatherproof elements such as asphalt and drainage, while excluding subgrade and pavement layers awaiting further work, is particularly consequential. This policy creates a perverse incentive structure: contractors must invest in early-stage work without financial recognition until that work is fully enclosed by later-stage activities. In a road project where earthworks and subgrade preparation precede and enable all subsequent paving operations, this policy effectively means the contractor must finance weeks or months of high-intensity activity before receiving any payment.

The cumulative effect of these mechanisms is a structural cash flow deficit that, in the interview data, was directly linked to the 'no pay, no work' operational posture adopted by CCECC during periods of payment delay. This posture is rational from the contractor's perspective but catastrophic for project continuity. It transforms temporary financial disruption into an extended construction suspension, exactly the pattern observed during the 2022 stagnation period.

4.4 The Redesign Disruption: A Ministerially-Generated Delay

The original contract scope included the rehabilitation of the existing carriageway and the construction of a new one. A subsequent directive from the Federal Ministry of Works required full reconstruction of both carriageways, including complete replacement of the sub-base. This change was not a contractor decision; it was imposed by the client mid-execution.

The consequences were threefold: a revised Bill of Engineering Measurement and Evaluation (R-BEME) was required, increasing the contract sum by ₦10 billion; redesigned work disrupted the established construction programme; and scope creep created ambiguity about what was included in existing valuations. The residual increase from ₦24 billion to approximately ₦68 billion, beyond the ₦10 billion attributable to the R-BEME redesign, is described in project correspondence as arising from cumulative inflationary adjustments; however, an itemized breakdown of this escalation was not available within the documentary record accessed for this study, and this is acknowledged as a limitation of the financial analysis presented. What is absent from the documentary record is any evidence that the time implications of this redesign were formally incorporated into an extended contract programme. The contractor absorbed the schedule impact without contractual relief due to contract administration failures that directly contributed to the growing schedule gap.

4.5 Geotechnical Failure and the Cost of Inadequate Pre-Construction Assessment

Interview data identified geotechnical instability along approximately one kilometer of roadway traversing Bichi town, where rising groundwater caused surface settlement. This problem was attributed to inadequate Environmental Impact Assessment at the planning stage and the inadvertent removal of natural geological barriers during initial earthworks.

The remediation of this failed excavation, the installation of a drainage layer, and recompaction consumed time and resources without advancing the recorded percentage completion in the progress report. It represents a category of 'invisible work': labour and materials expended on rectifying avoidable problems rather than constructing new infrastructure. The absence of a thorough pre-construction geotechnical investigation is a planning failure with compounding consequences. It not only caused direct delays but also imposed costs that reduced the contractor's already-constrained working capital.

4.6 The Seven-Kilometer Measurement Error

A further factor reportedly identified by interviewees, though not independently verifiable from the documentary record available to this study, concerns an approximately seven-kilometre discrepancy in the project's defined scope. In the absence of full supporting documentation, this is treated here as a tentative, anecdotal observation warranting future documentary confirmation, rather than as an established causal factor. While the full documentation of this discrepancy was not available for analysis, its existence raises serious questions about the adequacy of the original site investigation and contract documentation. A 9.5% error in the fundamental physical parameter of a road contract is not a minor administrative oversight; it represents a failure at the earliest stage of project definition that propagated uncertainty in cost and schedule throughout execution.

4.7 Synthesis: Financial Dysfunction as Systemic Amplifier

The four causal factors identified: financial dysfunction, ministerially-imposed redesign, geotechnical inadequacy, and measurement error, are not independent (see **Table 3**). They interact through a common mechanism: financial constraint. Technical problems require financial resources to remedy. Redesign disruptions generate contractor claims that must be financially resolved. Measurement errors create cost uncertainty, delaying financial settlement. In each case, the financial system's inability to process and pay claims in a timely manner transforms a solvable technical problem into an extended delay.

This is the central analytical contribution of this study: financial dysfunction is not merely one causal factor among several. It is the transmission mechanism through which all other delay factors propagate into extended schedule overrun. A project with robust, timely payment systems would still face technical challenges, but those challenges would be remedied within weeks rather than allowed to fester into months of construction suspension.

Table 3: Causal Factor Assessment and Financial Interaction

Causal Category	Specific Factor	Assessed Impact	Interaction with Finance
Financial	Delayed IPC payment; reduced net payable; protected works policy	Critical	Primary driver; directly halts site operations
Technical / Design	Ministerially-directed full reconstruction; scope creep; R-BEME preparation	High	Generates unresolved claims; delays financial settlement
Geotechnical	Groundwater-induced settlement at Bichi; inadequate EIA	High	Remediation costs exhaust constrained working capital
Institutional	Measurement error (7 km discrepancy); bureaucratic approval delays	Moderate–High	Creates cost uncertainty; delays certificate processing
Environmental	Seasonal rainfall; washout and rework on the initial carriageway	Moderate	Exacerbates delays when financial resources to remediate are absent

5. CONCLUSIONS AND RECOMMENDATIONS

5.1 Conclusions

This study has demonstrated, through a triangulated analysis of interviews, progress documentation, and financial records, that the Kano–Katsina Road Dualization Project experienced a schedule overrun of approximately 73.20 percentage points relative to its planned completion trajectory as at April 2025 (163.33% planned physical progress against 90.13% actual physical progress; see Table 1), underscoring the scale of delay accumulated over the review period. It is a failure that was neither sudden nor confined to a single causal source, but progressive, systemic, and rooted fundamentally in financial dysfunction.

The study advances three principal conclusions. First, delayed and structurally reduced interim payments are the primary causal driver of schedule overrun on this project, operating both directly (through construction suspension) and indirectly (by reducing the contractor's capacity to respond to technical challenges). Second, a mid-construction redesign imposed by the client without corresponding contractual time relief is a distinct and significant source of delay that existing literature has underexamined in the Nigerian federal infrastructure context. Third, inadequate pre-construction investigation (geotechnical, environmental, and physical) created avoidable problems that consumed resources, inflated costs, and extended the project duration.

5.2 Recommendations

The following recommendations are advanced based on these conclusions:

- Payment Mechanism Reform: The Federal Government should institute mandatory payment timelines for interim certificates on infrastructure contracts, with automatic interest accrual on delayed payments. The 'protected works only' certification policy should be reviewed to ensure that subgrade and pavement layer works are certifiable in proportion to their completion, rather than only upon enclosure by subsequent works.
- Pre-Construction Investigation Standards: Mandatory geotechnical and hydrological surveys should be completed and independently reviewed prior to contract award. Environmental Impact Assessments should be conducted to a standard sufficient to identify seasonal groundwater behaviour, not merely surface conditions.
- Contractual Provisions for Client-Directed Scope Changes: Standard government road contracts should include explicit clauses requiring that ministerially-directed scope changes be accompanied within 30 days by a formal variation order specifying additional cost and time allowances. Scope changes unaccompanied by such orders should be subject to suspension by the contractor.

- Physical Quantity Verification: Independent physical surveys verifying project length and scope should be completed and documented before contract execution. The seven-kilometer measurement discrepancy identified in this project would have been avoidable through basic pre-award verification.
- Progress Monitoring Reform: Progress reports should be submitted monthly and should include earned value metrics (not merely percentage completion vs. time elapsed) to enable early identification of emerging schedule deviations.

5.3 Contribution to Knowledge

This study contributes to construction delay literature in three ways. It provides empirical evidence linking financial disbursement structure, as revealed by interim certificate analysis, directly to physical progress outcomes on a major Nigerian road project. It advances a hierarchical causal model that positions financial dysfunction as the systemic amplifier of other delay factors, rather than one equivalent variable among many. It provides a documented analysis of a large-scale Northern Nigerian Road dualization project, a category that is underrepresented in existing delay research.

Financial disbursement dysfunction does not act as an independent delay factor but as an amplifier that increases the schedule impact of co-occurring technical and environmental delay factors (refer to **Fig. 1**). The magnitude of schedule overrun on a project is better explained by the interaction between financial dysfunction and technical/environmental factors than by any single factor category in isolation. Contrary to Amarkhil et al. (2023) taxonomy, they categorize delay factors as a flat, non-hierarchical list grouped by source (e.g., client-related, contractor-related, external), the hierarchical causal model proposed here explicitly nests categorical delay factors beneath a systemic financial driver, offering a mechanism (amplification) rather than only a classification, and is thus positioned as complementary to, rather than a replacement for, existing taxonomies.

ABSTRACT

In the quest to decarbonize, decentralize, and digitalize the global energy systems, the conventional electricity consumers are becoming prosumers. This transition has challenged the traditional centralized utility model and demanded a direct, local energy exchange mechanism. Existing literature has neglected the influence of network security constraints on Peer-to-Peer (P2P) energy transactions. This paper therefore introduces a decentralized market framework designed to facilitate localized energy trading within physical grid constraints. An interior-point optimization algorithm balances economic welfare and network stability in the proposed framework. P2P outperforms a holistic benchmark against traditional centralized economic dispatch (CED) based on the IEEE 14-bus test system. The results show a net welfare gain of 375.54 m.u./h under the P2P framework; local generation of 57.83 MW compared to 57.97 MW under CED, achieves a lower operational cost ($1125.10\ m.u./h$*) and higher total consumer utility (*$2783.44\ m.u./h$*) under the proposed P2P market, while nodal voltage profiles remained within the secure operating limit of 1.0206 p.u. Further rigorous testing across different Distributed Energy Resources penetration scenarios shows that the model is stress-resistant for grids. This will provide a scalable and robust solution for modern distribution network operators, where decentralized market clearing discovers previously unavailable network capacity without compromising the network's physical operating limits.*

1. INTRODUCTION

Modern electrical distribution networks are rapidly evolving with the integration of small-scale renewables like rooftop solar and local energy storage. This shift has transformed traditional consumers into prosumers who consume and produce electricity, challenging the centralized utility model and creating new operational complexities, such as undervalued local generation and bidirectional power flows (Zheng et al., 2022). Peer-to-peer (P2P) energy trading offers a promising alternative, enabling prosumers and consumers to exchange energy locally without relying solely on utility intermediaries. This approach can enhance community self-sufficiency, reduce transmission losses, and optimize grid asset usage. P2P markets are typically structured across four layers (Aitzhan & Svetinovic, 2018; Dang et al., 2019; Lüth et al., 2018; Ping et al., 2026; Wu et al., 2023; Yan et al., 2023): business (market rules and financial flows), control (grid operations and transactive control), information and communication (secure data exchange and smart metering), and the physical network (infrastructure and reliability) (Ali et al., 2021; Nasiri, 2023; Soto et al., 2021; Zhang et al., 2018). All these layers must coordinate securely and interoperate seamlessly. To preserve overall grid integrity, any proposed energy transaction must be evaluated and either approved or denied based on strict network technical constraints (Nasiri, 2023).

The literature survey has shown that existing research in P2P spans these market layers, with each layer specifically focused on one of the layers within the energy trading framework. (Kang et al., 2017) proposed a secure, decentralized P2P electricity trading system among Plug-in Hybrid Electric Vehicles (PHEVs) using consortium blockchain technology to enhance security and privacy. The system aimed to maximize social welfare by optimizing electricity prices and the amount traded;

however, the system relies on local aggregators (LAGs) to act as energy brokers, run the consensus process, and maintain the blockchain. While this reduces the load on individual PHEVs, it introduces a semi-centralized element. If LAGs are compromised or malfunction, the system's security and reliability could be affected. The paper mentions mechanisms for accountability, but the risk remains.

A framework for prosumer participation in peer-to-peer (P2P) energy trading and flexibility markets was presented in (Khorasany et al., 2022), aiming to enhance grid stability and reduce costs. The flexibility market is cleared through an iterative auction, in which the distribution system operator adjusts the flexibility price to minimize costs, while prosumers independently decide how much flexibility to offer. A graph-based framework for allocating losses in unbalanced radial distribution networks within transactive energy markets was developed in (Nikolaidis et al., 2018), considering physical topology and financial transactions. The sensitivity analysis in the paper reveals that as DG penetration increases, neutral losses also increase. While DG can reduce total phase losses, the increased use of the neutral conductor can counteract these benefits. This introduces a trade-off that is not always straightforward to manage, especially as the impact of DG on neutral losses may not be fully captured in simpler allocation methods.

In (Hoque et al., 2024), a framework for prosumer-centric peer-to-peer energy trading was proposed. A double auction-based P2P trading mechanism was employed, allowing prosumers to submit offers within their dynamic operating envelope limits. In (Morstyn et al., 2018), a Federated Power Plant (FPP) was proposed as a new model that combines the benefits of virtual power plants and P2P energy trading platforms. The FPP is a VPP formed through P2P transactions between self-organizing prosumers. The paper aims to solve the problem of incentivizing coordination among large numbers of DERs owned by different prosumers, each with unique characteristics and preferences. The paper acknowledges that while the FPP concept is promising, several technical and operational challenges remain. For example, it is unclear to what extent a P2P energy trading market can achieve optimal economic benefits for a DER portfolio, or how to ensure that bilateral energy transactions do not breach the physical constraints of local distribution networks.

The application of blockchain technology for managing energy transactions and technical operations in microgrids was proposed in (Di Silvestre et al., 2018). The authors emphasize real-time attribution of power losses to specific transactions and address the complexity introduced by reactive power flows. The blockchain approach was integrated with power flow analysis to improve technical management of microgrids. In (Tong et al., 2026), a non-convex peer-to-peer (P2P) energy trading model for prosumer-based distribution networks was proposed, explicitly accounting for the binary (on/off) operating states of distributed energy resources (DERs), such as gas turbines and energy storage systems. A prosumer-centric internal uncertainty-balancing mechanism using stochastic programming was introduced, allowing each prosumer to absorb uncertainty in renewable generation locally and deliver deterministic net power injections to the network. While the two-stage distributed framework improves convergence and scalability compared to traditional methods, the approach still involves significant computational tasks, especially in large-scale systems with many prosumers and DERs.

Existing literature has focused on business and market layers, with extensive research on market design and loss allocation mechanisms. However, these economic frameworks frequently overlook the physical operational limits of the power network, leading to dispatch strategies that may prove operationally infeasible in practice. This paper introduces a security-constrained P2P market framework that integrates AC power flow into the market clearing process. By integrating physical network constraints directly into the optimization, the proposed approach ensures that all local energy trades are both economically efficient and physically viable. Comparative analysis with traditional centralized dispatch demonstrates that this framework can unlock new network capacity, improve welfare, and maintain grid stability under diverse operating scenarios.

2. METHODOLOGY

This section outlines the integrated framework that bridges the business layer (market clearing) and the physical layer (grid security). The proposed SC-P2P framework models the distribution network as a balanced, single-phase equivalent AC system. The methodology is structured to maximize community social welfare by matching localized generation and demand (Dong et al., 2025). Unlike traditional economic models that focus on economic dispatch without considering consumer benefit,

this framework explicitly couples the economic objective function to nonlinear AC power-flow equations, nodal voltage boundaries, and line thermal limits (Tarashandeh & Karimi, 2024) to maximize participants' welfare. The resulting non-linear, non-convex optimization problem is solved using an Interior Point Method (IPM), ensuring that all cleared Peer-to-Peer (P2P) trades are physically viable and do not compromise the operational stability of the distribution network.

2.1. Participant characteristics

Let $N = \{1,2, \dots, N\}$ represent the set of all participants (nodes) connected to the local distribution network. At any dispatch interval t, a peer $i \in N$ is characterized by its net power profile, determined by its local load and generation (Hoque et al., 2024; Zhang et al., 2018):

$$P_i^{net}(t) = P_i^{load}(t) - P_i^{gen}(t) \tag{1}$$

Based on this profile, the participant's role is defined as follows:

Buyer: if $P_i^{net}(t) > 0$, peer i has a power deficit and demands $P_i^d(t) = P_i^{net}(t)$.

Seller (prosumer): $P_i^{net}(t) < 0$, peer i has surplus generation to sell, denoted by $P_i^s(t) = P_i^{net}(t)$.

2.2. Market Objective Formulation

The fundamental objective of the local P2P market coordinator is to maximize the total social welfare (W). Welfare is defined as the net difference between the total utility gained by consumers and the total operational cost incurred by producers during the interval t (Kang et al., 2017; Khorasany et al., 2022):

$$\max_{P_{i,j}^{trade}} W = \sum_{i \in N_{buyer}} U_i(P_i^d) - \sum_{j \in N_{seller}} C_j(P_j^s) \tag{2}$$

where

$U_i()$ is the economic benefit function of the consumer i, $C_j()$ is the cost function of generation for the prosumer j and $P_{i,j}^{trade}$ denotes the matched energy quantity cleared between peers i and j.

The economic benefit derived by a consumer i consuming power P_i^{d} (in MW) is modeled using a concave quadratic utility function:

$$U_i\left(P_i^{\mathrm{d}}\right) = \alpha_i P_i^{\mathrm{d}} - \beta_i \left(P_i^{\mathrm{d}}\right)^2 \tag{3}$$

where $\alpha_i > 0$ denotes the consumer's baseline willingness-to-pay and $\beta_i > 0$ represents the marginal utility decline parameter.

The operational cost incurred by a prosumer j producing active power P_j^{s} (in MW) is modeled using a standard convex quadratic function:

$$C_j\left(P_j^{\mathrm{s}}\right) = a_j \left(P_j^{\mathrm{s}}\right)^2 + b_j P_j^{\mathrm{s}} + c_j \tag{4}$$

where $a_j > 0$, $b_j \geq 0$, and $c_j \geq 0$ represent the cost coefficients reflecting fuel, degradation, and operational expenses of localized DERs.

Before market clearing, participant net injections are calculated as $P_i^{\mathrm{net}} = P_i^{\mathrm{load}} - P_i^{\mathrm{gen}}$. Participants with $P_i^{\mathrm{net}} > 0$ bid into the market as buyers demanding $P_i^{\mathrm{d}} = P_i^{\mathrm{net}}$, while those with $P_i^{\mathrm{net}} < 0$ offer surplus capacity as sellers with $P_j^{\mathrm{s}} = |P_i^{\mathrm{net}}|$.

Table 1: Economic Utility and Generation Cost Parameters

Participant	Role	Utility / Cost Function Coefficients	Parameter Values
Bus 2	Seller	$C_2(P_2^s) = a_2(P_2^s)^2 + b_2P_2^s + c_2$	$a_2 = 0.035$ m.u./MW^{2}h, $b_2 = 20.0$ m.u./MWh, $c_2 = 0.0$
Bus 5	Seller	$C_5(P_5^s) = a_5(P_5^s)^2 + b_5P_5^s + c_5$	$a_5 = 0.025$ m.u./MW^{2}h, $b_5 = 18.0$ m.u./MWh, $c_5 = 0.0$
Bus 6	Seller	$C_6(P_6^s) = a_6(P_6^s)^2 + b_6P_6^s + c_6$	$a_6 = 0.015$ m.u./MW^{2}h, $b_6 = 15.0$ m.u./MWh, $c_6 = 0.0$
Bus 8	Seller	$C_8(P_8^s) = a_8(P_8^s)^2 + b_8P_8^s + c_8$	$a_8 = 0.040$ m.u./MW^{2}h, $b_8 = 25.0$ m.u./MWh, $c_8 = 0.0$
Bus 3	Buyer	$U_3(P_3^d) = \alpha_3P_3^d - \beta_3(P_3^d)^2$	$\alpha_3 = 60.0$ m.u./MWh, $\beta_3 = 0.50$ m.u./MW^{2}h
Bus 9	Buyer	$U_9(P_9^d) = \alpha_9P_9^d - \beta_9(P_9^d)^2$	$\alpha_9 = 55.0$ m.u./MWh, $\beta_9 = 0.45$ m.u./MW^{2}h
Bus 10	Buyer	$U_{10}(P_{10}^d) = \alpha_{10}P_{10}^d - \beta_{10}(P_{10}^d)^2$	$\alpha_{10} = 58.0$ m.u./MWh, $\beta_{10} = 0.55$ m.u./MW^{2}h
Bus 11	Buyer	$U_{11}(P_{11}^d) = \alpha_{11}P_{11}^d - \beta_{11}(P_{11}^d)^2$	$\alpha_{11} = 62.0$ m.u./MWh, $\beta_{11} = 0.60$ m.u./MW^{2}h
Bus 14	Buyer	$U_{14}(P_{14}^d) = \alpha_{14}P_{14}^d - \beta_{14}(P_{14}^d)^2$	$\alpha_{14} = 50.0$ m.u./MWh, $\beta_{14} = 0.40$ m.u./MW^{2}h

2.3. Network Constraints

To guarantee that the market-cleared transactions are secure and physically executable, the optimization is heavily constrained by the physical layer (Dong et al., 2025; Nasiri, 2023; Zimmerman et al., 2010).

2.3.1. *AC Power Flow Constraints*

The active and reactive power injections at each bus i must satisfy the non-linear AC power balance equations:

$$P_i^{inj} = V_i \sum_{k \in N} V_k \left(G_{ik}cos\theta_{ik} + B_{ik}sin\theta_{ik}\right) \quad (5)$$

$$Q_i^{inj} = V_i \sum_{k \in N} V_k \left(G_{ik}sin\theta_{ik} - B_{ik}cos\theta_{ik}\right) \quad (6)$$

where V_i and V_k are the voltage magnitudes at buses i and k, θ_{ik} is the voltage angle difference, and G_{ik} and B_{ik} represent the conductance and susceptance elements of the bus admittance matrix (Y_{bus}).

2.3.2. *Inequality constraints*

To prevent voltage collapse and equipment damage, strict operational boundaries are enforced:

$$V_{min} \leq V_i(t) \leq V_{max} \quad \forall i \in N \tag{7}$$

$$|S_{ik}(t)| \leq S_{ik}^{max} \quad \forall (i,k) \in L \tag{8}$$

where V_{min} and V_{max} are the nodal voltage limits (0.95 p.u. to 1.05 p.u.), $S_{ik}(t)$ is the apparent power flowing through the line connecting the buses $i\ and\ k$, and S_{ik}^{max} is the maximum thermal capacity of branch L.

2.3.3. *The Interior Point Method*

AC power-flow constraints are highly nonlinear and nonconvex; standard linear-matching algorithms are inadequate. To solve this complex constrained optimization problem, we employ the Interior Point Method (IPM). The IPM is particularly powerful for large-scale Non-Linear Programming (NLP) because it avoids the combinatorial complexity of active-set methods. It handles inequality constraints by converting them into equality constraints with slack variables, then penalizing the slack variables in the objective function via a logarithmic barrier. As the algorithm iterates, a barrier parameter (μ) is gradually reduced toward zero, forcing the solution to converge to the optimal feasible point strictly from within the feasible region (Tarashandeh & Karimi, 2024; Zimmerman et al., 2010).

To apply the IPM, the original welfare maximization problem is rewritten in the standard NLP minimization form:

$$\min_x f(x) = -W \tag{9}$$

Subject to the equality constraints $g(x) = 0$ (the AC power balance equations) and inequality constraints $h(x) \leq 0$ (the voltage and thermal limits), where x represents the vector of state variables (voltages, angles, and power injections).

The IPM transforms the inequality constraints into equality constraints by introducing a vector of strictly positive slack variables s:

$$h(x) + s = 0, \quad s > 0 \tag{10}$$

The objective function is then augmented with a logarithmic barrier term to prevent the slack variables from reaching zero prematurely:

$$\min_{x,s} \left(f(x) - \mu \sum_{m=1}^{M} \ln(s_m) \right) \tag{11}$$

where: $\mu > 0$ is the barrier parameter, M is the total number of inequality constraints, s_m represents the m-th slack variable.

The Lagrangian of this barrier problem is formulated as:

$$\mathcal{L}_\mu(x, s, \lambda, \gamma) = f(x) - \mu \sum_{m=1}^{M} \ln(s_m) + \lambda^T g(x) + \gamma^T (h(x) + s) \tag{12}$$

where x represents the decision variables of the grid ($P_{gen}, Q_{gen}, V, \theta$), $f(x)$ is the objective function, representing the negative of the social welfare function ($-W$), s is the slack variable, representing the distance a specific bus or line is from the limit, λ and γ are the Lagrange multipliers associated with equality and transformed inequality constraints, respectively. Figure 1 summarises the methodology framework.

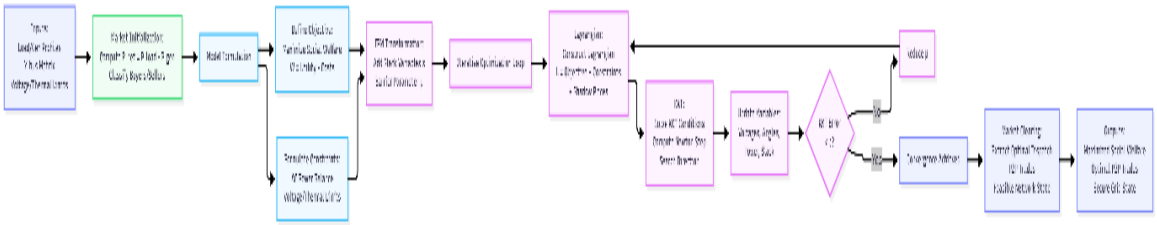

Figure 1: Methodology Framework

3. RESULTS AND DISCUSSION

We evaluate the performance of the proposed security-constrained P2P market framework on a modified IEEE 14-bus test system. The network consists of 14 buses, 20 transmission/distribution branches, 5 generating units (prosumers with dispatchable DERs), and 11 load centers.

Table 2: System Parameters

Parameter	Value / Range	Unit
System Base Power (S_{base})	100	MVA
Voltage Boundaries ($V_{\min} - V_{\max}$)	$0.95 - 1.05$	p.u.
Number of Buses (N)	14	Nodes
Number of Branches (L)	20	Lines/Transformers
Active Generators / DERs	Buses 1, 2, 3, 6, & 8	Units
Line Limits ($S_{ik}^{\max}$)	$10 - 50$	MVA

The optimization is modelled in MATLAB using the MATPOWER environment modified for non-convex P2P market formulations. The interior-point optimization solver (MIPS) handles the nonlinear AC power-flow balance equations and inequality constraints. Convergence is set to $\epsilon = 10^{-6}$ for KKT optimality conditions. Per-unit (p.u.) state variables are explicitly scaled by a base MVA of 100 during optimization and converted back to real-power units (MW) for welfare and dispatch evaluation. To evaluate performance, the proposed P2P framework is benchmarked directly against a standard Centralized Economic Dispatch (CED) model. CED optimizes generation to meet aggregate system demand through a single utility entity. In contrast, the P2P mechanism clears bilateral localized trades while respecting non-linear AC power flows and thermal branch limits.

The net active power balance determines participant selection ($P_i^{\text{net}} = P_i^{\text{load}} - P_i^{\text{gen}}$) at each node i during a given dispatch interval. Seller (Prosumer) Buses are selected when local generation exceeds local demand ($P_i^{\text{net}} < 0$). In the modified IEEE 14-bus distribution system, these correspond to nodes equipped with surplus dispatchable DER capacity, specifically Buses 2, 5, 6, and 8. Buyer Buses are selected when local load demand exceeds local generation ($P_i^{\text{net}} > 0$), these correspond to net load centers across the network, specifically Buses 3, 9, 10, 11, and 14. Slack and Passive/Transit Buses**:** Bus 1 serves as the main utility grid inertia (slack bus) to balance residual power exchange, while the remaining nodes (Buses 4, 7, 12, and 13) act as passive transit buses ($P_i^{\text{net}} = 0$) participating exclusively in AC power-flow routing rather than active P2P bidding.

3.1. Baseline Market Clearing and Network Security

Under base case operating conditions, the P2P market coordinator successfully matched local demand and generation across the 14-bus test system while enforcing nonlinear AC power-flow equations and operational limits. From Table 3, the base case P2P market achieved exact contractual clearing between local participants, with total cleared seller generation (57.00 MW) perfectly

matching total buyer demand (57.00 MW). The slack bus (Bus 1) injected an additional 0.83 MW into the network, serving exclusively as loss-compensation power to cover active transmission line losses (P_{loss}) across the feeder branches without forcing prosumers to bear unallocated physical grid losses.

Table 3: Base case P2P Market Dispatch

Bus Index	Participant Role	Max Capacity (MW)	Cleared Power (MW)	Market Status
Bus 2	Seller	15.00	15.00	Fully Cleared
Bus 3	Buyer	12.00	12.00	100% Demand Met
Bus 5	Seller	20.00	16.84	Partially Cleared
Bus 6	Seller	25.00	25.00	Fully Cleared
Bus 8	Seller	15.00	0.16	Marginal Reserve
Bus 9	Buyer	15.00	15.00	100% Demand Met
Bus 10	Buyer	10.00	10.00	100% Demand Met
Bus 11	Buyer	8.00	8.00	100% Demand Met
Bus 14	Buyer	12.00	12.00	100% Demand Met

Total Slack Grid Power Exchange: 0.83 MW

From Table 3, all buyer demands (Buses 3, 9, 10, 11, and 14) were fully satisfied, totaling 57.00 MW of cleared consumption. Sellers at Buses 2 and 6 operated at full capacity (15.00 MW and 25.00 MW respectively), while Bus 5 cleared 16.84 MW and Bus 8 served as the marginal unit clearing 0.16 MW. Figure 2 illustrates the nodal voltage profile under baseline P2P market clearing. The voltage remains strictly within statutory bounds ($0.95 - 1.05$ p.u.), peaking at Bus 9 with $V_9 = 1.0361$ p.u.

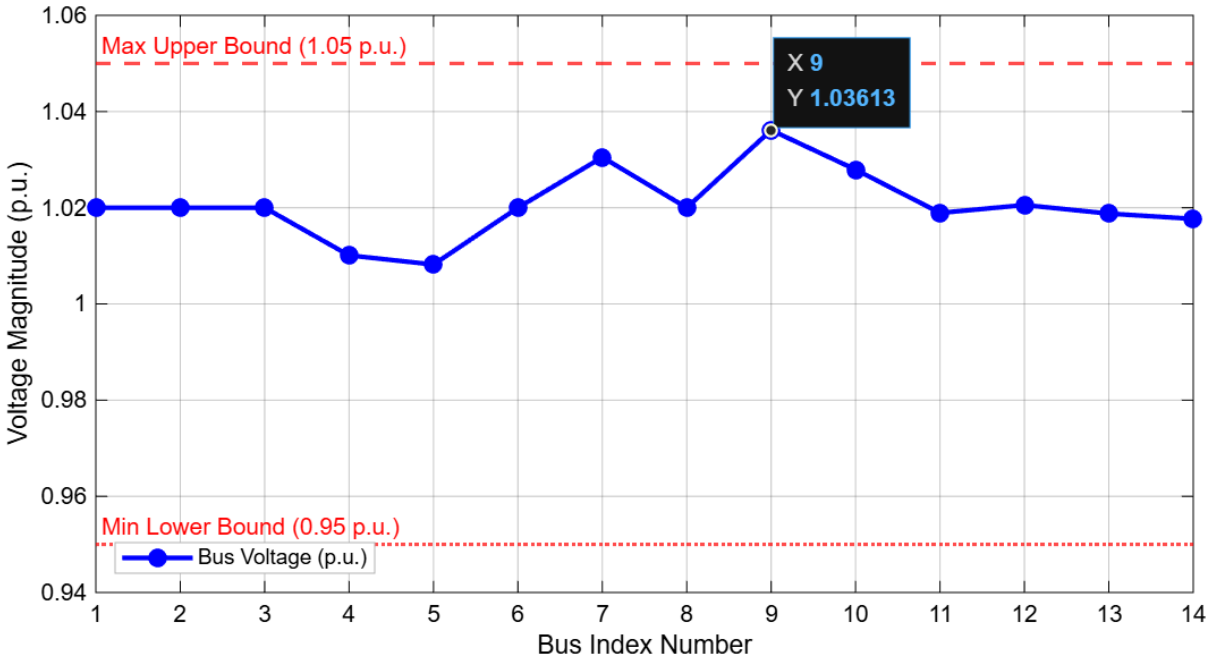

Figure 2: *Voltage profile under optimal P2P dispatches for base case scenario*

3.2. Comparative Economic and Operational Benchmarking: P2P vs. CED

To quantify performance gains, the proposed framework was benchmarked against traditional centralized economic dispatch.

Table 4: Economic and Operational Benchmarking Metrics

Performance Metric	**Centralized Economic Dispatch (CED)**	**Security-Constrained P2P Market**	**Operational Differential**
Total Operating Cost (C) (m.u./h)	1282.80	1125.10	-157.70 (Lower Cost)
Total Consumer Utility (U) (m.u./h)	2565.60	2783.44	217.84 (Higher Utility)
Net Social Welfare ($W = U - C$) (m.u./h)	1282.80	1658.34	375.54 **(**Welfare Improvement)
Total Power Generation ()	57.97	57.83	-0.14 (Loss Reduction)
Average Nodal Voltage (p.u.)	1.0430	1.0206	-0.0224 p.u.

From Table 4, the P2P market structure achieves a lower operational cost and higher total consumer utility (U) achieved under the proposed P2P market (2783.44 m.u./h) compared to CED (2565.60 m.u./h). The P2P market framework achieved a net social welfare of 1658.34 m.u./h, while CED achieved 1282.80 m.u./h, resulting in a net economic welfare improvement of 375.54 m.u./h in addition to loss reduction. Under Centralized Economic Dispatch (CED), consumer demand is inelastic, giving a base-case total utility $U = 2565.60$ m.u./h. The resulting minimum operating cost $C = 1282.80$ m.u./h yields $W = U - C = 1282.80$ m.u./h. The numerical identity $W = C$ shows that C is equal to $0.5 \times U$ at the fixed CED dispatch point. The P2P market reduces system losses by matching buyers with nearby prosumer generation, requiring 0.14 MW less slack grid compensation than centralized dispatch. Total required generation dropped from 57.97 MW under CED to 57.83 MW under P2P, reducing 0.14 MW loss compensation from the slack Bus. The voltage regulation is improved, as CED tends to push generator node voltages higher to force power across long feeder lines, leading to an elevated average nodal voltage of 1.0430 p.u. P2P decentralized clearing maintains a flatter, less stressed voltage profile averaging 1.0206 p.u. preserving distribution equipment health. This demonstrates superior demand-side value realization. While traditional CED exclusively minimizes generator production costs ($\min C$) under passive load constraints, the P2P market-clearing algorithm maximizes net social welfare ($\max W = U - C$). Higher consumer utility (U) in the P2P market indicates that consumers derive greater economic value, satisfaction, and demand fulfillment from their energy consumption compared to traditional Centralized Economic Dispatch (CED).

3.3. Dynamic Operational Stress Scenarios

To verify framework robustness, three severe grid stress scenarios were evaluated: Bus 6 Generation Outage Contingency, High Solar DER Penetration Scenario, and Peak (150%) vs. Off-Peak (50%) Demand Variations.

Table 5: Contingency (Gen outage at Bus 6) P2P Market Dispatch

BUS	ROLE	MAX Capacity (MW)	Cleared (MW)
2	Seller	15.00	15.00
3	Buyer	12.00	12.00
5	Seller	20.00	20.00
6	Seller	0.00	0.00
8	Seller	15.00	15.00
9	Buyer	15.00	15.00
10	Buyer	10.00	10.00
11	Buyer	8.00	1.00
14	Buyer	12.00	12.00

An unexpected loss of the primary supplier at Bus 6 (25.00 MW → 0.00 MW) was simulated. Table 5 shows that the algorithm automatically re-cleared the market by ramping up Seller 5 from 16.84 MW (base case) to its maximum capacity of 20.00 MW and ramping up Seller 8 from 0.16 MWto 15.00 MW. Due to localized line thermal capacity bottlenecks following the outage, Buyer 11 demand was partially curtailed from 8.0 MW to 1.0 MW to prevent line overloading. Figure 3 shows the voltage profile under N-1 contingency, where Bus 9 voltage reached a maximum of 1.04167 p.u., proving that the framework successfully maintains voltage stability under major supply contingencies without exceeding the 1.05 p.u. limit.

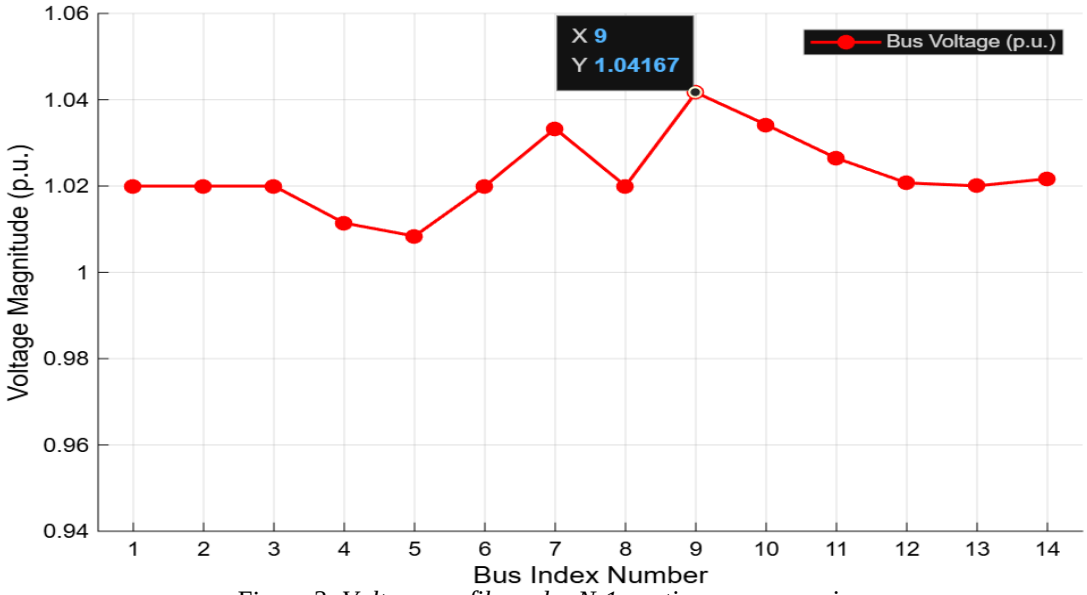

Figure 3: *Voltage profile under N-1 contingency scenario*

Under high solar DER availability, generation capacity shifts across the network. From Table 6, Seller 8 cleared its maximum capacity of 15.00 MW, allowing Seller 6 to back off generation to 7.00 MW while Seller 5 cleared 20.00 MW. All buyers' demand across all nodes was cleared while maintaining a stable voltage profile peaking at 1.04027 p.u. at Bus 9 as shown in Figure 4.

Table 6: P2P Market Dispatch under High Solar DER penetration

Bus Index	Participant Role	Max Capacity (MW)	Cleared Power (MW)
Bus 2	Seller	15.00	15.00
Bus 3	Buyer	12.00	12.00
Bus 5	Seller	20.00	20.00
Bus 6	Seller	25.00	7.00
Bus 8	Seller	15.00	15.00
Bus 9	Buyer	15.00	15.00
Bus 10	Buyer	10.00	10.00
Bus 11	Buyer	8.00	8.00
Bus 14	Buyer	12.00	12.00

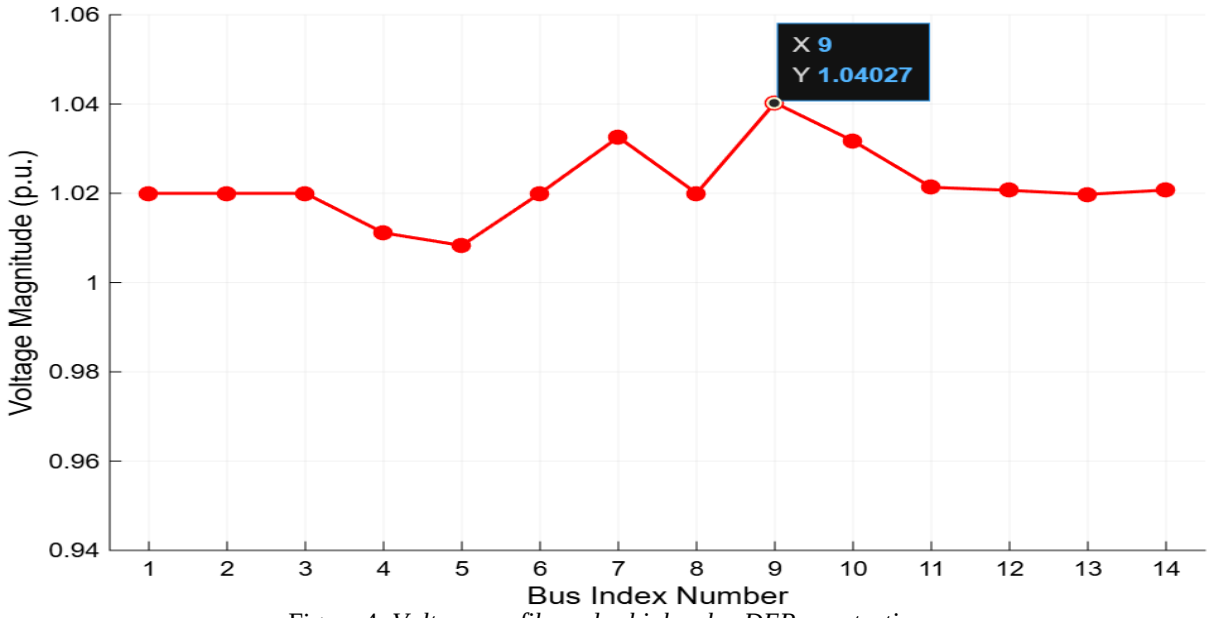

Figure 4: *Voltage profile under high solar DER penetration*

System performance was evaluated across contrasting loading conditions. At 50% demand, local generation demands are low. It can be seen from Table 7 that high-cost Seller 8 remained offline (0.00 MW), and Seller 5 ramped down to 0.40 MW. Reduced power flows resulted in higher overall line voltages, peaking at 1.03938 at Bus 9 and 1.02054 p.u. at Bus 14 as seen in Figure 5. At 150% demand, all local generators (Sellers 2, 5, 6, and 8) reached their capacity limits (75.00 MW total generation). Heavy power flow caused increased line drops, lowering Bus 14 voltage to 1.00265 p.u. as seen in Figure 5. To prevent thermal overload on feeder branches, Buyer 11 was curtailed to 1.50 MW (out of 12.00 MW demanded), demonstrating that the algorithm prioritizes physical line limits over unconstrained market clearing. Under the 150% peak load scenario, total cleared prosumer generation reaches its aggregate capacity limit of 75.00 MW (15.00 + 20.00 + 25.00 + 15.00 MW). Summing the cleared buyer allocations, Bus 3 (18.00 MW), Bus 9 (22.50 MW), Bus 10 (15.00 MW), Bus 11 (1.50 MW post-curtailment), and Bus 14 (18.00 MW) yields exactly 75.00 MW, confirming power balance consistency across the market.

Table 7: P2P Market Dispatch under off-peak, base case and peak scenarios

Participant Index	Off-Peak (50% Load) Cleared (MW)	Baseline (100% Load) Cleared (MW)	Peak (150% Load) Cleared (MW)
Seller 2	15.00	15.00	15.00
Buyer 3	6.00	12.00	18.00
Seller 5	0.40	16.84	20.00
Seller 6	13.10	25.00	25.00
Seller 8	0.00	0.16	15.00
Buyer 9	7.50	15.00	22.50
Buyer 10	5.00	10.00	15.00
Buyer 11	4.00	8.00	1.500 (Curtailed)
Buyer 14	6.00	12.00	18.00

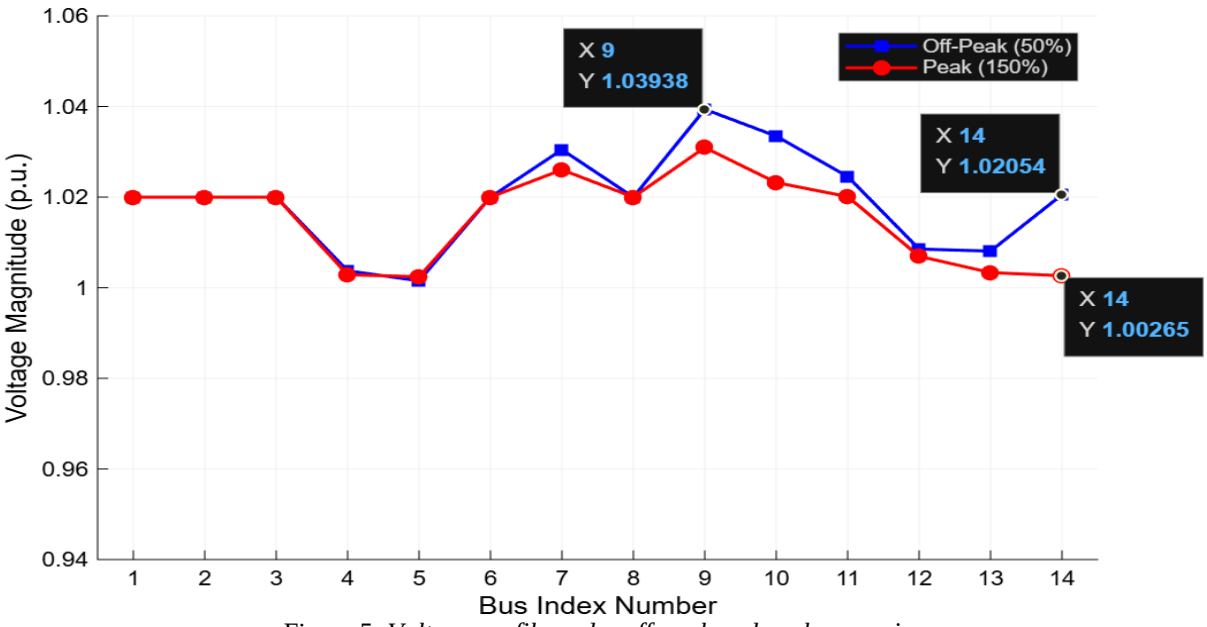

Figure 5: *Voltage profile under off-peak and peak scenarios*

3.4. IPM Solver Computational Convergence Performance

For the base-case P2P market clearing took 12 iterations to converge within 0.048 seconds, while CED involved 10 iterations to converge within 0.039 seconds. For the N-1 contingency, it took 15 iterations to converge within 0.062 seconds. For high DER penetration, it took 11 iterations to converge within 0.045 seconds. For the off-peak demand, it took 9 iterations to converge within 0.038 seconds, while for peak demand it took 18 iterations to converge within 0.076 seconds. The KKT residual ($\epsilon < 10^{-6}$) for all scenarios.

4. CONCLUSION

This paper presented a security-constrained Peer-to-Peer (P2P) energy market framework designed to bridge the gap between decentralized market clearing and physical distribution network security. By integrating non-linear AC power-flow equations, nodal-voltage boundaries, and branch thermal-capacity limits into a social-welfare maximisation objective, the proposed model ensures that all cleared bilateral trades are physically executable. The non-convex optimisation problem was solved using an Interior Point Method (IPM) with logarithmic barrier penalties, ensuring robust numerical convergence while strictly adhering to operational limits.

Validation on a modified IEEE 14-bus test system demonstrated the operational and economic superiority of the proposed framework over traditional Centralised Economic Dispatch (CED). The P2P market achieved a net economic welfare improvement differential of 375.54 m.u./h while reducing total

required system generation from 57.97 MW to 57.83 MW, yielding a 0.14 MW reduction in active power losses through localised power matching. Furthermore, the market enabled 100% community self-sufficiency for local demand, requiring only 0.83 MW of slack grid power exchange to compensate for network losses. Nodal voltage profiles remained strictly within statutory bounds (0.95 to 1.05 p.u.), yielding a less stressed average nodal voltage of 1.0206 p.u. compared to 1.0430 p.u. under CED.

Rigorous stress testing confirmed the algorithm's adaptability under dynamic grid conditions. During a 25 MW generator contingency at Bus 6, the IPM algorithm seamlessly re-cleared local reserves to maintain system stability. Under a 150% peak load surge, the framework intelligently curtailed demand at Bus 11 to 1.50 MW, proving that physical grid limits are strictly prioritized over unconstrained trade clearing. Overall, the framework provides distribution network operators with a scalable tool to unlock localised DER capacity without compromising grid reliability. Future work will expand this framework to multi-period operational horizons with energy storage degradation models and extend the formulation to unbalanced three-phase distribution systems.

ABSTRACT

Urban air quality deterioration driven by vehicular traffic is a critical public health challenge in rapidly growing Nigerian cities. Road intersections represent pollution hotspots where idling, acceleration, and deceleration generate elevated concentrations of harmful pollutants. This study assesses air quality at four major intersections in Kano metropolis by evaluating spatial-temporal pollutant variations and compliance with World Health Organization (WHO) and Nigerian Ambient Air Quality Standards (NAQS). Field measurements were conducted for eight weeks at the intersections; NNPC Mega (P1), Kwanar Sabo (P2), Aliko by Maiduguri Road (P3), and Gadar Lado (P4) intersections, with Hotoro GRA serving as a control site (P5). Concentrations of $PM_{1.0}$, $PM_{2.5}$, PM_{10}, CO, NO_2, SO_2, and total volatile organic compounds (TVOCs) were measured twice weekly on Sundays and Mondays during morning, afternoon, and evening periods using a multi-gas detector and air quality monitor. All four sites recorded pollutant concentrations significantly higher than the control site (intersection-to-control ratios: 3.5 – 8.6×; Welch's t-test, $p < 0.001$ for all pollutants). $PM_{2.5}$ was the dominant pollutant, exceeding WHO guidelines (15 µg/m³) by up to 13.9-fold on weekdays. At all four intersections, SO_2 exceeded the NAQS limit (0.048 ppm) on both measurement days, and NO_2 exceeded the NAQS limit (0.064 ppm) at three of the four intersections on Mondays. Weekday concentrations were 49 – 95% higher than weekend values across all parameters. Evening periods consistently produced the highest pollution levels. The signalized 4-way intersection (P2) recorded the highest overall pollution, while the T-junction (P3) recorded the lowest values, suggesting intersection geometry substantially influences pollutant dispersion. Air quality at major intersections in Kano metropolis frequently falls within moderate to severe pollution categories, posing substantial health risks to commuters, pedestrians, and roadside workers. Urgent implementation of intelligent traffic management, vehicle emission controls, and continuous monitoring systems is recommended.

Keywords: *Air quality assessment; traffic-related air pollution; road intersections; particulate matter; Kano metropolis; WHO; NAQS*

1. INTRODUCTION

Urban air quality has become a defining environmental and public health challenge in rapidly growing developing-world cities, where vehicular expansion frequently outpaces regulatory and infrastructural capacity (Emereibeole et al., 2023). Road traffic is a principal source of pollutants such as carbon monoxide (CO), nitrogen oxides (NOx), sulphur dioxide (SO_2), total volatile organic compounds (TVOCs) and particulate matter (PM), all of which are associated with adverse respiratory and cardiovascular outcomes (Chen et al., 2022; Amegah & Agyei-Mensah, 2017).

Road intersections are especially critical microenvironments within the urban transport network. Unlike free-flowing sections of road, intersections concentrate vehicle idling, deceleration and acceleration events tied to traffic signal phases, queue formation and geometric constraints, producing localized emission "hotspots" that can differ markedly from ambient background levels (Šarić et al., 2023; Hailu et al., 2024). Emission rates during acceleration and idling are disproportionately higher than during steady cruising, so the exposure experienced by commuters, traders and traffic personnel at junctions can be substantially elevated relative to general roadside conditions.

Kano, northwestern Nigeria's largest commercial hub with a population exceeding four million, exhibits many of the classic conditions associated with severe intersection pollution: high vehicular density, mixed heavy- and light-duty fleets, largely unsignalized or under-optimized junction control,

and a harmattan-dominated dry season that elevates background particulate loads through Saharan dust intrusion (Akinlade et al., 2020). Despite this, empirical, intersection-scale air quality data for Kano remain scarce compared with cities such as Lagos, Port Harcourt, Owerri and Warri, where similar assessments have been conducted (Nwankwo & Bamidele, 2025; Emereibeole et al., 2023). For context, the Ogbomoso study reported a wet-season particulate matter mean of 27.7 µg/m3, with spikes up to 70.15 µg/m3 at unpaved road intersections, attributed to heavy vehicular traffic, charcoal burning and seasonal harmattan dust (Nwankwo & Bamidele, 2025). In Owerri, particulate matter ranged from 8-27 µg/m3 at strategic intersections but reached 400-500 µg/m3 near open-air markets, while a co-monitored gaseous pollutant reached 0.055-0.089 ppm (approximately 100-160 µg/m3) at busy junctions, linked to peak-hour congestion and market waste dumpsites (Emereibeole et al., 2023). In Warri, an annual baseline particulate matter mean of 36.38 µg/m3 was recorded around petrochemical refinery buffer zones, with spikes exceeding 133 µg/m3 near major transport corridors and a co-monitored gaseous pollutant averaging 0.0063 ppm, reflecting industrial and heavy diesel-traffic emissions. These comparator values are broadly consistent with the intersection-level concentrations reported for Kano in the present study (Table 3), though direct comparison is limited by differences in monitoring season, averaging period and instrumentation across studies.

This study addresses that gap by systematically measuring $PM_{1.0}$, $PM_{2.5}$, PM_{10}, CO, NO_2, SO_2 and TVOC concentrations, together with temperature, relative humidity and the Air Quality Index (AQI), at four strategically selected road intersections and one residential control site in Tarauni Local Government Area, Kano State. The specific objectives are to (i) quantify and compare pollutant concentrations across intersections of differing geometry and traffic control; (ii) evaluate compliance with WHO and NAQS air quality guidelines; (iii) characterize temporal variation between weekday and weekend conditions and across morning, afternoon and evening peak periods; and (iv) draw evidence-based recommendations for traffic management and public health protection.

2. MATERIALS AND METHODS

2.1 Study Area

The study was conducted at four major road intersections and one residential control site within Kano metropolis, along the city's principal arterial corridors: Maiduguri Road (A3, the international corridor linking Kano to Borno, Yobe, Chad and Niger) and Zaria Road (A2, the national corridor linking Kano to Kaduna, Abuja and southwestern Nigeria). Sampling was carried out during the peak harmattan season (mid-December 2025 to mid-February 2026), characterized by Saharan dust intrusion (background PM_{10} frequently exceeding 100 µg/m3), low relative humidity (<20%) and a wide diurnal temperature range (15-35 °C). Four intersections and one control site were selected using stratified purposive sampling to capture a representative range of traffic-control regimes and geometric configurations, as summarized in Table 1.

Table 1: Classification of sampling stations

Code	Station	Traffic control	Geometry	Corridor
P1	NNPC Mega Intersection	Unsignalized	4-way cross	Maiduguri Rd (A3)
P2	Kwanar Sabo Intersection	Signalized	4-way cross	Secondary arterial
P3	Aliko Maiduguri Rd Intersection	Signalized	3-way T-junction	Maiduguri Rd (A3)
P4	Gadar Lado Intersection	Unsignalized	4-way cross	A2 / A3
P5	Hotoro GRA (Control)	None (residential)	N/A	Estate roads

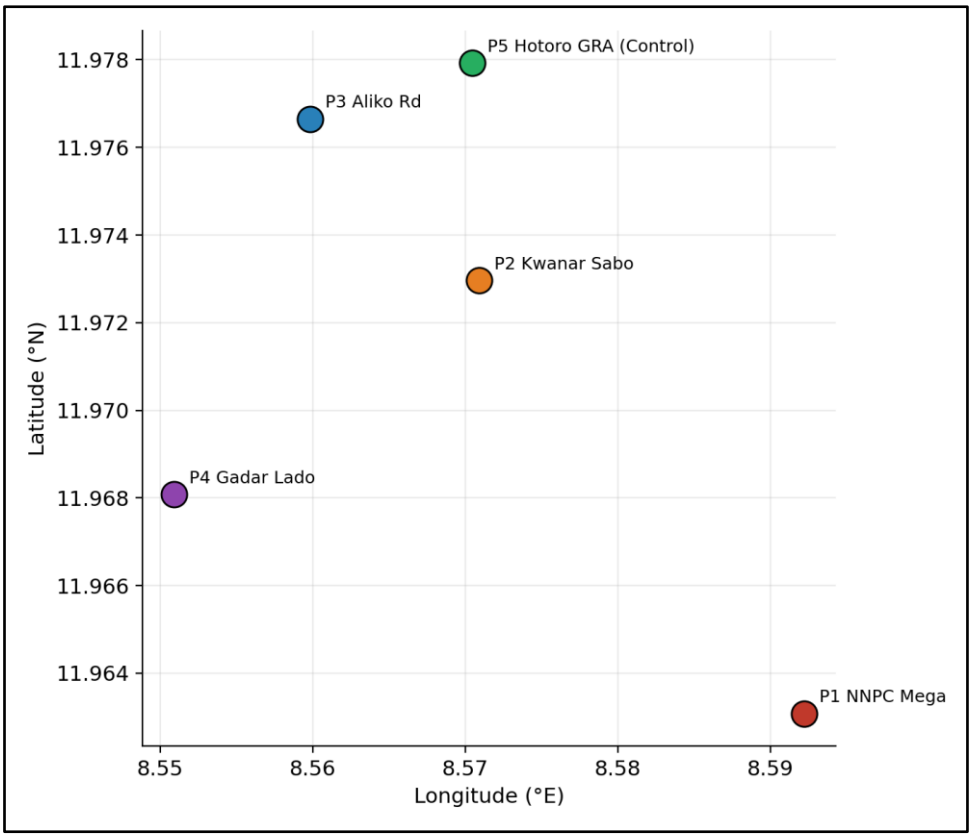

Figure 1: Spatial distribution of the five sampling stations in Tarauni LGA, Kano State

P1 (NNPC Mega) and P4 (Gadar Lado) are unsignalized four-way crossings characterized by high-speed, multi-directional approaches and a heavy proportion of inter-city trucks and articulated vehicles (35-45%). P2 (Kwanar Sabo) is a signalized four-way junction bounded by a partial street-canyon (motorcycle garage and buildings), which restricts pollutant dispersion. P3 (Aliko) is a signalized three-way T-junction with more open geometry. P5 (Hotoro GRA) is a low-density residential estate with negligible through-traffic (<50 vehicles/hour) and no signalized junction, serving as the non-intersection urban baseline.

2.2 Data Collection

Measurements were taken twice weekly - once on a working day (Monday) and once on a weekend day (Sunday) - over eight consecutive weeks, during three daily periods: morning peak (7:30-9:00 AM), midday off-peak (12:00-1:30 PM) and evening peak (4:30-6:00 PM). All readings were taken at 1.5 m height, corresponding to the breathing zone of drivers, pedestrians and traffic personnel.

Gaseous pollutants (CO, NO_2, SO_2) were measured using a calibrated Bosean BH-4S 4-in-1 portable multi-gas detector (Henan Bosean Electronic Technology Co., Ltd., China), configured with electrochemical sensor channels for CO (0-1000 ppm range, 1 ppm resolution), NO_2 (0-20 ppm range, 0.1 ppm resolution) and SO_2 (0-20 ppm range, 0.1 ppm resolution); manufacturer-stated accuracy $\leq \pm 5\%$ F.S., response time ≤ 30 s, natural-diffusion sampling, and factory calibration with a 2-year rated sensor life. TVOC, together with particulate matter ($PM_{1.0}$, $PM_{2.5}$, PM_{10}), temperature, relative humidity and AQI were measured using a portable laser-scattering air quality monitor. At each visit, instruments were allowed to stabilize before recording; GPS coordinates were used to ensure identical sampling positions were revisited across the study period.

2.3 Standards and Data Analysis

Measured concentrations were compared against the WHO Global Air Quality Guidelines (2021) and the Nigerian Ambient Air Quality Standards (NAQS) under the National Environmental (Air Quality Control) Regulations (NESREA, 2014), summarized in Table 2. Descriptive statistics

(station means, weekday/weekend means, diurnal means) were computed from 207 valid station-period observations collected across the eight-week campaign, and pollutant exceedance ratios were calculated as the ratio of station mean concentration to the corresponding WHO guideline value. Standard deviations are reported alongside station means in Table 3. To test for differences in pollutant concentrations, one-way analysis of variance (ANOVA) was used to compare mean concentrations among the five stations for each pollutant, and Welch's independent-samples t-tests (unequal variances assumed) were used to compare weekday (Monday) versus weekend (Sunday) concentrations and intersection (P1-P4, pooled) versus control (P5) concentrations. All tests were evaluated at $\alpha = 0.05$ using the full station-period dataset (n up to 240 station-period-pollutant records per parameter, varying slightly by pollutant owing to isolated missing readings).

Table 2: WHO and NAQS air quality standards used for compliance assessment

Pollutant	WHO Guideline	NAQS Standard	Averaging period
$PM_{2.5}$	15 µg/m^3	35 µg/m^3	24-hour
PM_{10}	45 µg/m^3	150 µg/m^3	24-hour
NO_2	0.013 ppm	0.064 ppm	24-hour
SO_2	0.015 ppm	0.048 ppm	24-hour
CO	4 mg/m^3	10 mg/m^3	8-hour

3. RESULTS AND DISCUSSION

A total of 207 valid station-period observations were recorded across the eight-week sampling campaign. Table 3 summarizes the overall mean pollutant concentrations by station.

Table 3: Overall mean ± standard deviation of pollutant concentrations by station (entire sampling period)

Station	$PM_{2.5}$ (µg/m3)	$PM_{1.0}$ (µg/m3)	PM_{10} (µg/m3)	CO (mg/m3)	NO_2 (ppm)	SO_2 (ppm)	TVOC (mg/m3)
P1	130.8 ± 50.0	72.6 ± 27.2	142.0 ± 60.9	5.40 ± 3.15	0.081 ± 0.061	0.119 ± 0.067	0.58 ± 1.42
P2	148.7 ± 76.6	83.6 ± 40.6	148.7 ± 65.5	7.94 ± 5.86	0.121 ± 0.068	0.140 ± 0.061	2.65 ± 4.16
P3	91.6 ± 48.5	53.6 ± 25.9	98.5 ± 52.0	4.43 ± 4.13	0.049 ± 0.065	0.090 ± 0.068	0.48 ± 1.41
P4	109.3 ± 59.7	63.9 ± 32.5	122.6 ± 67.5	4.19 ± 3.92	0.091 ± 0.053	0.111 ± 0.077	0.31 ± 0.14
P5 (control)	30.0 ± 10.3	16.8 ± 6.7	33.1 ± 12.0	0.56 ± 0.86	0.006 ± 0.02	0.041 ± 0.048	0.02 ± 0.05

Across every pollutant, P5 (control) recorded the lowest concentrations by a wide margin, confirming its suitability as a non-intersection baseline. P2 (Kwanar Sabo) recorded the highest mean concentrations for nearly all parameters, consistent with its partial street-canyon geometry, signalized stop-and-go operation, and mixed commercial/motorcycle traffic. P3, the open T-junction, consistently recorded the lowest pollutant levels among the four intersections, suggesting that junction geometry - specifically the number of conflicting approaches and the degree of physical enclosure - exerts a measurable influence on local pollutant accumulation.

The station-to-station differences summarized in Table 3 were confirmed by one-way ANOVA, which found significant effects of station on mean concentration for every pollutant ($PM_{2.5}$: $F(4,235) = 34.5$, $p < 0.001$; $PM_{1.0}$: $F = 37.6$, $p < 0.001$; PM_{10}: $F = 32.6$, $p < 0.001$; CO: $F = 21.3$, $p < 0.001$; NO_2: $F = 29.7$, $p < 0.001$; SO_2: $F = 19.0$, $p < 0.001$; TVOC: $F = 12.2$, $p < 0.001$). Welch's t-tests further confirmed that concentrations at the four intersections (P1-P4, pooled) were significantly higher than at the control site (P5) for every pollutant (all $p < 0.001$, t-values ranging from 5.1 for TVOC to 19.4 for $PM_{1.0}$), and that weekday (Monday) concentrations were significantly higher than weekend (Sunday) concentrations for every pollutant ($p < 0.05$ for all seven parameters, $p < 0.001$ for $PM_{2.5}$, $PM_{1.0}$, PM_{10} and SO_2). These results provide statistical support for the "significantly higher" language used elsewhere in this paper to describe intersection-to-control and weekday-to-weekend contrasts.

3.1 Particulate Matter ($PM_{1.0}$, $PM_{2.5}$, PM_{10})

Particulate matter was the most critical pollutant class recorded in this study. Figure 2 compares overall mean $PM_{1.0}$, $PM_{2.5}$ and PM_{10} concentrations across the five stations against WHO and NAQS reference limits.

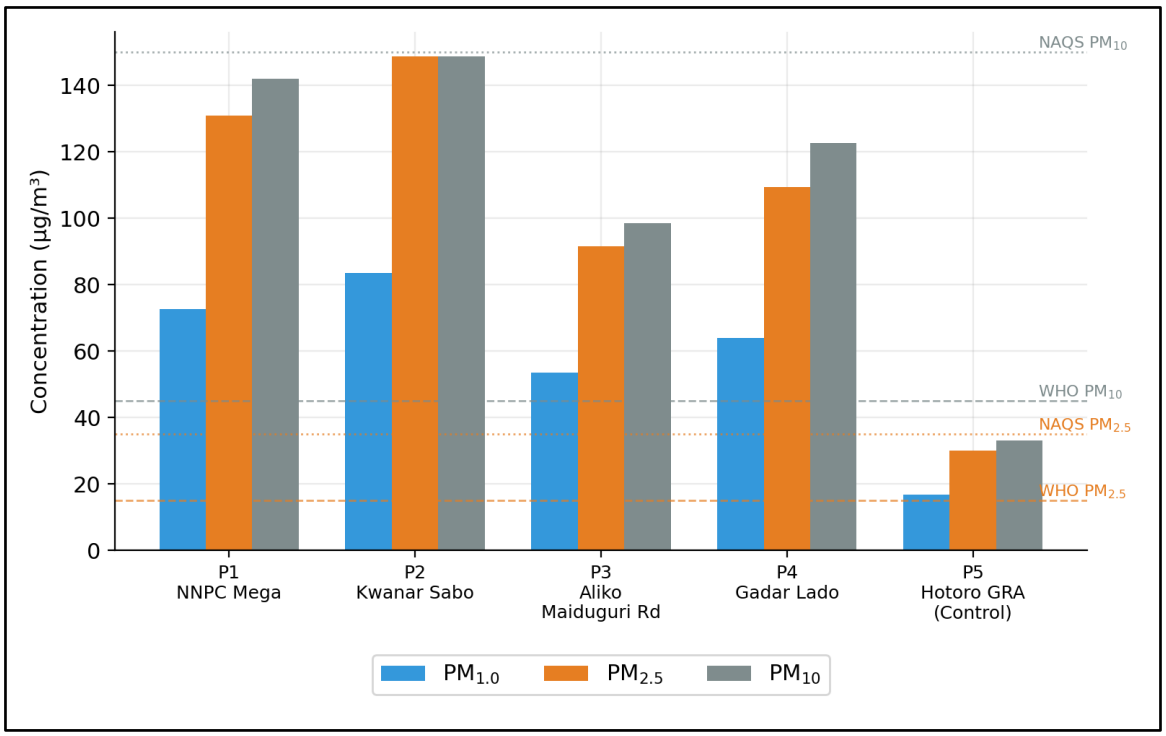

Figure 2: Overall mean particulate matter concentrations by station

Mean $PM_{2.5}$ concentrations at the four intersections (91.6-148.7 µg/m3) exceeded the WHO 24-hour guideline (15 µg/m3) by factors of 6.1 to 9.9, and the NAQS limit (35 µg/m3) by factors of 2.6 to 4.2. Even the control site (30.0 µg/m3) exceeded the WHO guideline by a factor of 2.0, though it remained below the NAQS threshold, indicating a substantial regional background contribution from harmattan dust in addition to traffic-related emissions. PM_{10} followed a similar pattern, with intersection means (98.5-148.7 µg/m3) consistently exceeding the WHO guideline (45 µg/m3) while remaining, on average, below the more permissive NAQS limit (150 µg/m3) except during isolated high-traffic episodes. Weekday-weekend contrasts were pronounced. Figure 3 and Figure 5 present station-level $PM_{2.5}$ and PM_{10} concentrations split by sampling day.

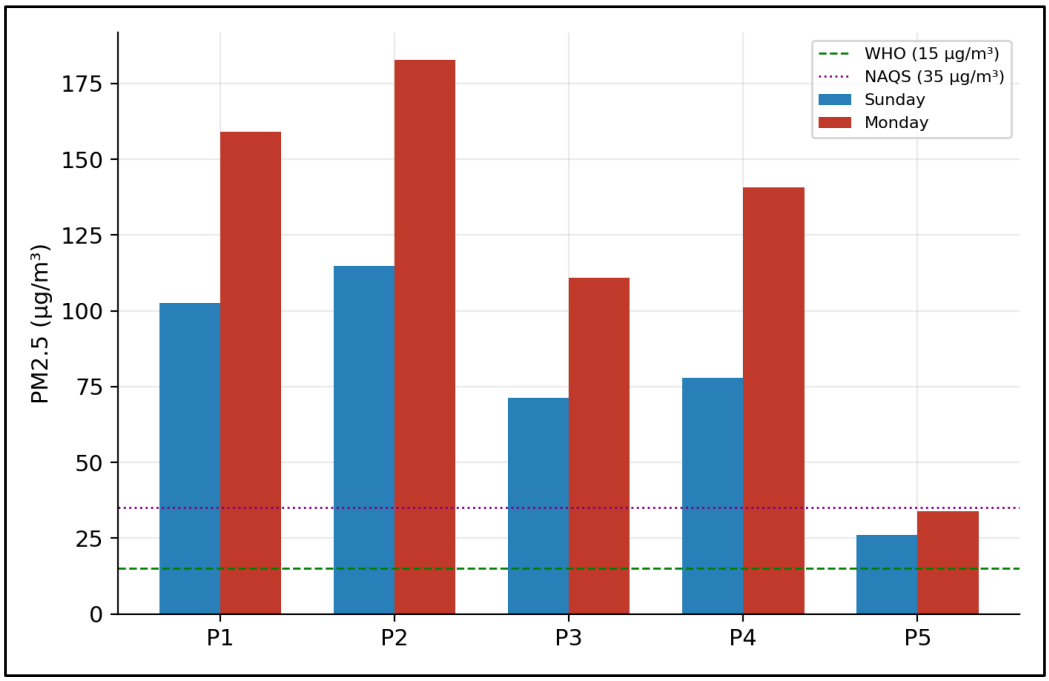

Figure 3: Weekend (Sunday) versus weekday (Monday) $PM_{2.5}$ by station

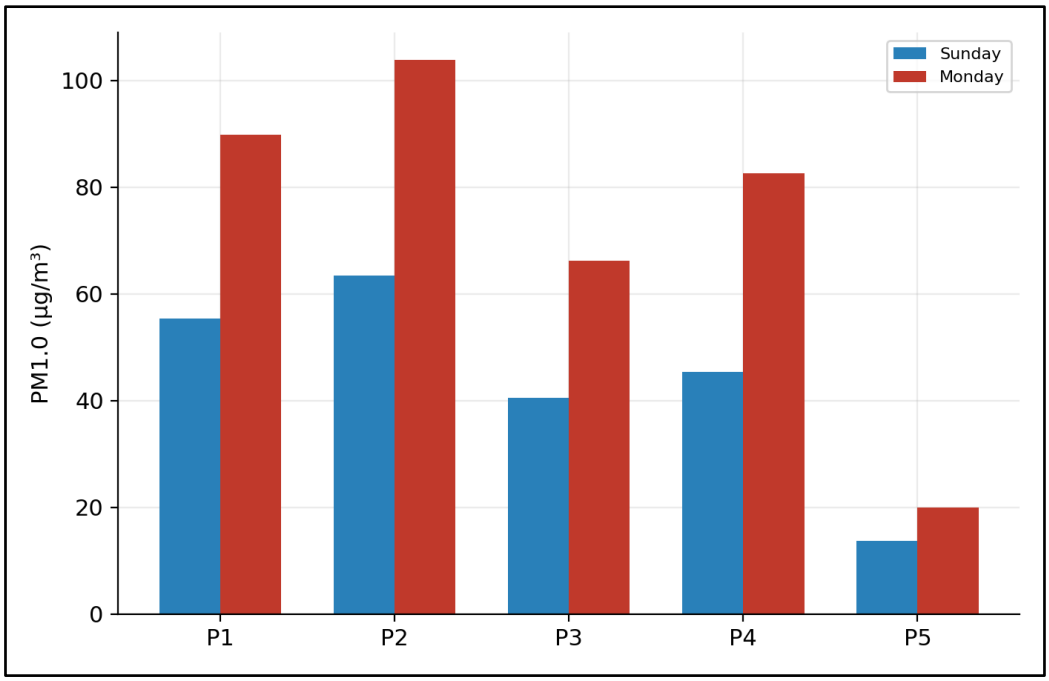

Figure 4: Weekend versus weekday $PM_{1.0}$ (ultrafine particulate matter) by station

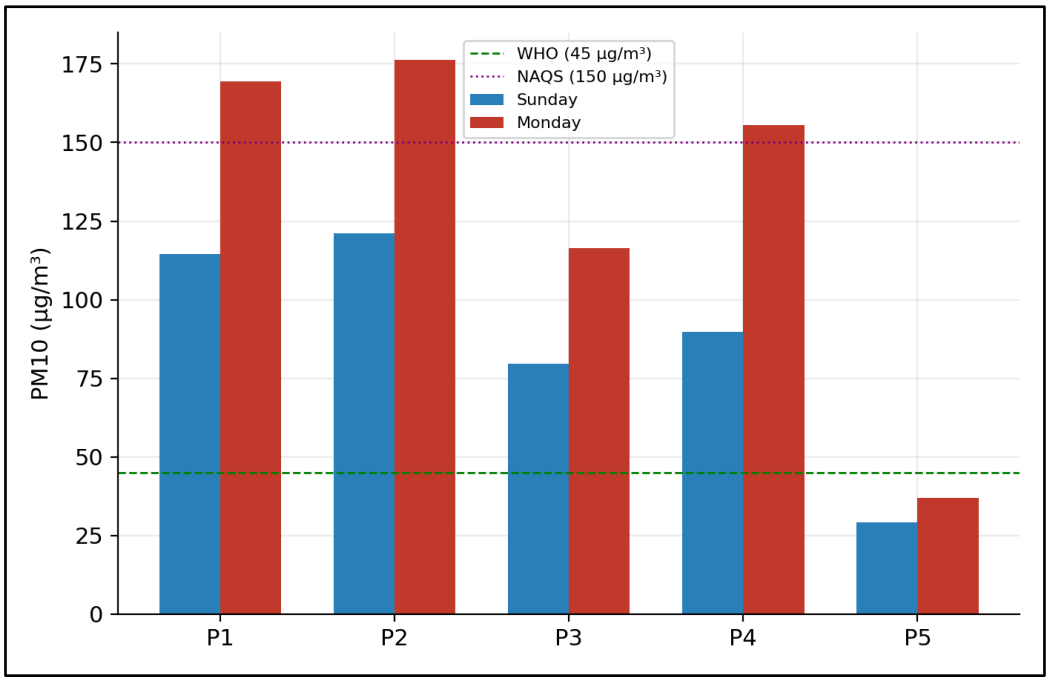

Figure 5: Weekend versus weekday PM_{10} by station

$PM_{2.5}$ concentrations on Mondays were 30-80% higher than on Sundays at all four intersections (e.g., P2: 114.7 µg/m3 on Sunday versus 182.7 µg/m3 on Monday), while the control site increased by a comparatively modest margin (26.1 to 33.9 µg/m3), confirming that the weekday excess is predominantly traffic-driven rather than purely meteorological. Ultrafine particulate matter ($PM_{1.0}$), attributable primarily to combustion aerosol from vehicle exhaust and diesel acceleration events, exhibited the same weekday elevation, with P2 rising from 63.4 µg/m3 (Sunday) to 103.8 µg/m3 (Monday).

Diurnal patterns (Figure 6) show a consistent rise from morning to evening across all stations, with evening peak-period concentrations 30-70% higher than morning concentrations. This pattern reflects the compounding effect of heavier evening traffic volumes, hotter engine operation, and the day's accumulated pollutant loading in the absence of strong atmospheric mixing during the harmattan season.

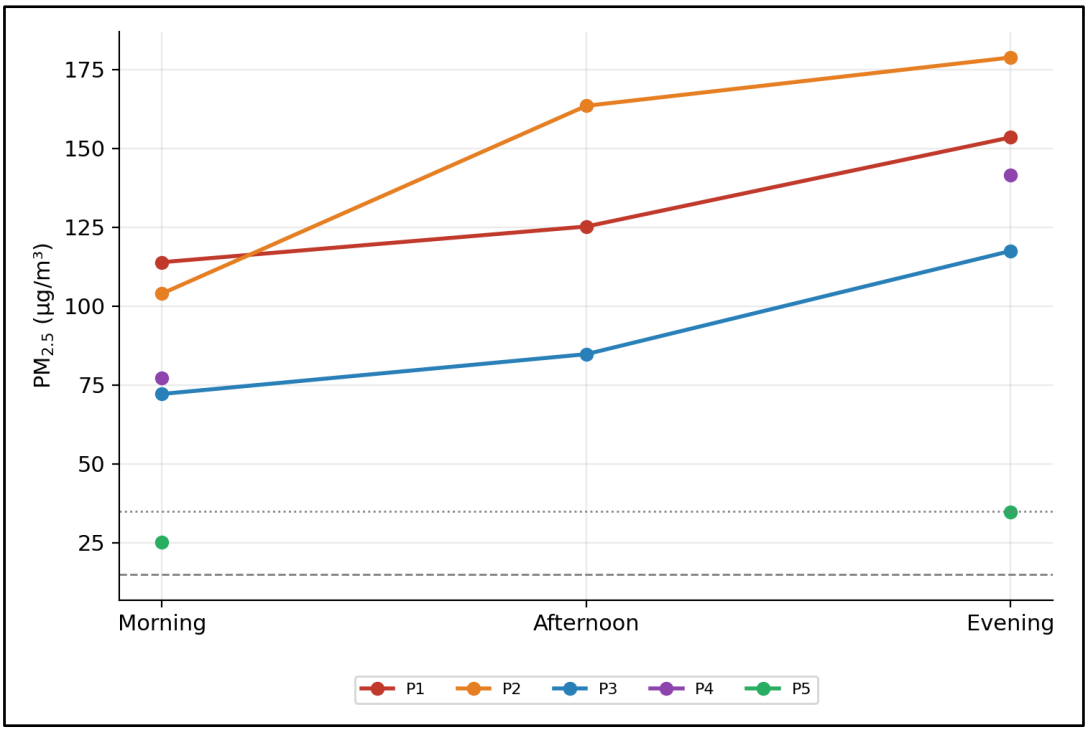

Figure 6: Diurnal variation of $PM_{2.5}$ across sampling stations

The eight-week temporal trend of mean $PM_{2.5}$ concentration (Figure 7) further shows that although week-to-week variability exists (attributable to fluctuating harmattan dust intensity and traffic volume), intersection stations remained persistently elevated above the control site throughout the entire monitoring period, with a marked spike in Week 8 across all stations, coincident with intensified regional dust loading toward the end of the harmattan season.

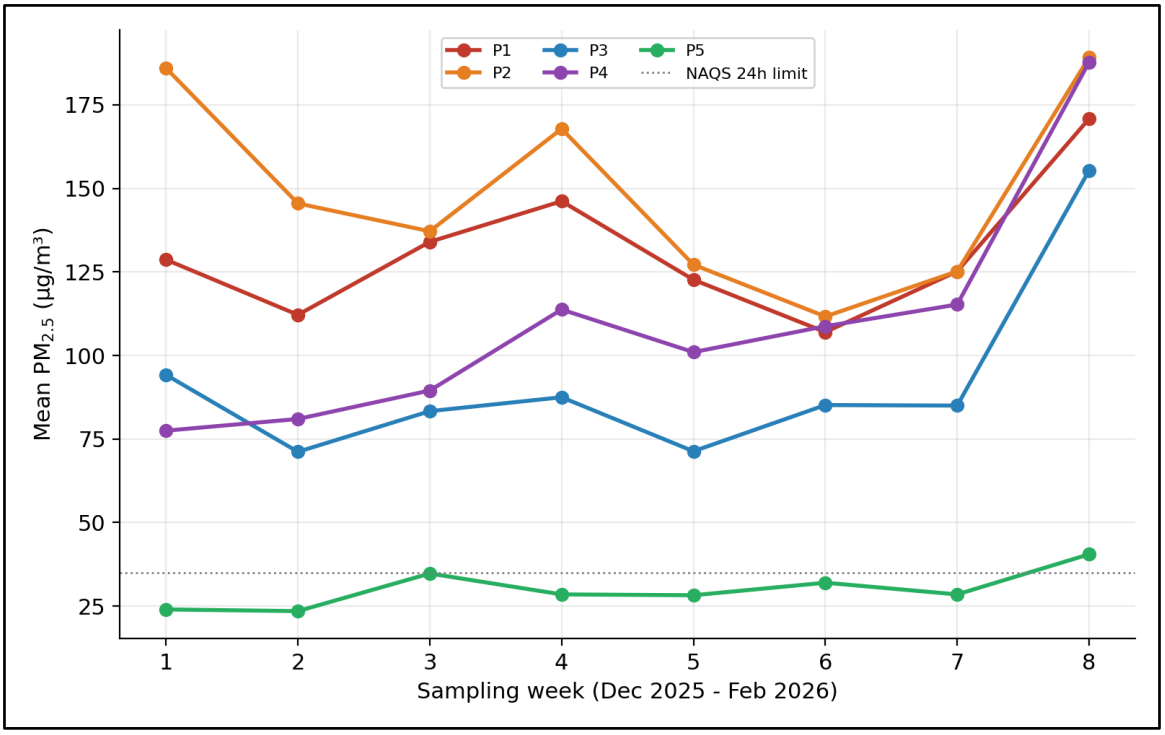

Figure 7: Eight-week temporal trend of mean $PM_{2.5}$ concentration by station

The pronounced weekday-weekend and diurnal contrasts observed across all pollutants - with Monday and evening-period concentrations consistently the highest - indicate that traffic volume and congestion state, rather than fixed emission sources, are the principal short-term determinants of

exposure at these locations. This has direct implications for exposure-reduction strategies, since even modest reductions in queuing and idling time at the most heavily trafficked junctions (P1 and P2) could yield disproportionate air quality benefits.

3.2 Gaseous Pollutants (CO, NO_2, SO_2)

Figure 8 presents overall mean CO, NO_2 and SO_2 concentrations by station relative to WHO and NAQS limits.

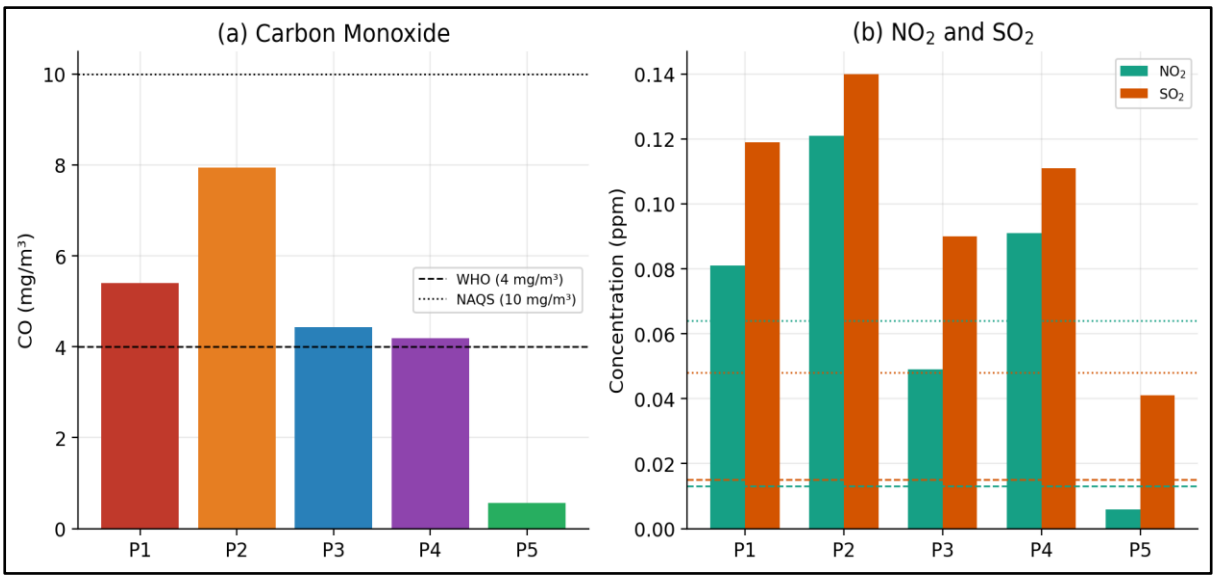

Figure 8: Overall mean gaseous pollutant concentrations by station

Mean CO concentrations at P1 (5.40 mg/m3) and P2 (7.94 mg/m3) exceeded the WHO guideline (4 mg/m3), while P3, P4 and P5 remained, on average, compliant. However, individual evening-period readings at P2 reached as high as 11.5 mg/m3 on Mondays, approaching the NAQS 8-hour limit (10 mg/m3) and reflecting severe idling combined with restricted dispersion from the partial street-canyon at that junction.

NO_2 and SO_2 concentrations were consistently elevated at all four intersections relative to WHO guidelines (0.013 ppm and 0.015 ppm respectively), by factors of up to 9.3x for NO_2 and 9.3x for SO_2 at P2 (0.121 ppm / 0.013 ppm ≈ 9.31 and 0.140 ppm / 0.015 ppm ≈ 9.33, respectively; the near-identical values are a numerical coincidence rather than a rounding artefact). Monday NO_2 concentrations at P2 (0.150 ppm) exceeded even the more permissive NAQS limit (0.064 ppm) by a factor of approximately 2.3, identifying this junction as the most critical NO_2 hotspot in the study. Notably, SO_2 at the control site rose to a mean of 0.041 ppm (and individual Monday values above 0.06 ppm), exceeding the WHO guideline even in the residential control area - evidence that SO_2 pollution in Kano is not confined to intersection microenvironments but reflects a broader urban emissions background, likely including generator use and fuel combustion beyond road traffic. Weekday-weekend and station-level comparisons for CO, NO_2 and SO_2 are presented in Figures 9-11.

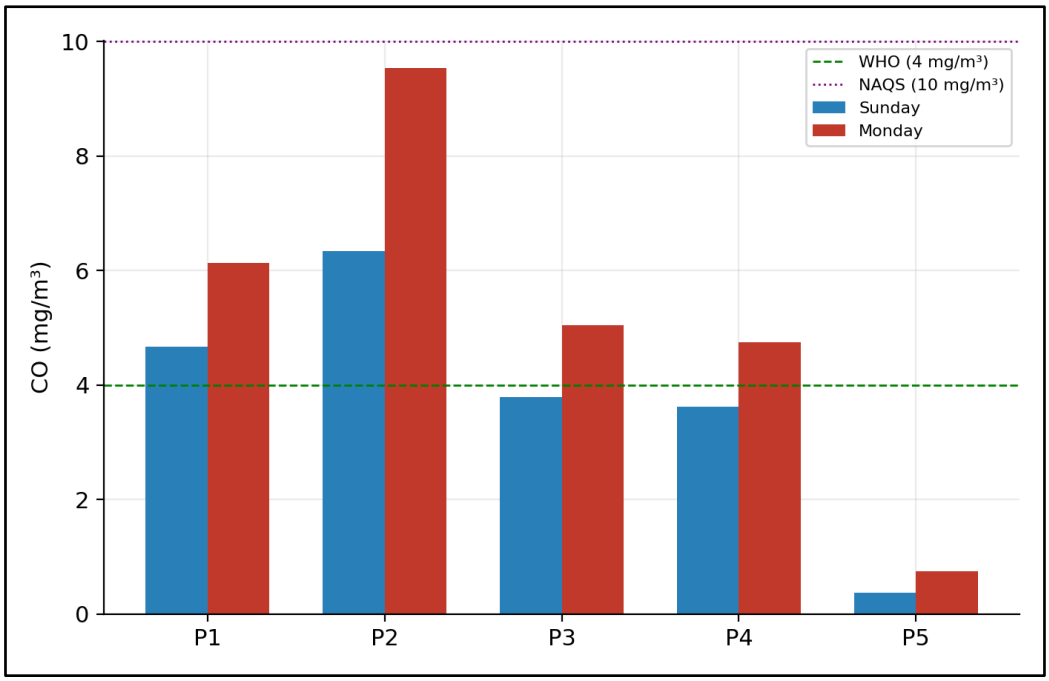

Figure 9: Weekend versus weekday Carbon Monoxide (CO) by station

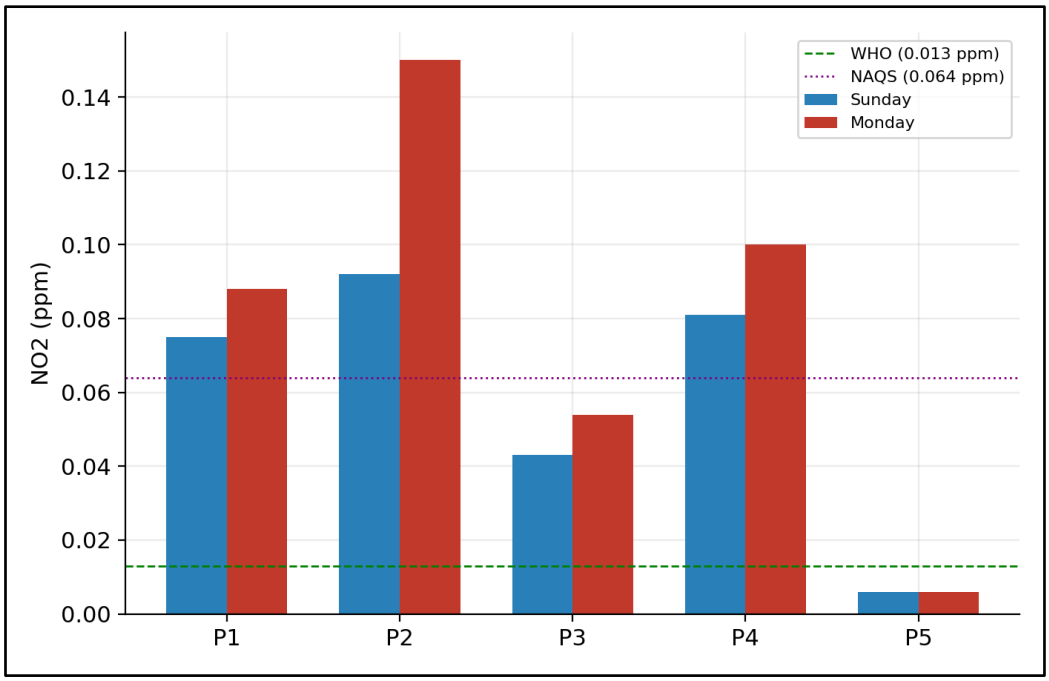

Figure 10: Weekend versus weekday Nitrogen Dioxide (NO_2) by station

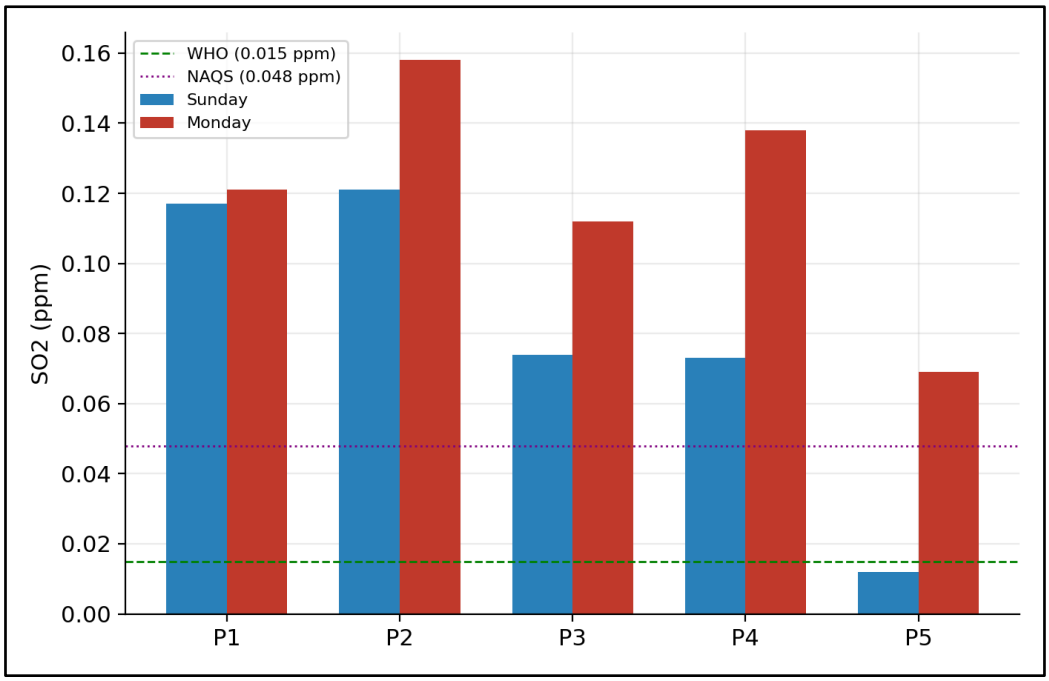

Figure 11: Weekend versus weekday Sulphur Dioxide (SO_2) by station

Across all three gaseous pollutants, Monday concentrations exceeded Sunday concentrations by 15-90%, with the largest relative increases recorded at P2, mirroring the pattern observed for particulate matter and reinforcing the conclusion that weekday commercial and inter-city traffic is the dominant driver of intersection-scale pollution in the study area.

3.3 Total Volatile Organic Compounds (TVOC)

TVOC concentrations, associated with fuel evaporation and incomplete combustion, were markedly higher at P2 (2.65 mg/m3) than at any other station - roughly 4.6 to 8.5 times the levels recorded at the other three intersections (P1: 4.6x; P3: 5.5x; P4: 8.5x) (Figure 12). This is consistent with the dense motorcycle and commercial-taxi traffic and fuel-vending activity historically associated with this junction, and suggests that fuel-handling and idling-related VOC emissions, rather than through-traffic alone, may be an important local contributor at this specific site.

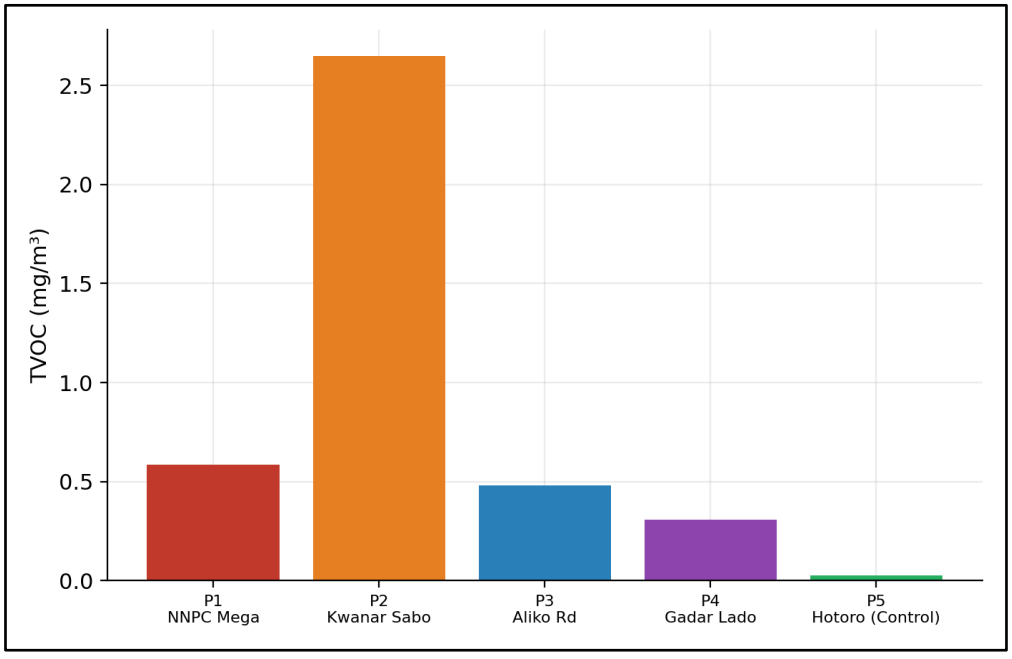

Figure 12: Overall mean TVOC concentration by station

3.4 Compliance with Air Quality Standards

Figure 13 summarizes pollutant-specific exceedance ratios (station mean concentration divided by the corresponding WHO guideline value) across all five stations, providing a unified view of relative severity across pollutant types.

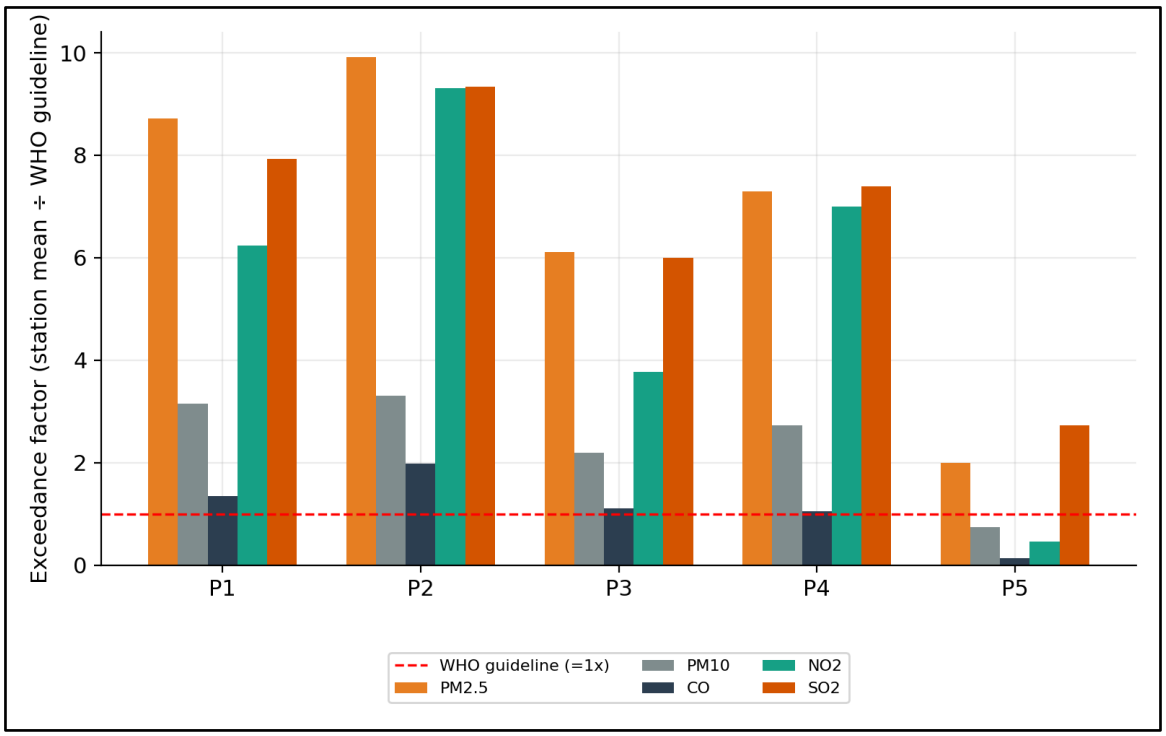

Figure 13: Pollutant exceedance ratios relative to WHO Air Quality Guidelines

$PM_{2.5}$ and NO_2 emerge as the pollutants of greatest concern, with exceedance ratios reaching approximately 9.9x and 9.3x, respectively, at P2. CO showed the smallest relative exceedance, remaining close to or below the WHO guideline at P3, P4 and P5. The ranking P2 > P1 > P4 > P3 > P5 holds exactly for the particulate pollutants (PM2.5, PM1.0, PM10) and for SO2, while CO, NO2 and TVOC show minor rank reversals between P1, P3 and P4 (e.g., P4 > P1 for NO2; P3 > P4 for CO and TVOC) (Figure 13). This pattern nonetheless mirrors the traffic-control and geometric classification in Table 1: the signalized, partially enclosed four-way junction (P2) is the most polluted, the open T-junction (P3) is generally among the least polluted of the four intersections, and the residential control site (P5) is consistently and substantially cleaner than any intersection.

This consistent elevation of pollutant concentrations at intersections relative to the control site (by factors of roughly 3.5x to 8.6x depending on pollutant) confirms that vehicular traffic is the dominant local source of air pollution at the studied locations, in agreement with comparable studies conducted at road junctions in Ogbomoso and Owerri, Nigeria (Nwankwo & Bamidele, 2025; Emereibeole et al., 2023) and in Warri Metropolis, where NO_2, SO_2, CO and PM_{10} levels at major junctions similarly approached or exceeded national standards. The results further indicate that intersection geometry and control type modulate pollutant accumulation: the partially enclosed, signalized four-way junction (P2) consistently recorded the highest concentrations, plausibly reflecting a street-canyon effect that traps pollutants and repeated stop-start cycling at the signal, while the open three-way T-junction (P3) allowed comparatively better dispersion. This is consistent with findings that intersection geometry meaningfully affects urban air pollution management outcomes (Šarić et al., 2023).

4. CONCLUSION

This study assessed traffic-related air quality at four major road intersections and one residential control site in Tarauni Local Government Area, Kano State, over an eight-week harmattan-season campaign. The results show that road intersections are significant, geometry- and control-dependent pollution hotspots, with $PM_{2.5}$, $PM_{1.0}$, PM_{10}, NO_2 and SO_2 concentrations consistently exceeding WHO

Air Quality Guidelines - and, for $PM_{2.5}$ and NO_2 in particular, frequently exceeding the more permissive Nigerian Ambient Air Quality Standards as well. The signalized, partially enclosed Kwanar Sabo intersection (P2) recorded the highest pollution levels across nearly all parameters, while the open T-junction (P3) recorded the lowest among the four intersections, underscoring the influence of junction geometry on local air quality. Weekday concentrations were consistently higher than weekend concentrations, and evening peak periods recorded the highest pollutant loads, confirming that vehicular traffic volume and congestion are the principal drivers of intersection-scale air pollution in the study area. These findings highlight an urgent need for targeted traffic management, vehicle emission control and continuous air quality monitoring at major Kano intersections to protect the health of commuters, roadside traders and traffic personnel.

A key limitation of this study is that sampling was confined to the harmattan season (mid-December 2025 to mid-February 2026), a period characterized by elevated regional background particulate loading from Saharan dust intrusion. Because harmattan-season background PM levels are substantially higher than during the wet season, the absolute pollutant concentrations and exceedance ratios reported here may not be representative of year-round conditions, and the relative contribution of traffic versus meteorology to observed pollution levels cannot be fully disentangled from a single-season campaign. Findings on comparative station rankings and weekday/weekend or diurnal contrasts are likely more robust to this limitation than the absolute concentration values, since traffic patterns rather than dust loading primarily drive these relative differences. Future work should extend monitoring across seasons, including the wet season, and incorporate traffic-count data to more precisely apportion intersection pollution between exhaust emissions and non-exhaust road-dust resuspension.

5. RECOMMENDATIONS

- Deploy intelligent/adaptive traffic signal systems at high-volume junctions (notably P1 and P2) to reduce idling time and queue lengths.
- Enforce regular vehicle inspection and emission-testing programmes, with priority given to the heavy-duty and inter-city fleet using the A2/A3 corridors.
- Improve road-surface conditions at unsignalized junctions to reduce dust resuspension contributing to PM_{10} loading.
- Establish vegetative buffer zones and roadside green belts between major intersections and adjacent residential and commercial areas.
- Install permanent, continuous air quality monitoring stations at the most heavily polluted junctions to support real-time public health advisories.
- Extend future monitoring across the wet season to separate meteorological (harmattan dust) from traffic-driven contributions to particulate matter.

ACKNOWLEDGEMENTS

The authors acknowledge the Department of Civil Engineering, Faculty of Engineering, Bayero University, Kano, for logistical and technical support during the field campaign. The authors also thank Abu Precious Isah and Mikail Jibrin Gimba for data collection and analysis, and all field assistants who supported the eight-week sampling exercise.

ABSTRACT

Groundwater is the principal domestic and irrigation water source in Jere Local Government Area (LGA), Borno State, Nigeria, but population growth, agriculture and inadequate sanitation threaten its quality. This study assessed water from five boreholes (BH1-BH5), five hand-dug wells (HW1-HW5) and one lake source (LW1) using physicochemical and bacteriological analyses, Water Quality Index (WQI), and irrigation indices (SAR, Na%, KR, PI and RSC). pH ranged from 6.7-7.5, EC from 420-1,210 µS/cm and TDS from 280-790 mg/L. Nitrate ranged from 12.5-72.6 mg/L, with HW3-HW5 exceeding 50 mg/L. All hand-dug wells and the lake exceeded 5 NTU turbidity and were positive for E. coli, whereas boreholes had turbidity below 5 NTU and no detected E. coli. WQI values of 42.6-57.8 classified boreholes as good, while HW3-HW5 were unsuitable for drinking. All sources were generally suitable for irrigation, but HW3-HW5 were classified as permissible and require active sodium-management measures. Engineering responses include priority boreholes (80-120 m depth; 150 mm PVC casing; gravel pack and sanitary seal), multi-barrier treatment for hand-dug wells, wellhead protection, differentiated irrigation management, and tiered monitoring. These interventions translate the empirical findings into practical measures supporting SDGs 2, 3 and 6.

Keywords: *groundwater quality; engineering solutions; water treatment; irrigation management; borehole design; sustainable development*

1. INTRODUCTION

Groundwater is a critical resource for domestic supply, agriculture and economic activity, particularly in regions where surface-water infrastructure is inadequate. In Jere Local Government Area (LGA), Borno State, communities depend heavily on boreholes and hand-dug wells, while increasing population, intensive agriculture, waste disposal and inadequate sanitation create pathways for groundwater contamination. Shallow wells are especially vulnerable because of their hydraulic connection with surface activities, including septic-tank seepage, agricultural runoff, livestock wastes and refuse leachate.

Groundwater-quality assessment increasingly combines physicochemical and bacteriological indicators with integrated indices. Water Quality Index (WQI) provides a single decision-support measure for drinking-water quality, while Sodium Adsorption Ratio (SAR), Sodium Percentage (Na%), Kelly Ratio (KR), Permeability Index (PI) and Residual Sodium Carbonate (RSC) provide complementary evidence for irrigation suitability. Nigerian studies have reported nitrate enrichment, microbial contamination and spatial variation associated with urbanisation, waste-management practices and land use (Banerjee et al., 2023; Ezechinyere & Stanislaus, 2023; Abanyie et al., 2023; Opasola et al., 2025; Thomas, 2023).

Despite these findings elsewhere, empirical information integrating drinking-water and irrigation suitability in Jere LGA remains limited. This study therefore evaluates selected groundwater and surface-water sources to establish a baseline for evidence-based water-resource management. The objectives were to determine major physicochemical parameters; assess bacteriological quality through

coliform and E. coli detection; compare results with WHO and Nigerian drinking-water standards; calculate WQI and irrigation-quality indices; and translate the empirical findings into engineering interventions. The work directly addresses the conference sub-themes of Innovative Resource Utilization and Management and Emerging Technologies for Safe Engineering Practices and Environmental Protection.

2. METHODOLOGY

2.1 Study Area

The study was conducted in Jere LGA, Borno State, north-eastern Nigeria, between 11°45′N-11°55′N and 13°05′E-13°20′E. The area has distinct wet and dry seasons, annual rainfall of approximately 500-700 mm and mean temperatures of 25-40°C. The geology is dominated by Chad Formation sediments comprising sands, silts and clays that host productive aquifers. Farming, livestock rearing, trading and small-scale commercial activities are major land uses and potential pressures on groundwater quality (NMA, 2008).

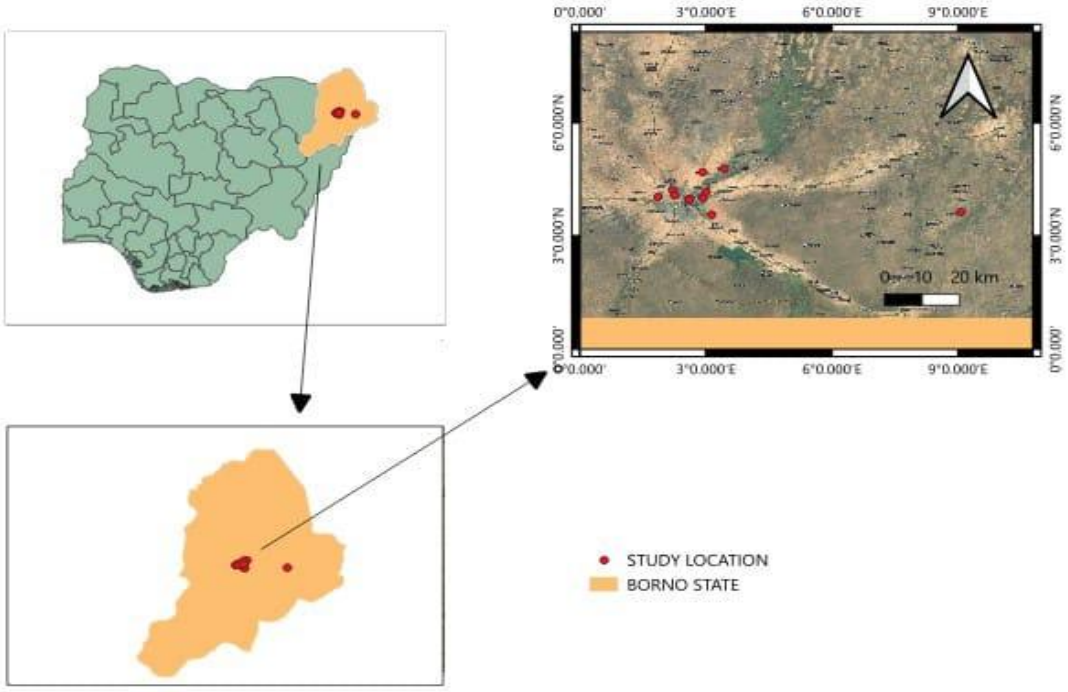

Figure 1: Map of the study area (Source: QGIS 3.44.12)

2.2 Sampling Locations and Collection

Eleven sampling locations were selected: five boreholes (BH1–BH5), five hand-dug wells (HW1–HW5) and one lake source (LW1). Selection considered accessibility, usage intensity, population served and proximity to potential contamination sources. Samples were collected in pre-cleaned 1-L polyethylene bottles following American Public Health Association (APHA, 2017); bacteriological samples were collected in sterile containers, transported in ice-packed coolers, and physicochemical analyses were completed within 24 h.

Table 1: *Sampling Locations and Water Sources*

Sample Code	Water Source	Location
BH1	Borehole	Cross Na Mala
BH2	Borehole	Gomari Airport
BH3	Borehole	Mairi Kuwait
BH4	Borehole	Mashamari
BH5	Borehole	Custom Area
HW1	Hand-dug Well	Jakana
HW2	Hand-dug Well	Dusuman
HW3	Hand-dug Well	Gongulong
HW4	Hand-dug Well	Old Maiduguri Road
HW5	Hand-dug Well	Shuwari
LW1	Lake Water	Coca-Cola Area

2.3 Parameters Analyzed

Analysed parameters comprised pH, temperature, electrical conductivity (EC), total dissolved solids (TDS), turbidity, hardness, nitrate, chloride, colour, acidity, alkalinity, total coliform count and E. coli presence. Laboratory analyses were conducted at the Department of Soil Science, Faculty of Agriculture, Ahmadu Bello University, Zaria.

2.4 Analytical Methods and Instrumentation

Physicochemical analyses followed APHA (2017): pH by electrometric method (4500-H^+ B; Jenway 370); EC by conductivity (2510 B; Jenway 470); TDS by gravimetry at 180°C; turbidity by nephelometry (2130 B; HACH 2100P); hardness by EDTA titration (2340 C); nitrate by cadmium-reduction spectrophotometry (4500-NO_3^- E; Genesys 10S at 540 nm); chloride by Mohr titration (4500-Cl^- B); alkalinity by titration to pH 4.5 (2320 B). Total coliform and E. coli were determined by membrane filtration (9222 B and 9222 G, respectively). Detection limits ranged from 0.01 pH unit to 5 mg/L for the principal physicochemical measures and 1 CFU/100 mL for bacteriological counts; calibration used certified standards and daily checks.

QA/QC included field blanks, duplicate analysis of at least 10% of samples, spike-recovery tests, method-detection-limit assessment, daily instrument calibration and positive/negative bacteriological controls. Physicochemical RSD was below 5%, bacteriological RSD below 10%, nitrate recovery 95-103%, chloride recovery 97-101%, all samples exceeded MDLs, and accepted calibration curves had $R^2 > 0.995$.

2.5 Statistical Analysis

Descriptive statistics comprised mean, standard deviation, minimum and maximum. Differences among water sources were evaluated by one-way ANOVA at $\alpha = 0.05$, followed where significant by Tukey's HSD. Analyses were performed in IBM SPSS Version 25. The model was $Y_{ij} = \mu + \alpha_i + \varepsilon_{ij}$, where Y_{ij} is the observed parameter, μ the overall mean, α_i the effect of water source i, and ε_{ij} the random error.

2.6 Water Quality Index (WQI)

WQI was calculated using the Weighted Arithmetic Index method (Shukla & Ram, 2015; Opasola et al., 2025). Nine parameters were included: pH, EC, TDS, turbidity, hardness, nitrate, chloride, alkalinity and total coliform count. The adopted weights were 0.09, 0.11, 0.10, 0.14, 0.07, 0.19, 0.07, 0.06 and 0.17, respectively; ideal values were 7.0 for pH and 0 for the other parameters. The WQI values were interpreted using the classification scheme adopted in the present study: < 50 = Excellent, 50-100 = Good, 100-200 = Poor, 200-300 = Very Poor, and > 300 = Unsuitable for drinking. The selected classification scheme was retained consistently for all sampling sources to permit direct comparison among the sampled groundwater sources

2.7 Irrigation Water Quality Assessment

Irrigation-water suitability was evaluated using the Sodium Adsorption Ratio (SAR), sodium percentage (Na%), Kelly's Ratio (KR), Permeability Index (PI), and Residual Sodium Carbonate (RSC). The interpretation of these indices was based on established irrigation-water classification criteria reported in the literature (Richards, 1954; FAO, 2009). SAR was used primarily to assess the potential sodium hazard, while Na%, KR, PI, and RSC were used to evaluate complementary sodium, alkalinity, and soil-permeability hazards. Accordingly, the irrigation-water quality classes reported in this study were assigned from the respective published classification ranges for each index rather than from SAR alone. The combined interpretation of the indices was used to determine the overall irrigation suitability of each sampled water source. $SAR = Na^+/\sqrt{[(Ca^{2+} + Mg^{2+})/2]}$, $Na\% = [(Na^+ + K^+)\times100]/(Ca^{2+} + Mg^{2+} + Na^+ + K^+)$, $KR = Na^+/(Ca^{2+} + Mg^{2+})$, $RSC = (CO_3^{2-} + HCO_3^-) - (Ca^{2+} + Mg^{2+})$, and $PI = [(Na^+ + \sqrt{HCO_3^-})\times100]/(Ca^{2+} + Mg^{2+} + Na^+)$. All ionic concentrations were expressed in meq/L.

3. RESULTS AND DISCUSSION

3.1 Physicochemical Parameters

Table 4 presents the physicochemical results. pH ranged from 6.7-7.5; EC from 420-1,210 µS/cm; TDS from 280-790 mg/L; turbidity from 2.1-18.3 NTU; hardness from 118-245 mg/L; nitrate from 12.5-72.6 mg/L; chloride from 32-125 mg/L; and alkalinity from 94-161 mg/L. All boreholes complied with the cited limits for the measured parameters. In contrast, all hand-dug wells and the lake exceeded the 5-NTU turbidity guideline, while HW3, HW4 and HW5 exceeded 50 mg/L nitrate. Hand-dug wells also showed higher EC and TDS, indicating greater exposure to surface-derived inputs.

Table 2: Physicochemical Characteristics of Water Samples

Parameter	WHO Limit	BH1	BH2	BH3	BH4	BH5	HW1	HW2	HW3	HW4	HW5	LW1
pH	6.5–8.5	7.2	7.4	7.1	7.5	7.3	6.8	6.9	6.7	6.8	6.9	7.1
EC (µS/cm)	1500	420	510	580	640	690	980	1040	1180	1210	1105	970
TDS (mg/L)	1000	280	340	380	430	450	620	680	760	790	720	610
Turbidity (NTU)	5	2.1	2.5	2.8	3.1	3.5	8.4	10.2	12.5	14.6	11.8	18.3
Hardness (mg/L)	500	118	132	145	152	167	185	210	230	245	221	196
Nitrate (mg/L)	50	12.5	14.3	16.7	18.4	20.1	41.5	48.2	68.3	72.6	61.4	42.1
Chloride (mg/L)	250	32	38	42	48	51	86	102	116	125	118	95
Alkalinity (mg/L)	200	94	98	102	106	112	135	148	152	161	158	148

Hardness remained below the 500 mg/L WHO limit. Borehole hardness ranged from 118-167 mg/L, whereas hand-dug wells ranged from 185-245 mg/L and the lake was 196 mg/L. The higher hardness has mainly operational implications, including scale formation and increased detergent demand, rather than a direct health hazard at the measured concentrations. These patterns are consistent with Nigerian groundwater studies reporting greater dissolved-ion loading in shallow sources (Ezechinyere & Stanislaus, 2023; Opasola et al., 2025; Thomas, 2023).

3.2 Bacteriological Quality Assessment

Total coliform counts ranged from 0-85 CFU/100 mL. No E. coli was detected in BH1–BH5, whereas all hand-dug wells and LW1 were positive. The pattern indicates greater vulnerability of shallow sources to faecal contamination associated with poor sanitation, septic seepage, livestock activities and runoff.

Table 3: Bacteriological Characteristics of Water Samples

Source	Total Coliform (CFU/100 mL)	E. coli
BH1	0	ND
BH2	0	ND
BH3	1	ND
BH4	2	ND
BH5	1	ND
HW1	35	Present
HW2	49	Present
HW3	78	Present
HW4	85	Present
HW5	69	Present
LW1	45	Present

3.3 Comparative Evaluation with WHO (2017) and NIS/NSDWQ (2015) Standards

Boreholes complied with the cited WHO (2017) and NSDWQ (2015) requirements for pH, EC, TDS, hardness, chloride, alkalinity and nitrate. All hand-dug wells exceeded the turbidity guideline, and HW3-HW5 exceeded the nitrate limit. E. coli occurrence in all hand-dug wells and the lake makes these sources unsuitable for direct drinking without treatment. The results reinforce evidence that shallow groundwater is more susceptible to anthropogenic contamination than deeper aquifer sources.

3.4 Water Quality Index (WQI) Assessment

WQI values ranged from 42.6-136.2. BH1–BH5 ranged from 42.6-57.8 and were classified as Good; HW1 and HW2 were Poor (88.5-97.3); HW3, HW4 and HW5 were Unsuitable (118.7-136.2); and LW1 was Poor (95.2). The principal contributors to deterioration were nitrate, EC, turbidity and coliform contamination.

Table 4: Water Quality Index Classification

Sample	WQI	Classification
BH1	42.6	Good
BH2	46.1	Good
BH3	49.4	Good
BH4	53.2	Good
BH5	57.8	Good
HW1	88.5	Poor
HW2	97.3	Poor
HW3	128.4	Unsuitable
HW4	136.2	Unsuitable
HW5	118.7	Unsuitable
LW1	95.2	Poor

3.5 Irrigation Suitability Assessment

SAR ranged from 2.1-4.9, Na% from 24.3-44.1%, KR from 0.31-0.82, PI from 61.5-72.4% and RSC from 0.8-1.9 meq/L. All sampled sources were usable for irrigation, with BH1-BH2 classified Excellent, BH3-BH5, HW1-HW2 and LW1 Good, and HW3-HW5 Permissible. The latter category does not mean unsafe irrigation; it indicates a higher sodium-management requirement. Recommended controls are a 10-20% leaching fraction, gypsum at 2-5 t/ha every 3-5 years, salt-tolerant crops, soil EC/SAR monitoring and blending where feasible.

Table 5: Irrigation Water Quality Indices

Source	SAR	Na%	KR	PI (%)	RSC	Classification
BH1	2.1	24.3	0.31	61.5	0.8	Excellent
BH2	2.4	26.2	0.35	63.0	0.9	Excellent
BH3	2.8	28.5	0.44	65.2	1.0	Good
BH4	3.1	30.8	0.49	66.8	1.1	Good
BH5	3.3	32.1	0.55	67.5	1.2	Good
HW1	3.9	36.4	0.64	68.1	1.4	Good
HW2	4.2	39.5	0.71	69.8	1.6	Good
HW3	4.6	42.7	0.78	71.6	1.8	Permissible
HW4	4.9	44.1	0.82	72.4	1.9	Permissible
HW5	4.5	41.8	0.76	70.9	1.7	Permissible
LW1	3.9	38.2	0.69	69.4	1.5	Good

3.6 Engineering Implications

3.6.1 Borehole Design Specifications

The superior quality of borehole samples (WQI: 42.6-57.8; *E. coli*: absent; turbidity: <5 NTU; nitrate: 12.5-20.1 mg/L) supports source substitution as the preferred intervention for communities reliant on contaminated shallow wells. Borehole specifications are presented as preliminary design ranges rather than fixed values. Recommended parameters include: 80-120 m depth, 60-100 m screened interval, 150 mm PVC-U casing, 0.5-1.0 mm continuous-slot screen, 3-6 mm gravel pack, and 3 m bentonite sanitary seal-final dimensions to be confirmed by site-specific lithological logs, sieve analysis, and well-development results. Abstraction is via a solar-powered 1.5-3.0 HP submersible pump delivering approximately 2-5 L/s at 30-50 m total dynamic head, with final capacity determined by pumping-test results and community demand.

Estimated cost is ₦11.61-17.38 million per installation, covering survey, drilling, casing, screen, gravel pack, sanitary works, solar pumping, distribution, and supervision. The exchange rate adopted for this conference version is ₦1,350/USD (August 2026); direct Naira estimates are retained from the source manuscript (₦1,420/USD). Each borehole serves 300–500 persons, with a six-month implementation period encompassing hydrogeological survey, drilling and casing, pump installation and testing, community training, and baseline water-quality testing.

3.6.2 Treatment Train Configurations for Hand-Dug Wells

All hand-dug wells require treatment before drinking because turbidity was 8.4-14.6 NTU, coliform counts were 35-85 CFU/100 mL and E. coli was present. Three scalable configurations are proposed. Configuration A serves 5-7 persons using a 200-L sedimentation tank (24-h retention), three 100-L slow-sand filter drums and chlorination at 2-4 mg/L with 30-min contact; capital cost is ₦138,375 with annual O&M of ₦13,838. Configuration B serves 100-300 households using a 5,000-L baffled settling tank, roughing filter, 2-m-diameter × 1.5-m biosand filter and solar UV or chlorination; capital cost is ₦415,125 with chlorine or ₦718,875 with UV, with annual O&M of about ₦42,000. Configuration C serves 1,000-5,000 persons using coagulation–flocculation, sedimentation, rapid sand filtration and chlorination; capital cost is ₦10.1-16.9 million, with ion exchange for nitrate at ₦13.5-23.6 million or blending at ₦8.1-13.5 million where required. For Jere, borehole source substitution is preferred to intensive nitrate-removal treatment where feasible.

3.6.3 Wellhead Protection and Setback Distance Enforcement

Source-protection measures are proposed around boreholes and hand-dug wells as engineering control distances for Jere LGA, not universal statutory requirements, with final protection radii to consider local hydrogeology, groundwater flow, aquifer vulnerability, contaminant characteristics, well construction, and Nigerian regulations. Hand-dug wells require sanitary wellheads comprising a 1.5 m × 1.5 m × 0.15 m concrete platform, drainage apron, lockable cover, casing raised 0.3-0.5 m above platform, and bentonite or bentonite–cement sanitary seals to 3 m depth to reduce contaminant ingress.

Recommended setbacks for boreholes and hand-dug wells respectively are: septic systems 50 m and 30 m; agricultural fields 100 m up-gradient and 50 m; livestock areas 50 m and 30 m; refuse dumps 100 m and 50 m; fuel stations 150 m and 100 m. Within protection zones, waste disposal, wastewater discharge, sanitation facilities, and contaminating activities should be restricted, with enforcement combining GIS mapping, registration and licensing, annual compliance verification, and community-based surveillance.

3.6.4 Irrigation Water Management Strategy

Excellent and Good sources can be managed with standard irrigation practices and annual soil monitoring. HW3-HW5 require active management because SAR is 4.5-4.9: apply gypsum at 2-5 t/ha every 3-5 years, maintain a 10-20% leaching fraction, use salt-tolerant crops such as millet, sorghum and date palm, monitor soil EC and SAR at least twice annually, maintain drainage and blend with lower-SAR water when available. Sensitive crops such as onion and pepper should preferentially use the better-quality borehole sources.

3.6.5 Groundwater Monitoring System

A tiered monitoring system is recommended: Tier 1 comprises quarterly manual sampling of all sources for pH, EC, TDS, nitrate, turbidity, coliform, and *E. coli* at ₦2.025-3.375 million/year; Tier 2 adds semi-automated sensors at 3-5 high-risk sites (₦6.75-10.1 million capital, ₦4.05-6.75 million/year O&M); Tier 3 provides telemetry and web dashboards (₦27-40.5 million capital, ₦20.25-33.75 million/year O&M) if capacity develops. Yellow alerts: nitrate 40-45 mg/L, turbidity 3-5 NTU, *E. coli* 1-10 CFU/100 mL, EC 1,200-1,500 µS/cm; red alerts: nitrate >50 mg/L, turbidity >5 NTU, *E. coli* >10 CFU/100 mL, EC >1,500 µS/cm.

The costs are preliminary estimates for planning and comparison, not fixed market prices; they require BOQ, unit-rate analysis, equipment specs, labour, installation, and local market validation, with updates using current supplier quotes at procurement. The monitoring programme is an engineering planning framework; final costs depend on monitoring points, sampling frequency, parameters, lab charges, field measurements, transport, equipment, and duration, with BOQ assumptions retained as supporting documentation.

3.6.6 Implementation Roadmap

The five-year phased roadmap priorities: Year 1-community awareness, wellhead platforms at HW1-HW5, household treatment kits for 500 households, and quarterly baseline monitoring; Years 2-3-5-10 priority boreholes, community bio-sand filters at three hand-dug wells, GIS-based setback enforcement, and annual soil monitoring; Years 4-5-Tier 2 monitoring upgrade, sustainable agriculture programme, and groundwater-quality protection by-laws.

The 2026 population projection for Jere LGA (306,400-337,108 persons) is extrapolated from the 2006 NPC census (209,107-211,204), supported by World Population Review (337,108) and City Population (306,400), and serves as a planning estimate. For actual implementation, design population should be based on the most recent authoritative data, incorporating design period, growth rate, per-capita demand, and allowances for institutional, commercial, and livestock uses.

3.7 Study Limitations

The study involved only eleven locations (five boreholes, five hand-dug wells and one lake), limiting representation of spatial variability and giving the lake sample (n=1) little statistical power. Sampling was conducted during one campaign, so seasonal variability was not evaluated. Heavy metals, pesticide residues, hydrocarbons and emerging contaminants were outside the analytical scope. Strategic rather than random site selection may introduce selection bias. Irrigation indices were based on one ionic-composition dataset and could change seasonally. Future work should use larger wet- and dry-season samples, broader contaminant screening and spatially explicit monitoring.

4. CONCLUSION

The investigation demonstrates a clear quality contrast between deeper boreholes and shallow hand-dug wells in Jere LGA. Boreholes recorded WQI values of 42.6-57.8, turbidity below 5 NTU,

nitrate of 12.5-20.1 mg/L and no detected E. coli, whereas hand-dug wells showed elevated turbidity, widespread faecal contamination and nitrate up to 72.6 mg/L. HW3-HW5 were unsuitable for drinking and require priority intervention. All sampled sources remained generally usable for irrigation, but HW3-HW5 require active sodium-management practices because of their Permissible classification. The engineering response should therefore prioritise source substitution through protected boreholes, multi-barrier treatment where shallow wells remain necessary, wellhead protection and setback enforcement, differentiated irrigation management, and a tiered monitoring system. These interventions directly address the identified microbial, nitrate, turbidity and sodium hazards and support SDGs 2, 3 and 6. The study consequently contributes to Innovative Resource Utilization and Management and Emerging Technologies for Safe Engineering Practices and Environmental Protection by converting site-specific water-quality evidence into implementable engineering decisions.

ABSTRACT

Construction & Demolition (C&D) waste has been identified as one of the major problems facing rapidly growing cities in Nigeria and has both environmental and economic consequences. The methods through which waste is managed in this industry continue to be largely linear: dispose by default. Circular economy (CE) principles provide a pathway towards sustainable construction; however, their implementation in Nigeria's construction sector remains poorly researched. This study examines CE awareness, practices, attitudes, and barriers using a cross-sectional survey of 110 construction professionals. A seven-item CE-attitude scale was tested for internal consistency (Cronbach's $\alpha = 0.803$). Professional role, years of experience, and educational attainment were examined in relation to CE attitudes and practices using chi-square tests and Spearman correlation. There were no statistically significant differences between professionals' awareness of CE in terms of their professional roles ($p = 0.71$) or levels of education ($p = 0.81$). Yet, professionals' roles turned out to be significantly correlated with the frequency of waste separation ($\chi^2 = 10.86$, $p = 0.028$) and readiness to engage in CE practices if incentivized ($\chi^2 = 11.19$, $p = 0.025$). While contractors and builders were more behaviorally responsive to CE than engineers, there were no statistically significant differences between their levels of awareness of the concept. The quality of recycled materials was found to be the most influential factor when respondents decided to pay for them ($\rho = 0.61$). The main barriers included the lack of awareness (59.1%), the lack of proper recycling infrastructure (48.2%), and the lack of regulation enforcement (40.0%). Guaranteed markets (49.1%) and technical training (47.3%) appeared to be the most important enablers of CE.

Keywords: *circular economy; construction and demolition waste; barriers; enablers; and sustainable construction*

1. INTRODUCTION

The construction industry is among the biggest users of natural resources across the world, accounting for 35% of all material consumption and 40% of the annual waste (Dsilva et al., 2023). The C&D waste types comprise concrete, masonry, wood, metal, glass, plastics, and asphalt. The sources of such wastes are construction, remodelling, and demolition of structures, whereby the occurrence of C&D wastes is common in fast and poorly regulated urban cities. Nigeria offers a useful example, where the construction industry contributes about 3–5% to the nation's GDP (National Bureau of Statistics, 2023). However, the inefficiency in materials utilization, inadequacy of regulation regarding demolition works, and lack of recycling opportunities negatively impact the competitiveness of the industry and overall sustainability goals of the country.

The Federal Capital Territory of Nigeria, Abuja, is an illustrative example in this field. Being an urban center, which has been expanding continuously for the last few decades in terms of residential areas, commerce, and infrastructure, Abuja produces significant amounts of construction and demolition (C&D) waste. A considerable amount of C&D waste in the city ends up in either unused lands, water bodies, or roads instead of being recovered (Lanrewaju, 2012; Ogunseye et al., 2023; Unegbu et al., 2024). However, such state of affairs contradicts the goals of SDG 11 (Sustainable Cities and Communities), SDG 12 (Responsible Consumption and Production), and SDG 13 (Climate Action). On the other hand, it is an untapped resource due to the fact that there is easily recoverable C&D waste in Abuja.

A circular economy (CE) approach that replaces the traditional "take-make-dispose" model through initiatives that help to reduce, reuse, recycle, and regenerate materials via closed loops

(Kirchherr et al., 2017, 2023) is one such model that has gained traction across the globe to address this problem. Countries like Germany, Sweden, and the Netherlands have shown that CE-related initiatives can help recover 80–90% of C&D wastes (Bonifazi et al., 2025; Shajidha & Mortula, 2025). The construction sector in Nigeria, on the other hand, is still rooted in linear processes with inefficient use of resources, poor regulation enforcement, and lack of awareness among stakeholders about CE (Bello & Idris, 2023; Unegbu et al., 2024).

The consistent finding across the Nigerian studies on CE among construction professionals is that there is a knowledge-to-action gap whereby most construction professionals claim to have knowledge about CE principles, but very few actually practice them (Unegbu et al., 2024). The current study aims to establish the reasons for the failure of knowledge translation into action and identify professional attributes that determine the size of the gap. The specific objectives are to (i) assess CE awareness and current C&D waste management practices among Abuja construction professionals; (ii) identify and rank key barriers and enablers of CE adoption; and (iii) test whether professional role, experience, and education are statistically associated with CE attitudes and behaviors. The remainder of the paper covers literature (Section 2), methodology (Section 3), results (Section 4), discussion (Section 5), and conclusions (Section 6).

2. LITERATURE REVIEW

2.1 The Circular Economy: Principles and Models

The circular economy (CE) has emerged as a widely recognized tool to harmonize economic growth with sustainable development. Unlike the linear economy model where the flow of materials follows a straight-line trajectory of "take-make-use-waste," the CE model entails a cyclic approach in which products, parts, and materials retain their value through processes of reusing, repairing, remanufacturing, and recycling (Kirchherr et al., 2017). This concept has been defined as a policy framework since the 1990s through initiatives of the Ellen MacArthur Foundation and the European Union (Kirchherr et al., 2023; Velenturf & Purnell, 2021). The circular economy is no longer seen as a solution to minimizing waste but as a revolutionary paradigm that considers economic, environmental, and social goals simultaneously.

The CE approach within the built environment is implemented through an integrated set of approaches that include elimination of waste at the source, sustaining the flow of materials through reuse and recycling, regeneration of natural systems, and systems thinking within the value chain (Velenturf & Purnell, 2021). In the built environment, material use constitutes around 40% of the overall material demand on Earth along with waste production, making the built environment one of the sectors where the CE can be most impactful.

2.2 Barriers and Enablers: A Four-Domain Framework

The literature clearly outlines the barriers and motivating factors behind the C&D waste recycling process through four related areas (Table 1). This typology, which was synthesized from international and local sources, serves as the foundation behind the barriers and motivators in the questionnaire for this study.

Table 1: Barriers and enablers of CE adoption in C&D waste management, by domain.

Domain	Key Barriers	Key Enablers
Technical	Heterogeneous, contaminated waste streams; absence of advanced sorting/recycling equipment; and designs that do not support disassembly.	On-site segregation; lean construction practices; optimized mechanical recycling
Economic/Market	Recycling is perceived as costlier than disposal; weak market demand; low trust in recycled material quality; unpredictable supply chains	Landfill taxes, subsidies for recyclers; cost savings from waste minimization
Institutional/Policy	Weak enforcement of regulations; absence of quality standards for recycled materials; few staff assigned to waste management	Mandatory waste management plans; green building certification; government procurement mandates
Social/Cultural	Low awareness; poor workmanship; prevailing use-and-discard culture; community nuisance from poor practice	Targeted training, incentive, and accountability systems; stakeholder engagement

2.3 Prior Survey-Based CE Studies in Nigeria and Comparable Contexts

Survey-based studies investigating the CE awareness in the construction industry of Nigeria are increasing in number. According to Unegbu et al. (2024), there is a significant gap in CE implementation where 58% of respondents had knowledge about CE principles, but only 15% implemented them, whereas 68% of companies were still using unsustainable practices in disposal. The major challenges included financial constraints (about 70%), lack of enforcement of regulations (65%), and poor infrastructure (63%). Similarly, Bello and Idris (2023) highlight that the adoption of CE in Nigeria is in a "know without doing" phase. In similar environments, a study conducted in Addis Ababa found that more than three-quarters of companies did not have staff designated for handling waste management issues (Shajidha & Mortula, 2025).

From a methodological perspective, the literature is highly descriptive in nature, recording frequency and average Likert scale ratings but rarely testing for scale validity or evaluating whether there is an association between respondents' demographics and their outcomes. One of the major policy-oriented questions that remain open is the following: Is the awareness-performance gap general in the construction sector, or is it limited to certain professions?

2.4 Conceptual Framework

The research has been conducted in the context of circular economy theory, which assumes that material value should be kept by repeating use, recovery, and regeneration continuously (Velenturf & Purnell, 2021). Figure 1 illustrates the theoretical framework where the link between CE approaches and the processes of construction and demolition waste management, along with enabling conditions that condition adoption outcomes, has been considered. The research framework is the basis for the analysis in this research: first, there will be the evaluation of CE knowledge and application; second, barriers and enabling factors will be analyzed; and, third, the moderation effect will be tested.

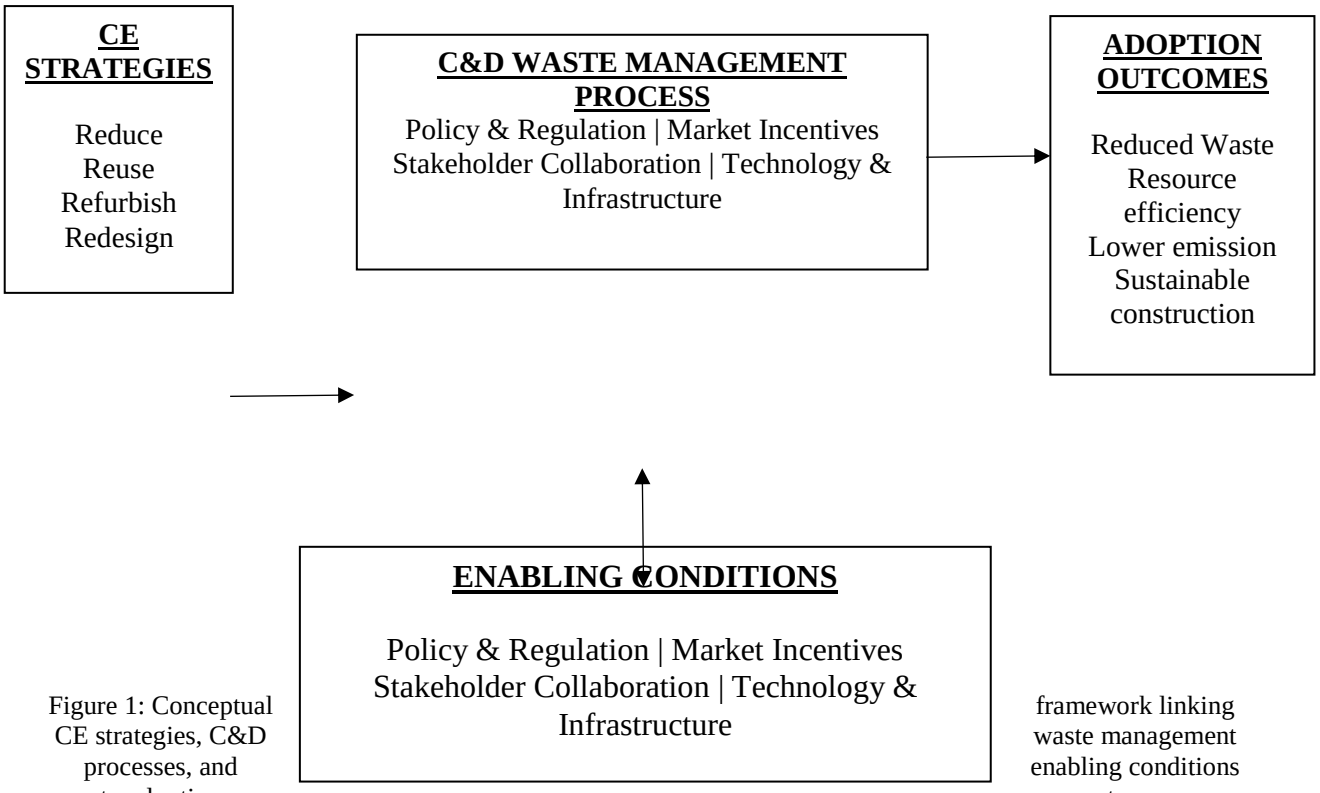

Figure 1: Conceptual framework linking CE strategies, C&D waste management processes, and enabling conditions to adoption outcomes.

3. METHODOLOGY

3.1 Research Design

In order to examine awareness, behaviors, and perception about CE barriers/enablers among construction professionals in Abuja, Nigeria, the study uses a descriptive-correlational questionnaire survey research design. In addition to presenting descriptive statistics about the data, it tests whether there exists a statistical relationship between the demographic variables of the respondents and CE-related behaviors/attitudes/perceptions. This paper reports only the perceptual and survey component of the broader research project. The associated waste-quantification component is outside the scope of the present paper and will be reported separately.

3.2 Study Area

This study was conducted in the Federal Capital Territory (FCT), Abuja, Nigeria. It is selected as the study area because it is among the fastest-growing construction markets in the country, with sustained residential, commercial, and infrastructural development generating substantial C&D waste volumes that are largely managed through informal or unregulated channels (Abah et al., 2023).

3.3 Population and Sampling

The sample for the study involved construction practitioners in Abuja; this included engineers, architects, quantity surveyors, contractors, builders, site supervisors, waste managers, and policymakers. Purposive sampling with participation in construction activities was employed to select the respondents, and a total of 111 questionnaire forms were issued, resulting in 110 valid responses since one participant withdrew his consent.

For inferential testing, professional roles were grouped into three categories to maintain adequate cell sizes: engineers/design professionals, including architects (n=76); contractors/builders (n=24); and managerial/policy professionals (n=7). This classification was chosen to facilitate the application of the requirements of the chi-square test. The fourth classification ('Others', n=3) was not included in any of the role-related chi-square tests, since the small size of its cells might lead to

insufficient expected values. Therefore, role-related tests were carried out based on n=107, while education/experience-related tests were on n=110.

3.4 Research Instrument

The data were collected using a standardized questionnaire that had five sections:

- Section A: Demographic and professional characteristics of the respondents
- Section B: Existing practices of C&D waste management
- Section C: Knowledge about the circular economy (CE)
- Section: D: Challenges/barriers and enablers for recycling C&D waste
- Section E: Instruments of policy and incentives

Most questions were answered on a five-point Likert scale (1 = strongly disagree to 5 = strongly agree). Content validity of the questionnaire was ensured by its verification by experts and practitioners.

3.5 Scale Reliability

A composite measure of CE-attitudes comprising seven Likert items based on Sections C and D was created and assessed for internal consistency using Cronbach's alpha prior to performing any further analysis. Seven Likert items were kept since there was acceptable correlation between all of them and a consistent alpha value (Section 4.1).

3.6 Data Analysis

The analysis was conducted in three steps. Firstly, the descriptive analysis involved calculating frequencies, percentages, means, standard deviation, and skewness. Secondly, the chi-square test of independence was used to establish the relationship between categorical respondent variables and categorical outcome variables. The Likert response was reduced into three categories (disagree 1-2, neutral 3, and agree 4-5), while the effect size was calculated using Cramér's V. Thirdly, the Spearman rank correlation (ρ) analysis was conducted on the relationship between the seven CE-attitude variables as well as the relationship between experience and each of the attitude variables. Spearman's rank correlation was used because the CE-attitude variables were measured using five-point Likert-scale responses, which are ordinal in nature. The non-parametric Spearman procedure was therefore considered appropriate for assessing monotonic associations without requiring the assumptions associated with Pearson correlation.

3.7 Ethical Considerations

Participation was entirely voluntary, and informed consent was obtained from all respondents. No personally identifying information was collected, ensuring respondent anonymity throughout.

4. RESULTS

4.1 Respondent Profile and Scale Reliability

Out of 111 surveys that were distributed, 110 responses were valid. Out of the total number of respondents, most were male (57, 91.8%), held a bachelor's degree (68.2%), and had fewer than five years of experience (58.2%). Engineering was the largest profession group (69.1%), while contractor/builders came second (21.8%), and management/policymaking third (6.4%).

Table 2: Respondent profile (n=110).

Characteristic	Category	n	%
Gender	Male	101	91.8
	Female	8	7.3
	Prefer not to say / Missing	1	0.9
Professional Role	Engineer (incl. Architect)	76	69.1
	Contractor / Builder	24	21.8
	Management / Policy	7	6.4
	Other (excl. from role tests)	3	2.7
Years of Experience	≤5 Years	64	58.2
	6–10 Years	35	31.8
	>10 Years	11	10.0
Educational Qualification	Bachelor's Degree	75	68.2
	Master's Degree	22	20.0
	Diploma / NCE	7	6.4
	PhD and above	3	2.7
	Secondary School (SSCE)	3	2.7

The internal consistency of the CE attitude scale consisting of seven items was satisfactory (Cronbach's $\alpha = 0.803$, $n = 110$), exceeding the generally acceptable standard of 0.70. The correlations between each item and total scores ranged between 0.39 (adequacy of regulation and enforcement) and 0.62 (quality beliefs). The elimination of any one of the items could increase the alpha value by at most 0.81; hence, all the items were kept.

Table 3: Descriptive statistics and reliability indices for the CE-attitude scale (n=110).

Item (Likert 1–5)	Mean	SD	Median	Skewness	Item-total r	n
Awareness of CE concept	3.67	1.12	4	−0.68	0.51	110
Knowledge of recycling techniques	3.56	1.11	4	−0.44	0.61	110
Organization has C&D waste policy	3.29	1.22	3	−0.36	0.54	110
Regulation/enforcement adequacy	3.04	1.31	3	0.03	0.39	110
Recycled materials meet quality needs	3.61	1.01	4	−0.25	0.62	110
Willingness to pay more	3.58	1.00	4	−0.75	0.58	110
Will adopt CE if incentives are introduced	3.86	1.00	4	−0.78	0.57	110
Cronbach's α = 0.803 (n=110)						

Note: Likert scale: 1=Strongly Disagree, 5=Strongly Agree. Item-total r = corrected item-total correlation.

4.2 Current C&D Waste Management Practices

Dumping of waste in dumping sites and landfills has been identified as the major method of waste disposal practice adopted by 80.2% of the respondents (n=89). Informal on-site reuse of waste ranked second at 42.3%, followed by selling waste to informal recyclers at 34.2%, and formal recycling at 17.1%. Waste separation too showed a degree of inconsistency in practice, with 39.6% not separating waste at all, 41.4% doing so occasionally, and only 19.0% doing so regularly.

4.3 CE Awareness and Applicability

The mean scores (Table 3) show that there is moderate to high CE awareness (M = 3.67) and moderate knowledge about the methods of recycling (M = 3.56). There is also a moderate belief in the quality of recycled products (M = 3.61) and moderate willingness to pay extra (M = 3.58). The highest mean score is obtained for conditional adoption (M = 3.86, SD = 1.00), while perceived adequacy of regulations scores the lowest and the most uniformly (M = 3.04, skewness ≈ 0.03).

4.4 Association Between Professional Characteristics and CE Attitudes/Practices

Chi-square tests for independence were used to investigate the relationships between respondent characteristics and circular economy (CE) results (Table 4). Professional role has been shown to be significantly related to waste segregation frequency ($\chi^2 = 10.86$, df = 4, p = 0.028, V = 0.225) and intention to practice CE when offered certain incentives ($\chi^2 = 11.19$, df = 4, p = 0.025, V = 0.229). There is no significant relationship between professional role and awareness of circular economy (p = 0.709). Education is not related to awareness of CE (p = 0.810). Years of experience are not significantly related to willingness to pay (p = 0.867) and regulatory effectiveness (p = 0.652).

Table 4: Chi-square tests of association between respondent characteristics and CE outcomes.

Test	**χ^2**	**df**	**n**	**p**	**Cramér's V**	**Result**
Role × Waste separation frequency	10.86	4	107	0.028	0.225	Significant*
Role × Adoption-if-incentives	11.19	4	107	0.025	0.229	Significant*
Role × CE awareness	2.14	4	107	0.709	0.100	Not significant
Education × CE awareness	4.49	8	107	0.810	0.143	Not significant
Experience × Willingness to pay	1.27	4	107	0.867	0.076	Not significant
Experience × Regulation adequacy	2.46	4	107	0.652	0.106	Not significant

Note: *p < 0.05. Cramér's V: <0.10 = negligible; 0.10–0.29 = small; 0.30–0.49 = moderate effect. Role-based tests exclude the 'Other' category (n=3) and therefore use n=107; all other tests use the full sample (n=110).

The cross-tabulation table for the professional roles and waste separation is illustrated in Figure 2 below. Of the 24 contractors/builders, 9 often/always separated their waste, while 1 never/rarely did, and in contrast, of the 76 engineers, 37 often/always separated their waste, and 18 never/rarely did. The variation in behavior but not in awareness is the main finding of this research.

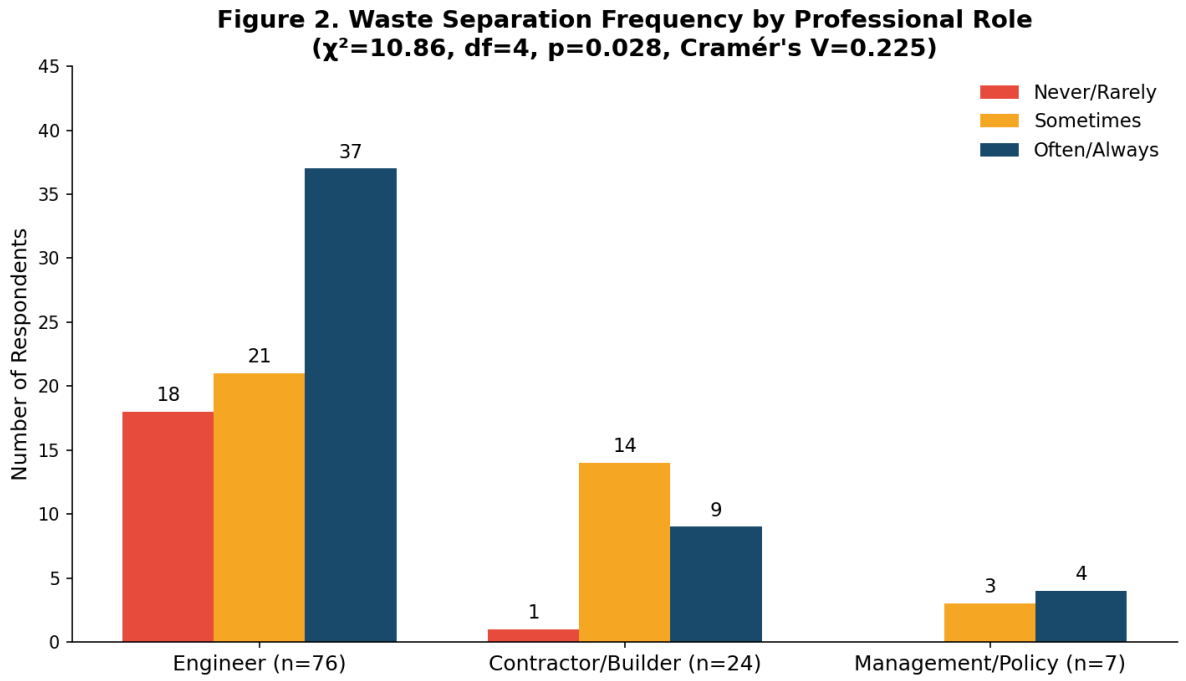

Figure 2: Waste separation frequency by professional role (χ^2=10.86, df=4, p=0.028, Cramér's V=0.225).

Supplementary ordinal correlation analysis found that years of experience were positively correlated with knowledge of recycling techniques (ρ=0.22, p=0.022) and adoption of incentives (ρ=0.26, p=0.006), though effect sizes were modest. All other experience correlations were non-significant (p > 0.06).

4.5 Barriers to C&D Waste Recycling

Barriers mentioned by the respondents have been presented in Table 5 on the basis of their frequency of mention. Lack of awareness was found to be the highest barrier, mentioned by 59.1% of respondents, followed by lack of recycling facilities (48.2%) and weak regulation/enforcement (40.0%).

Table 5: Ranked barriers to C&D waste recycling in Abuja (n=110; multiple selection, up to 3).

Barrier	**n**	**% of respondents**	**Rank**
Lack of awareness	65	59.1	1
Lack of recycling facilities	53	48.2	2
Weak regulation or enforcement.	44	40.0	3
High cost of processing.	42	38.2	4
Logistical challenges (transport/storage)	31	28.2	5
Preference for new materials	31	28.2	5
Low market demand for recycled materials	28	25.5	7

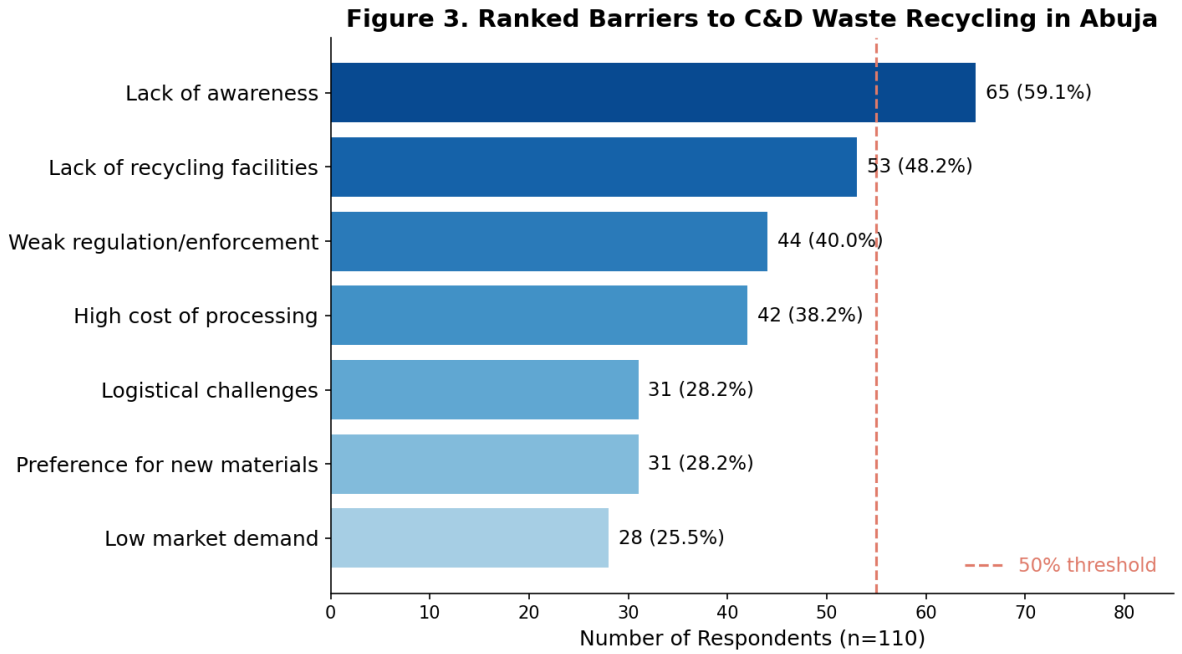

Figure 3: Ranked barriers to C&D waste recycling in Abuja (n=110). A dashed line indicates a 50% threshold.

4.6 Enablers and Preferred Incentives

The incentives that were seen to be more effective in fostering the use of CE have been highlighted in Table 6 below. The incentive that was the most widely selected was the assurance of markets for recycled products (49.1%), followed by technical training and development (47.3%), grant provision of recycling equipment (42.7%), and recycling legislation (40.9%). Respondents could select up to two incentives; therefore, the percentages represent the proportion selecting each option and are not expected to sum to 100%.

Table 6: Incentives most likely to encourage greater CE adoption (n=110; multiple selection, up to 2).

Incentive	**n**	**% of respondents**
Guaranteed markets for recycled materials	54	49.1
Technical training & capacity building	52	47.3
Grants for recycling equipment:	47	42.7
Mandatory recycling regulation	45	40.9
Tax rebates or subsidies	39	35.5

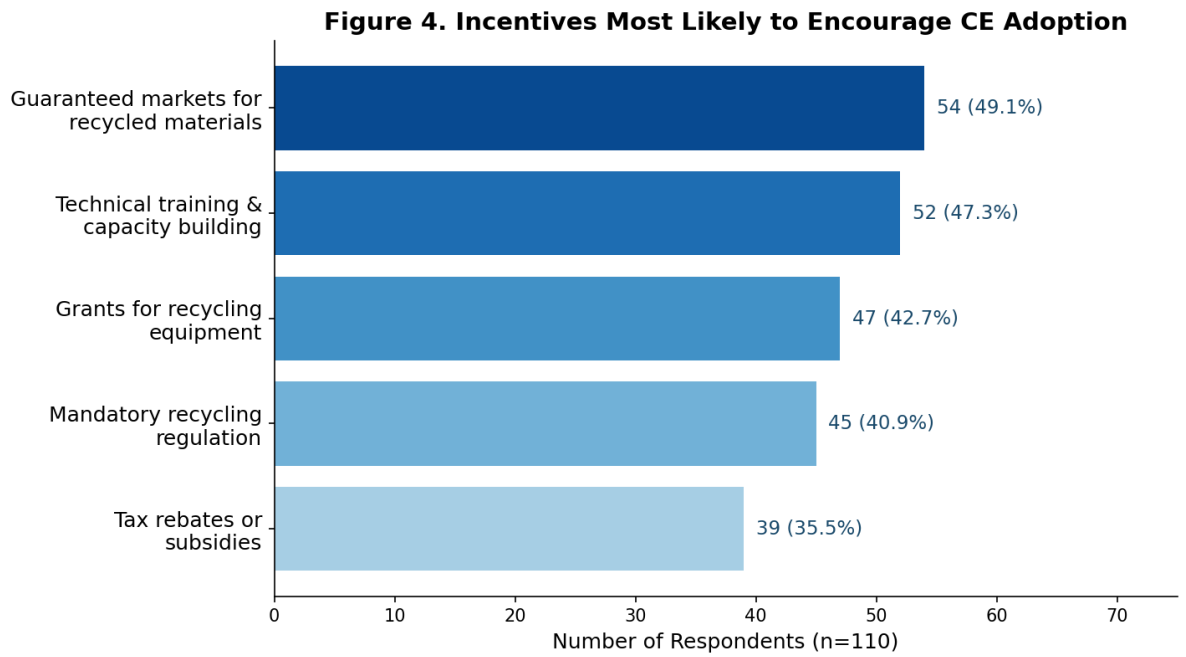

Figure 4: Preferred incentives for encouraging greater CE adoption (n=110).

4.7 Correlation Structure Among CE-Attitude Items

Positive Spearman rank correlations were found for all 21 pairings of the seven CE-attitude variables, thus demonstrating the internal consistency of the measure (see Table 7 and Figure 5). Strong correlations were observed between quality belief and willingness to pay ($\rho = 0.61$) as well as between knowledge and organizational policy ($\rho = 0.62$). There was a strong correlation between quality belief and adoption-if-incentives ($\rho = 0.52$), while there was an equally strong correlation between willingness to pay and adoption-if-incentives ($\rho = 0.50$). The variable that exhibited the weakest correlations was regulation adequacy ($\rho = 0.22–0.41$), owing to its institutional focus.

Table 7: Spearman correlation matrix of CE-attitude scale items (n=107–110).

	Awareness	**Knowledge**	**Org. Policy**	**Reg. Adequacy**	**Quality Belief**	**Willing to Pay**
Knowledge	0.46					
Org. Policy	0.40	0.62				
Reg. Adequacy	0.25*	0.22*	0.31**			
Quality Belief	0.38***	0.43***	0.44***	0.41***		
Willing to Pay	0.37***	0.48***	0.39***	0.35***	0.61***	
Adopt-if-Incentives	0.46***	0.37***	0.30**	0.29**	0.52***	0.50***
Note: * p<0.05; ** p<0.01; *** p<0.001; all non-starred values significant at p<0.0001						

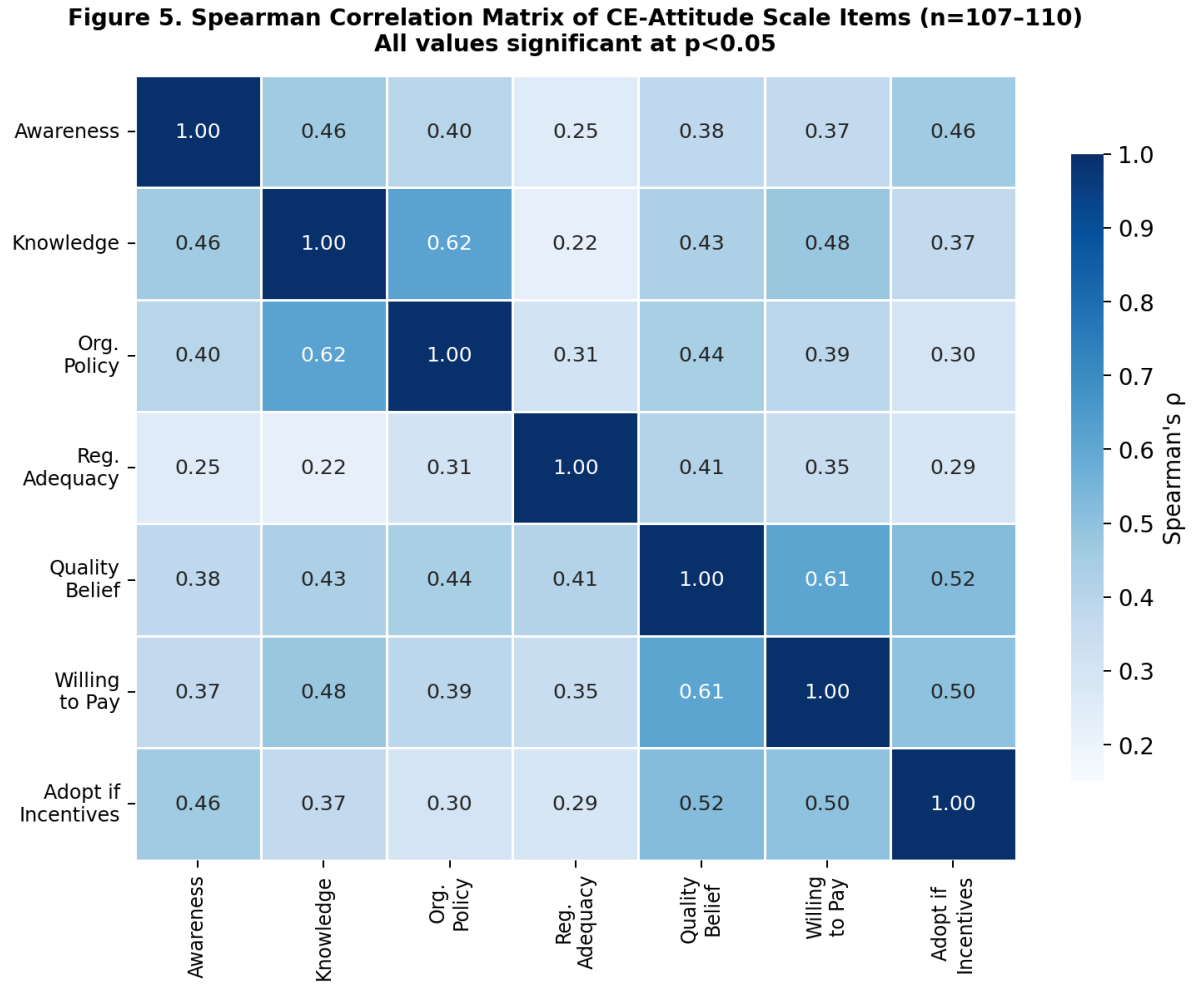

Figure 5: Spearman correlation heatmap of CE-attitude items. All values are significant at $p < 0.05$.

5. DISCUSSION

5.1 The Awareness-Practice-Incentive Decoupling

The main implication of the current study is that the gap in awareness and practice that is prevalent in Nigeria's construction CE literature (Unegbu et al., 2024) does not emerge due to differences in awareness amongst professionals. However, this interpretation should be considered in light of the measurement approach. Awareness was assessed through self-reported Likert-scale responses, which may capture perceived familiarity with CE concepts rather than the depth or quality of respondents' underlying knowledge. Consequently, professionals may report similar levels of awareness while still differing in their technical understanding or ability to apply CE principles in practice. There were no statistically significant differences in awareness levels with regard to role ($p = 0.709$) or education ($p = 0.810$). In turn, behavior related to waste separation and incentives showed statistically significant differences depending on role ($p = 0.028$ and $p = 0.025$, correspondingly). This separation of variables carries much significance in terms of intervention design, which should recognize that the variable on which it operates, "greater awareness leads to greater practice," is evenly distributed among professionals.

5.2 Quality Assurance as a Market-Side Lever

The most significant correlation found in attitude data was between perceptions regarding the quality of the recycled material and willingness to pay premium prices ($\rho = 0.61$). Such an observation adds empirically to the claim that has often been made in the academic literature but rarely tested, namely, that consumer acceptance of recycled construction and demolition (C&D) material is based more on perception of performance than on environmental attitudes (Ranasinghe et al., 2024). From

this, tools like certifications, material passports, and testing are demand-side tools, not auxiliary technical solutions. If there is a correlation between perception of quality and willingness to pay a higher price, it would mean that measures that enhance quality would be much more effective than measures focused on raising awareness in motivating recycling.

The findings provide evidence of particular engineering solutions that could transform the awareness of the circular economy into tangible construction techniques. It is clear that the strong correlation between the perception of the quality of recycled materials and willingness to pay should make engineering solutions to guarantee quality the key component of implementing the concept of a circular economy. This can be done through material testing, quality certification, and digital material passports for recycled construction materials. Similarly, the reported lack of recycling facilities indicates a need for accessible sorting and processing technologies, including on-site or decentralized systems for the separation, crushing, and recovery of recyclable construction materials. Such intervention techniques could be helpful in reducing the risk of contamination and increasing the reliability of recovered material. The implications of the research findings do not stop at awareness and policy but also help identify areas where the role of engineering and information technology is significant in transitioning from traditional waste management practices to material recovery and recycling techniques.

5.3 Why Contractors and Builders Behave Differently from Engineers

The most practically useful findings of this research can be obtained from the chi-square analysis carried out for every specific role separately. The contractors and the construction workers proved to separate waste more efficiently and be prepared to apply the principles of circular economy under the influence of motivation. The probable reason behind it, although not tested in the course of this research, is the fact that the contractors and builders may be more engaged in construction-related activity and, thus, more familiar with the waste generation process. It has to be considered a hypothesis that requires further research, as a cause-and-effect relationship has yet to be proven.

5.4 Institutional Constraints and the Limits of Voluntary Adoption

Lack of awareness was the most frequently reported barrier, cited by 59.1% of respondents, followed by lack of recycling infrastructure (48.2%) and weak regulation/enforcement (40.0%). However, this finding should be distinguished from the study's statistical assessment of individual CE awareness. The barrier question captures respondents' perceptions of constraints affecting CE adoption across the sector, whereas the awareness analysis measures respondents' own reported level of CE awareness. Thus, the fact that lack of awareness was frequently perceived as a sectoral barrier does not necessarily contradict the finding that reported awareness did not differ significantly by professional role or educational attainment. Respondents may, for example, perceive inadequate awareness among clients, workers, suppliers, policymakers, or other stakeholders even when their own reported awareness is relatively similar. It should be noted that infrastructure-/market-facilitating enablers such as guaranteed markets (49.1%) and equipment grants (42.7%) are preferred over regulation (40.9%) and tax incentives (35.5%), reflecting the view that the development of infrastructure and markets is more actionable for respondents compared to legislation. Internationally, a combination of regulatory, infrastructure investment, and market development was recognized as the most efficient approach to achieve high recovery rates of C&D in Sweden and Germany (Bonifazi et al., 2025). The attitude among the surveyed professionals is seen to be quite positive, with the respondents having moderately to highly aware levels and high conditional willingness to use CE ($M = 3.86$). When taking into consideration the other constraints such as infrastructure, markets, and enforcement, it is clear that there are many more constraints other than awareness.

The results from the analysis can be used to indicate that overcoming the implementation gap would require much more than just institutional reforms and awareness programs. The infrastructure and market gaps discussed above can be solved with a combination of C&D waste recovery systems, including source separation, mechanical sorting, processing, testing, and tracking of materials. For instance, proper sorting and crushing systems could enhance the process of recovering concrete, masonry, and other recoverable construction materials, whereas material testing and certification could

help generate the performance data required to improve market acceptance of recycled construction materials. The combination of the two approaches could create an efficient system of separation, processing, testing, and reutilization of recycled materials.

5.5 Limitations

There are various limitations to consider in relation to these results. Firstly, the use of cross-sectional methodology makes it impossible to determine causation. Secondly, purposive sampling prevents the results from being statistically generalized beyond the Abuja construction labor force. Thirdly, all practices under study are based on self-reporting and therefore prone to social desirability bias. Fourthly, the research is only done in one city. Fifthly, the limited size of the management/policy group (n = 7) limits the statistical comparison power. In addition, engineers and architects were combined into a single professional category for role-based analysis because of sample-size and cell-frequency considerations. Although this grouping supported the statistical analysis, the two professions may differ in training, responsibilities, and degree of site involvement, and their combination may therefore mask within-group differences.

6. CONCLUSION AND RECOMMENDATIONS

6.1 Conclusions

The current research seeks to assess the awareness level, practice, and determinants of construction waste management (CE) among 110 construction professionals in Abuja. For this purpose, a seven-question attitude scale (Cronbach's $\alpha = 0.803$) and inferential statistical techniques not typically applied to similar surveys of construction professionals in Nigeria have been used. Findings have confirmed the existence of the awareness-practice paradox previously reported in the literature as well as shed light on its nature: the awareness level is statistically consistent in terms of the professionals' positions and education levels; however, separation behaviors and reactions to incentives differ greatly depending on the position held. The belief in the high quality of the recycled materials proves to be the main determinant of willingness to pay, thus demonstrating that quality control is the key market-side determinant of CE. The findings also highlight the need to translate these behavioral and institutional insights into engineering practice through improved waste-separation systems, sorting and material-recovery technologies, standardized quality testing, and digital material traceability. Such interventions can help bridge the gap between willingness to adopt CE and actual recovery and reuse of construction materials."

6.2 Recommendations

For Policymakers and Regulators

Strengthen enforcement of existing C&D waste management regulations rather than relying on voluntary compliance; introduce mandatory waste management plans for projects above a defined size threshold; and develop standards and certification mechanisms for recycled C&D materials to directly address the quality-belief constraint identified as the strongest correlate of market willingness to pay.

For Training and Capacity-Building Programs

Target site-level contracting roles (contractors/builders) specifically, given this group's demonstrated stronger behavioral and incentive responsiveness; prioritize incentive-linked training formats, consistent with the high mean agreement (M=3.86) for incentive-conditional adoption; and invest in quality-assurance training as a mechanism for shifting quality perceptions that are holding back market demand.

For Industry and Market Actors

Make investments in engineering-based quality assurance measures such as standardized material testing, certification, and material passports to improve confidence in recycled construction materials. Construction firms and recyclers should also think about waste separation techniques at the job site, along with the proper technology for sorting, crushing, and recycling of the construction waste

materials. If there is no facility for centralized recycling available, then it will be better to use the decentralized technique. Digital material passports can further support traceability by recording material composition, quality characteristics, reuse potential, and recovery history. These methods can assist in turning willingness to embrace CE into actual processes of recovery and reuse, which is a problem for 48.2 percent of those surveyed, as lack of recycling facilities was mentioned as one of the key barriers. Public-private partnerships may be considered as a way to increase access to such facilities.

6.3 Suggestions for Future Research

Future research should:

i. Use probability-based sampling across a wider Abuja construction workforce to strengthen generalizability of role-based findings.
ii. Adopt a longitudinal design tracking the same cohort before and after specific regulatory or incentive interventions to test incentive responsiveness causally.
iii. Replicate this survey design in other rapidly urbanizing Nigerian cities to determine whether the awareness-practice decoupling observed in Abuja reflects a broader national pattern or FCT-specific conditions.

ABSTRACT
Heavy-duty haulage vehicles operating in tropical environments experience elevated engine oil temperatures that accelerate lubricant degradation and reduce engine reliability. Although Original Equipment Manufacturer (OEM) stacked-plate oil coolers provide compact thermal management, they are prone to irreversible fouling and limited serviceability under prolonged operation. Conventional shell-and-tube heat exchanger (STHE) retrofits offer improved maintainability but are generally oversized and excessively heavy, resulting in increased parasitic mass and reduced fuel efficiency. This study presents the design and optimization of lightweight STHE oil cooler for a Volvo D13 heavy-duty diesel engine using aluminum Alloy 6061-T6. Particle Swarm Optimization (PSO) was implemented in MATLAB to optimize the exchanger geometry, while the Kern design method was employed to evaluate thermal and hydraulic performance. The optimization objective was to minimize the total core weight subject to a maximum shell-side pressure drop of 50 kPa and an overall exchanger length of 1.5 m. The optimized TEMA E-shell configuration comprised 82 straight tubes (18 BWG), a shell diameter of 0.249m, a tube length of 1.471m, a tube outer diameter of 15.0 mm, and a baffle spacing of 0.064m. The resulting design achieved a total aluminum core weight of 23.80kg while maintaining shell-side and tube-side pressure drops of 49.98 kPa and 3.96 kPa, respectively, both within acceptable hydraulic limits for heavy-duty lubrication systems. The exchanger attained a thermal effectiveness of 83.3% with a Number of Transfer Units (NTU) of 2.37, demonstrating efficient heat transfer with low hydraulic resistance. The results confirm that integrating aluminum Alloy 6061-T6 with PSO-based geometric optimization significantly reduces exchanger weight while maintaining high thermal performance and hydraulic reliability. The proposed design provides a lightweight, maintainable, and locally manufacturable alternative to conventional oil coolers for heavy-duty diesel engines operating under demanding tropical conditions.

Keywords: *shell-and-tube heat exchanger; particle swarm optimization; Volvo D13; heavy-duty haulage*

1. INTRODUCTION

In Nigeria, heavy-duty haulage trucks are indispensable to the supply chain, facilitating approximately 95% of national freight movement (Federal Ministry of Works, 2025). However, operating in tropical Sub-Saharan environments with ambient temperatures frequently exceeding 35°C accelerates the thermal degradation of engine components. Excessive engine oil temperatures reduce lubricant viscosity, increase component wear, and ultimately shorten engine service life (Çengel & Ghajar, 2020). The Volvo D13 engine utilizes compact Original Equipment Manufacturer (OEM) stacked-plate oil coolers for thermal management; however, these sealed units are highly susceptible to irreversible fouling in dusty environments and cannot be serviced, leading to costly vehicle downtime.

Shell-and-tube heat exchangers (STHEs) provide a highly robust, maintainable alternative recommended for applications involving high operating pressures and severe environmental conditions due to their mechanical strength and serviceability (Shah & Sekulić, 2003). However, conventional STHE design heavily relies on empirical correlations like the Kern method, which utilizes conservative safety margins that frequently produce physically oversized and excessively heavy equipment (Kern, 1950). In automotive applications, this unnecessary structural mass is parasitic, increasing fuel consumption and carbon emissions, which directly conflicts with global climate change mitigation strategies for the transportation sector (IPCC, 2022).

To address these limitations, Particle Swarm Optimization (PSO) a swarm intelligence algorithm mimicking the social behaviour of bird flocks has emerged to effectively solve complex

nonlinear design problems (Kennedy & Eberhart, 1995). Previous studies demonstrate that PSO converges approximately 30% faster than Genetic Algorithms for STHE design (Fesanghary et al., 2009), consistently outperforming conventional deterministic techniques in constrained thermal design (Rao & Patel, 2010). Furthermore, automated MATLAB routines can significantly reduce material requirements within seconds. Balaban and Tadić (2021) developed a MATLAB-based automated shell-and-tube heat exchanger design program based on the Kern method. Their optimization reduced the required heat transfer area from 61.91 m² to 53.27 m², representing a 13.9% reduction in material requirement while obtaining the optimal solution within only a few seconds. Furthermore, recent evaluations of laboratory-scale STHEs operating specifically under northern Nigerian climatic conditions demonstrate the urgent need for robust computational optimisation to maximise thermal effectiveness in local applications (Hassan et al., 2025). Despite these advancements, existing literature frequently focuses on minimizing economic costs for stationary industrial applications (Khorasany & Fesanghary, 2009; Sai & Rao, 2022; Rao & Majethia, 2022). There remains a critical knowledge gap regarding weight minimization for automotive STHEs operating under strict spatial and tropical constraints.

Therefore, the aim of this study is to design and computationally optimize a lightweight STHE oil cooler retrofit for a Volvo D13 heavy-duty diesel engine. The specific objectives are to evaluate thermal-hydraulic performance using the Kern method, apply a PSO algorithm in MATLAB to minimize total aluminum core weight under strict pressure drop and spatial constraints, and validate hydraulic reliability using the Bell-Delaware method.

2. METHODOLOGY

2.1 Design Specifications and Material Selection

The shell-and-tube heat exchanger (STHE) was designed as a remote, chassis-mounted oil cooler for the 12.8-liter Volvo D13 heavy-duty diesel engine. The baseline thermal load was established at 63.0 kW, derived from a required temperature drop of 115°C to 90°C for a 1.2 kg/s mass flow rate of 15W-40 engine oil. To prioritize mechanical serviceability, the viscous engine oil was allocated to the shell side to exploit segmental baffle-induced turbulence, while the water-based engine coolant (3.0 kg/s at 85°C) was routed through the tube side because mineral scaling from coolant is effectively removed by passing a mechanical rod directly through the straight tubes, whereas the complex shell-side geometry is largely inaccessible for physical descaling. aluminum Alloy 6061-T6 was specified for both the shell and tube bundle (18 BWG, 1.25 mm wall thickness) to drastically minimize parasitic mass, leveraging its low density (2700 kg/m³) and superior strength-to-weight ratio compared to traditional carbon steel.

2.2 Mathematical Modelling

The Kern method was utilized to evaluate the thermal-hydraulic performance of the heat exchanger during optimization. The clean overall heat transfer coefficient (U_{clean}) was formulated based on the shell-side convective coefficient (h_s), the tube-side convective coefficient (h_t), and the thermal conductivity of the aluminum 6061-T6 tube wall (k_{wall}):

$$U_{clean} = \frac{1}{\frac{1}{h_s} + \frac{d_o}{d_i \times h_t} + \frac{d_o ln\left(\frac{d_o}{d_i}\right)}{2 \times k_{wall}}} \tag{1}$$

To evaluate the hydrodynamic constraints governing the required pumping power, the actual pressure drops for both the tube-side (ΔP_t) and shell-side (ΔP_s) were continuously calculated using the fundamental Kern method equations:

$$\Delta P_s = \frac{(f_s G_s^2\ (N_b + 1) D_s)}{(2\ \rho_h D_e \phi_s)} \tag{2}$$

$$\Delta P_t = \left(\frac{4\ f_t\ L\ n_p}{d_i} + 4\ n_p\right)\ (\frac{\rho_c v_t^2}{2}) \tag{3}$$

Where f_s and f_t are the respective friction factors, G_s is the shell-side mass velocity, N_b is the number of baffles, D_s is the shell inside diameter, ρ_h and ρ_c are the densities of the hot and cold liquid respectively, D_e is the equivalent diameter, φ_s is the viscosity correction factor, L is the tube length, n_p is the number of tube passes, d_i is the internal tube diameter and v_t is the tube-side fluid velocity.

2.3 Optimization Problem Formulation

The objective of the PSO algorithm was to minimize the total structural weight of the STHE core (f(X)), expressed as the sum of the shell and tube weights:

Minimize $f(X) = W_{tubes} + W_{shell}$ (4)

To ensure the physical manufacturability and hydraulic safety of the automotive retrofit, the objective function was subjected to strict inequality constraints:

$g_1(X) = \Delta P_s - 50 \leq 0$

$g_2(X) = \Delta P_t - 30 \leq 0$

$g_3(X) = L - 1.5 \leq 0$

$g_4(X) = D_s - 0.35 \leq 0$

2.4 Particle Swarm Optimization (PSO) Implementation

The optimization was executed in MATLAB using a swarm of 50 particles navigating a four-dimensional search space over 100 iterations. The decision variables vector X = [D_s, B, d_o, L] represented the core geometric parameters; specifically, the tube outer diameter (d_o) was established as a free optimisation variable bounded between 15.0 mm and 25.0 mm rather than a fixed constant. The kinematic movement of the particles was governed by velocity and position update equations, utilizing a dynamic inertia weight (w) that linearly decreased from 0.9 to 0.4 to transition the swarm from global exploration to localized exploitation. Mathematical penalty functions were embedded within the fitness evaluation to assign massive weight penalties to any geometric configuration that violated the defined pressure or spatial constraints, effectively forcing the algorithm to abandon those localized spaces.

The kinematic movement of the particles was governed by the velocity and position update equations:

$$v_i^{k+1} = wV_i^k + c_1 r_1 \left(P_{best,i} - X_i^k\right) + c_2 r_2 \left(G_{best} - X_i^k\right) \quad (5)$$

$$X_i^{k+1} = X_i^k + V_i^{k+1} \quad (6)$$

Where w is the dynamic inertia weight, c_1 and c_2 are acceleration coefficients, and r_1 and r_2 are stochastic random variables.

3. RESULTS AND DISCUSSION

3.1 PSO Convergence and Geometric Parameters

The PSO algorithm successfully navigated the geometric constraints, converging upon the global minimum after approximately 40 iterations.

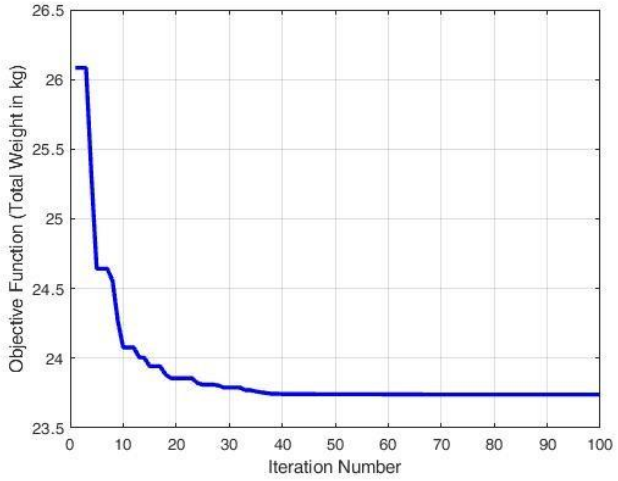

Figure 1: PSO Convergence Curve showing the minimization of total weight over successive iterations.

The dynamic inertia weight mechanism effectively transitioned the swarm from global exploration to localized exploitation, yielding an optimized core mass of 23.80 kg. The optimal TEMA E-shell configuration comprised 82 straight tubes, an inner shell diameter of 0.249 m, a tube length of 1.471 m, and a baffle spacing of 0.064 m. notably, the algorithm successfully drove the tube outer diameter to its absolute lower bound (15.0 mm) to strictly maximise the surface to area to volume ratio within the confined shell. The resulting baffle-to-shell diameter ratio (0.26) validated TEMA standards while maximizing shell-side turbulence. By utilizing aluminum 6061-T6 and optimal swarm sizing, the algorithm successfully eliminated the substantial excess mass inherent in traditional manual STHE design heuristics; an actual comparative baseline calculation utilising the unoptimized Kern method for this specific 63.0 kW thermal duty yielded a theoretical core mass of 58.6 kg.

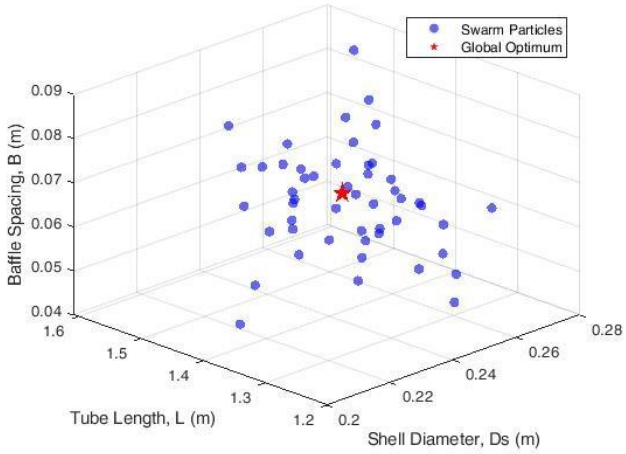

Figure 2.3: D visualization of the swarm particles navigating the geometric design space to isolate the global optimum.

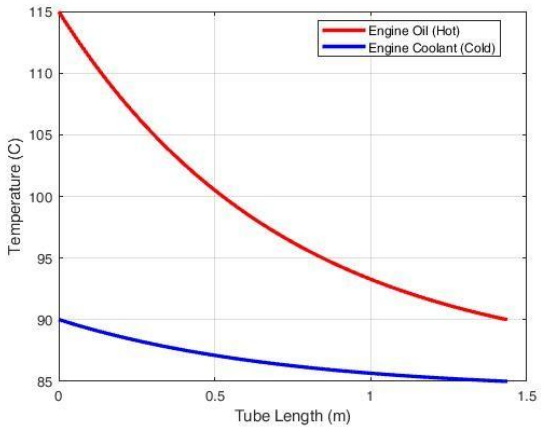
3.2 Thermal-Hydraulic Performance

The optimized design successfully managed the 63.0 kW thermal load, achieving a Number of Transfer Units (NTU) of 2.37 and an exceptional thermal effectiveness of 83.3%. Utilizing the Kern method, the initial shell-side pressure drop was calculated at 49.98 kPa, successfully riding the edge of the 50 kPa limit to maximize cross-flow heat transfer without violating the pump threshold. Conversely, the tube-side pressure drop was exceptionally low at 3.96 kPa against the 30 kPa limit, minimizing strain on the vehicle's coolant circuit.



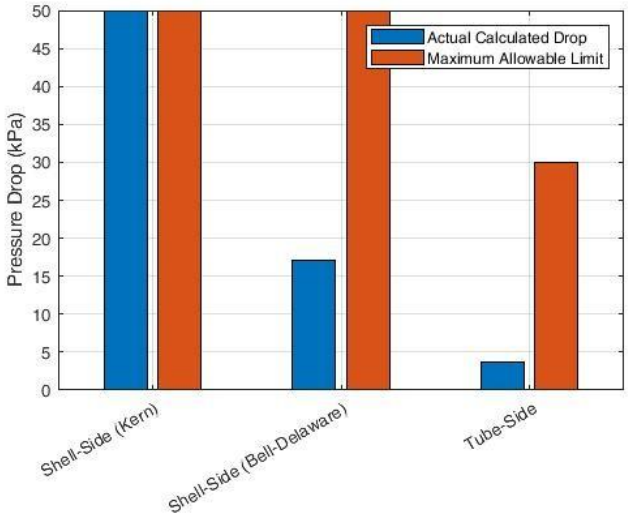


Figure 3: Longitudinal temperature profile illustrating the counter-flow thermal gradient between the hot engine oil and cold engine coolant.

While this mathematically maximises heat transfer, operating at 99.96% of a hard constraint limit reduces the real-world safety margin, necessitating strict adherence to maintenance schedules to prevent pressure-induced pump cavitation as fouling layers develop over time.

3.3 Bell-Delaware Hydraulic Validation

While the Kern method provided a fundamentally sound baseline, physical manufacturing of an STHE requires clearances that allow fluid to bypass the main cross-flow area, thereby reducing actual frictional resistance. To provide a post-optimization validation of the hydraulic safety margin, the optimized geometry was subjected to a simplified approximation of the Bell-Delaware method. By applying standard TEMA Class C empirical correction factors for baffle leakage ($R_l = 0.550$), bundle bypass ($R_b = 0.720$), and inlet/outlet spacing ($R_s = 0.862$) which were derived from standard TEMA graphical charts based on the optimised geometric baffle clearances, the actual shell-side pressure drop was approximated:

$$\Delta P_{shell} = 49.98 \times 0.550 \times 0.720 \times 0.862 \quad (7)$$

$$\Delta P_{shell} = 17.06\ kPa \quad (8)$$

Figure 4: Comparative bar chart of the simulated hydraulic pressure drops (Kern vs. Bell-Delaware) against the maximum allowable design limits.

(Note: The Kern shell-side actual value of 49.98kpa is displayed immediately adjacent to the 50.00 kpa limit bar).

This massive reduction from the 49.98 kPa Kern estimate confirms the Kern method is highly conservative. Consequently, if the rigorous, multi-zone Bell-Delaware formulation were integrated directly into the PSO objective function rather than the Kern method, the relaxed pressure constraints would likely allow the algorithm to achieve even further weight reductions, presenting a distinct pathway for future research

4. CONCLUSION

This study successfully addressed the serviceability limitations of heavy-duty OEM stacked-plate oil coolers by proposing a mathematically optimized, maintainable STHE retrofit. By implementing Particle Swarm Optimization in MATLAB, the structural mass of the aluminum 6061-T6 core was minimized to 23.80 kg. The system achieved a thermal effectiveness of 83.3% while maintaining a highly secure Bell-Delaware corrected pressure drop of 17.06 kPa. The results validate that computational swarm intelligence can successfully bridge the gap between heavy industrial STHE design and compact automotive constraints, offering the tropical haulage sector a lightweight and permanently serviceable cooling solution.

ABSTRACT

Fish dryers are heat-transfer devices designed to remove moisture from fish undergoing drying in order to improve the fish's shelf life. However, a dryer that relies only on thermal energy from solar power often performs poorly at night and on cloudy or raining days. These conditions reduce the solar collector's effectiveness and limit the drying rates. To address this, a hybrid dryer was developed, which uses solar energy as its main heat source and combusts biomass to make up for the absence of solar radiation. This study aimed to create a hybrid solar-biomass dryer that can sustain stable drying conditions regardless of the solar availability. The dryer, which consists of a flat-plate solar collector, biomass combustion chamber, and heat exchanger, was fabricated with low-cost, locally sourced materials. Performance test was conducted outdoors at the Federal University Otuoke, Bayelsa State, using one kilogram of catfish over seven effective daylight hours. To avoid drying interruption, biomass-fueled heating was used in the evening. The results demonstrated that the hybrid dryer reduced the fish drying time from 48 hours to 10 hours and decreased the moisture content from 75% to 15%. Effective conversion and use of renewable energy is demonstrated by the dryer's overall thermal efficiency, which ranges from 45 to 50%, and its average solar collector efficiency of 40%. This study highlights the potential of the hybrid dryer as an efficient, economical, and sustainable approach to enhance fish preservation, food security, small-scale business assistance, and reduce post-harvest losses.

Keywords: *Thermal performance; Hybrid dryer; Biomass; Solar energy; Fish drying*

1.0 INTRODUCTION

Dryers are devices designed to facilitate the removal of certain amount of liquid, usually water, from materials or products to reduce the residual liquid content to an acceptably low level using thermal energy. They are widely used in numerous applications such paper mill, food processing, pharmaceuticals, textiles, and manufacturing industries. In agriculture, dryers are used for processing and preservation of post-harvest produce, including fish through drying. This increases their shelf life, preserves quality and prevent microbial growth that causes spoilage (Hao *et al.*, 2021).

Among the numerous techniques for preserving fish, drying is the most popular and more economical. This method involves the application of dryers that operate with heat energy source to reduce the moisture content of the fish to a level that limits microbial growth and enzymatic reactions, thereby extending the fish's shelf life (Nwakuba *et al*., 2025).

Traditionally, fish are dried by exposing them directly to the sun and is commonly used in rural areas because of low capital cost and operational simplicity of the drying system (Vengsungnle *et al*., 2020). However, this practice has many disadvantages. One of the disadvantages is that significant amount of the thermal energy generated from solar irradiation is lost to the environment due to its dispersion, variability and relatively low intensity. This energy loss results in low drying efficiency, limiting the effectiveness of open sun solar-based dryers. Additionally, product dried using open sun solar-based dryer may be contaminated with dust and insects that compromises the product's quality and economic worth (Prabhu *et al*., 2023).

Conventional dryers that operate solely on fossil fuels are often more efficient, but their high fuel consumption makes them unaffordable for rural people, especially those with low agricultural output ability. Additionally, increasing fossil fuel prices, sporadic supply interruptions, and the related environmental effects such as greenhouse gas emissions that cause climate change have inspired a

search for efficient and sustainable renewable energy sources (Ambaye *et al*., 2021). Solar and biomass have been identified as the two primary renewable energy resources most suitable for drying applications (Lingayat *et al*., 2021; Anyaoha *et al*., 2025; Younis *et al*., 2025).

In recent years, researchers have developed solar dryers to surmount the problem of traditional fish drying. These dryers employ solar collector to heat the air and move it through the drying chamber, which acts as a controlled environment to increase drying efficiency, shield the fish from contaminants, and enable more reliable drying (Yuwana *et al*., 2020). However, solar energy is only available on sunny days. This condition limits solar fish dryers' capacity to operate continuously at night and during cloudy or raining weather (Murali *et al*., 2023).

Biomass drying systems employ burning of organic materials such as wood, charcoal, or agricultural waste. In many rural and coaster regions, biomass is a readily available and affordable source of energy. Researchers have demonstrated that biomass-fueled dryer provides a practical and effective solution for large-scale drying of marine post-harvest products (Alfiya *et al*., 2025). The systems' scalability also makes it appropriate for commercial use, so as to enable higher production capacity while reducing fossil fuel consumption and environmental effect. However, inadequate utility management of biomass drying equipment may result in issues with pollution, fuel supply, and heat regulation.

The disadvantages inherent in each of the aforementioned thermal energy sources have stimulated the development of a hybrid drying equipment, which combines solar and biomass energy to provide continuous supply of heat even during periods of low solar radiation, such as cloudy days or nights (Pawar *et al*., 2024). Researchers have shown that a temperature range of 40-50^{o}C was effectively maintained within the drying chamber of a hybrid fish dryer continuously for a duration of 15 hours using a solar dryer in conjunction with biomass heater (Hamdani *et al*., 2018). This range of temperatures promotes efficient moisture removal without causing the fish to deteriorate due to heat. Although studies have recognized the potential benefits of combining solar and biomass technologies earlier for drying, there is still a dearth of knowledge with respect to development and practical implementation of the hybrid equipment, especially for fish drying in rural communities.

Therefore, this study develops a hybrid solar-biomass fish dryer that uses a solar thermal collector in conjunction with biomass briquette source. The study also aims to evaluate the performance of the dryer.

2.0 METHODOLOGY

In this study, the deterministic approach, involving the application of energy and mass equations, was employed for the design. The drying equipment’s materials were selected and sourced locally to ensure affordability and accessibility while satisfying the necessary structural and thermal requirements. These materials constituted components for solar collector, drying chamber, insulation and biomass heating system. Drying tests were conducted to evaluate the dryer’s thermal performance.

2.1 Design Equations

The size of the solar collector was determined based on the drying area needed to dry a 1.0 kg load of 75% (wet basis) catfish between 9:00 AM and 5:00 PM. A target final moisture content of 12% (wet basis) was set for the dried fish. The design of the dry was carried out in accordance with the considerations listed in Table 1.

Table 1: Design considerations for the hybrid solar-biomass fish dryer

S/N	Parameters	Value
1	Drying material	Catfish
2	Initial mass of fish (m_w)	1.0 kg
3	Initial moisture content (M_i)	75% (wet basis)
4	Target final moisture content (M_f)	12% (wet basis)
5	Average solar irradiant (I_c)	600 W/m^2
6	Drying period (t_d) 9:00 AM and 5:00 PM	7 hours
7	Solar collector efficiency (η_c)	40%
8	Tilt angle	6^o
9	Ambient Temperature (T_a)	30 ^{o}C
10	Drying chamber temperature range	45 – 52 ^{o}C
11	Biomass briquette Lower Calorific value (LCV)	15 MJ/kg

For the design and performance evaluation, equations 1 to 14 were applied.

The amount of moisture to be removed is expressed by equation 1.

$$m_w = m_i \frac{M_i - M_f}{100 - m_f} \tag{1}$$

where m_i is the initial mass of fresh to be dried (kg), m_i is the initial moisture content (% wet basis), and m_f is the final moisture content (% wet basis).

The thermal load required consists of the latent heat to evaporate the water (Q_{lat}) and the sensible heating of the fish tissue ($Q_{s,fish}$) as expressed in equation 2.

$$Q_{req} = Q_{lat} + Q_{s,fish} = m_w h_{fg} + m_i C_p (T_c - T_a) \tag{2}$$

The total design thermal load was calculated by adding 15% for heat losses through the dryer walls. This is expressed in equation 3.

$$Q_{load} = 1.15 Q_{req} = 1.15 \left(m_w h_{fg} + m_i C_p (T_c - T_a) \right) \tag{3}$$

where C_p is the specific heat capacity of fish (J/kg.^{o}C), T_c is the target drying temperature (^{o}C), T_a is the ambient air temperature (^{o}C), and h_{fg} is the enthalpy of vaporization (J/kg).

The solar collector thermal efficiency η_c is expressed in equation 4.

$$\eta_c = \frac{Q_{load}}{t_d A_c I_c} \times 100 = \frac{\dot{m}_a C_{pa} (T_{co} - T_{ci})}{A_c I_c} \times 100 \tag{4}$$

The mass flow rate of drying air required to absorb the evaporated water is given by equation 5.

$$\dot{m}_a = \frac{m_w}{t_d (\omega_o - \omega_i)} \tag{5}$$

The collector area is expressed by equation 6.

$$A_c = \frac{Q_{load}}{I_c \eta_c t_d} \tag{6}$$

where I_c is the average solar irradiant (W/m^2), $\dot{m}_a$ is the air flow rate (kg/s), C_{pa} is the specific heat capacity of air at constant pressure (J/kg.K), t_d is the drying period or time (s), T_{co} is the collector air outlet temperature (^{o}C), T_{ci} is the collector air inlet temperature (^{o}C), ω_o is the relative humidity of exhaust air exiting the chamber (kg water/kg air), and ω_i is the relative humidity of inlet air (kg water/kg air)

The tray area is expressed in equation 7.

$$A_{tray} = \frac{m_i}{\rho_{fish}} \tag{7}$$

where ρ_{fish} is the loading density of fish (kg/m^2)

Energy generated by combustion of biomass is determine using equation 8.

$$Q_{bio} = \dot{m}_{bio} LHV \tag{8}$$

The biomass consumption rate is expressed in equation 9.

$$\dot{m}_{bio} = \frac{Q_{load}}{LHV \times \eta_{comb} t_d} = \frac{Q_{bio}}{LHV \times \eta_{comb}} \tag{9}$$

where $\dot{m}_{bio}$ is the biomass consumption rate (kg/hr), LHV is the biomass lower heating value (kJ/kg), and η_{comb} is the biomass combustion efficiency (%).

Equation 10 expresses the thermal efficiency, which measures how efficiently the total energy input is converted to heat for evaporating moisture.

$$\eta_d = \frac{\mathrm{Q}_{lat}}{\mathrm{Q}_{solar} + \mathrm{Q}_{bio}} \times 100 \tag{10}$$

Equations 11 expresses the latent heat of vaporization.

$$\mathrm{Q}_{lat} = m_w h_{fg} \tag{11}$$

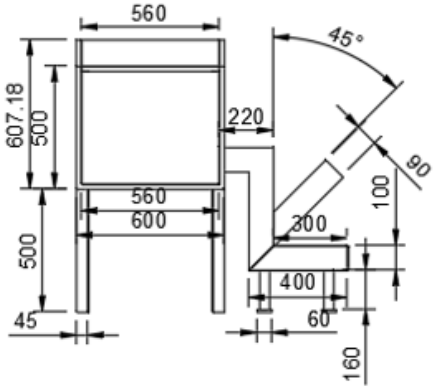
The solar energy collected by the solar collector during the drying period is represented by Equation 12.

$$\mathrm{Q}_{solar} = A_c I_c t_{d,solar} \tag{12}$$

Equation 13 represents the total heat energy of the burnt biomass fuel.

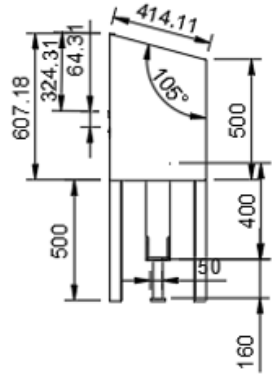
$$\mathrm{Q}_{bio} = \dot{m}_{bio} LHV \times \eta_{comb} t_{d,bio} \tag{13}$$

Equation 14 represents the hybrid dryer's overall energy consumption, which is the sum of the energy contributions from the solar and biomass sources.



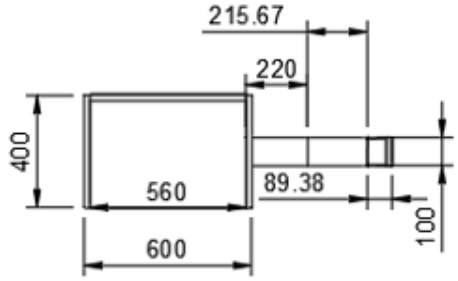
$$\mathrm{Q}_{tot} = \mathrm{Q}_{solar} + \mathrm{Q}_{bio} \tag{14}$$

2.2 Construction of the Dryer



The dimensions of the constructed dryer according to design Equations 1through 14 is shown in Fig. 1(a) - (d). The hybrid solar-biomass dryer consists of drying chamber, solar collector and biomass combustion unit. The drying chamber was fabricated as rectangular insulated box with timber studs and plywood cladding. All internal seams were sealed before applying the aluminum liner. The black absorber plate was fixed below the glazing at a shallow inclination to encourage buoyancy-driven flow. A 4 mm thick glass sheet was mounted in a wooden sash with rubber beading to limit leakage and allow maintenance. The biomass heater was constructed using mild steel and connected via an indirect hot-air duct to avoid smoke contact with fish. The duct entered near the chamber floor to mix incoming hot air before rising across the trays. A top flue maintained steady exhaust of warm, moist air. The solar collector was mounted directly on the chamber at 6^o, which nearly matched the local latitude of Bayelsa State, Nigeria ((about 5°N to 6°N). This orientation maximized solar energy capture for the area. The direct mounting of the solar collector also eliminated long ducts and reduced thermal losses across joints.

2.3 Performance Evaluation Test Procedure



A performance test of the fabricated hybrid solar-biomass fish dryer was conducted outdoor at the Faculty of Engineering, Federal University Otuoke, Bayelsa State, Nigeria using 1.0 kg of fresh catfish with approximately 75% (wet basis) initial moisture content. The tests were carried out over 7 hours drying period under ambient temperature ranging from 28-30°C with solar irradiance of 600 W/m² and moderate wind. During the drying period, the dryer was operated on solar mode for about 7 hours and then on biomass support through the evening to complete the drying process. The ambient and chamber temperatures were measured using thermometers. A hygrometer was used to measure the relative humidity trend. A digital weighing balance was used to measure the initial mass and subsequent mass of the fish at regular intervals.

3.0 RESULTS AND DISCUSSION

The design results obtained using equations 1 through 14 are shown in Table 2. The results of moisture removal and weight loss during the test are depicted in Fig. 2(a) and (b), respectively. The

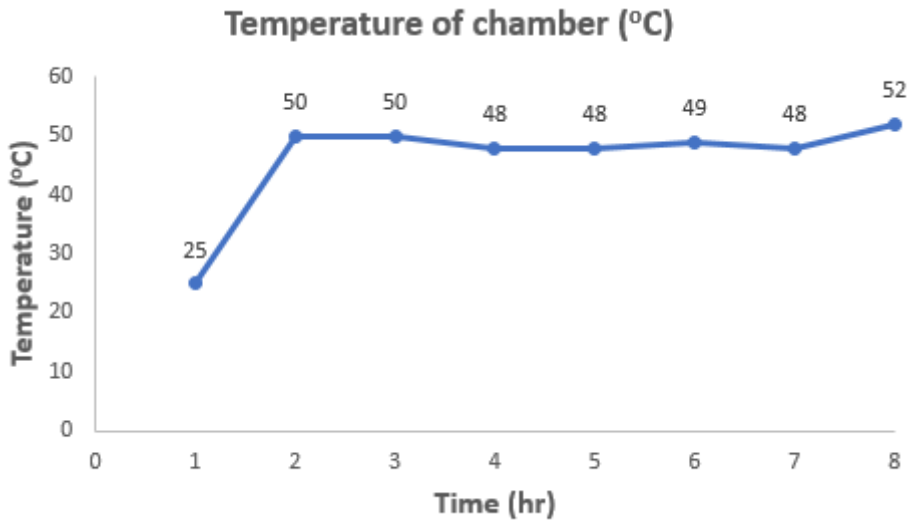
temperature trend results are presented in Fig. 3. Furthermore, the results of moisture removal and the drying chamber temperatures, which reveal the time of the solar energy utilisation phase and the biomass energy utilisation phase, respectively, are shown in Fig. 3(a) and (b).

Table 2: Design Calculation Parameters

S/N	Parameter	Value
1	Moisture to remove	0.7059kg
2	Moisture removed over 7hr	0.2896kg
3	Latent heat (Q_{lat})	1,595.3 kJ
4	Sensible heat ($Q_{s,fish}$)	92.5 kJ
5	Heat loss over 7hrs (Q_{loss})	540 kJ
6	Total heat (Q_{total})	2227.8 kJ
7	Solar collector surface area (A_c)	0.35 m^2

(a) Percentage Moisture versus time. (b) Fish weight loss versus time

Figure 2: Percentage moisture and weight losses against drying time.



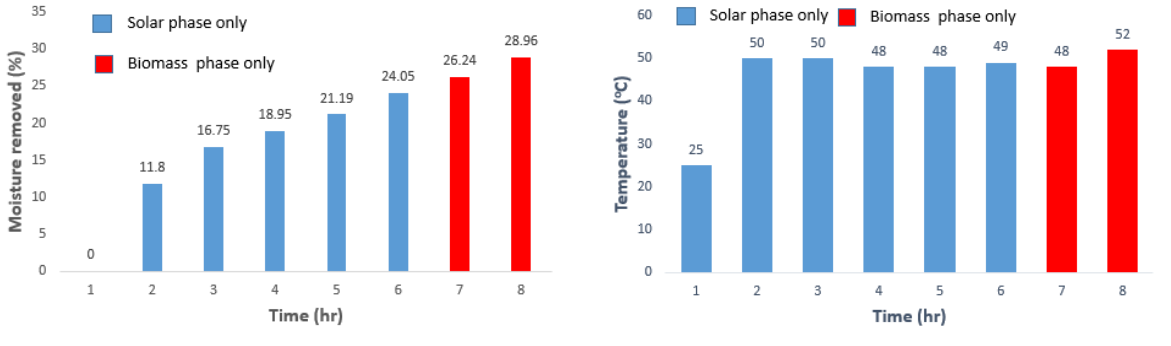


Figure 3: Drying chamber temperature profile.

(a) Moisture removal showing the solar energy and biomass energy.

(b) Drying chamber temperature showing solar energy and biomass energy

Figure 4: Moisture removal and chamber temperature showing solar energy and biomass energy supply.

Figure 2(a) shows the percentage of moisture content removed with time during the drying test. The moisture loss from the fresh fish increased from 0% to around 11.8% over the first hour of solar operation. The amount of moisture removed rises as the drying time increases, although more slowly and steadily to 24.05% during the solar phase as shown in Fig. 3(a). Approximately 28.96% of the

moisture content was removed within the other two hours of introducing biomass source of energy. After about 10 hours of total drying time, the fish's moisture decreased from 75% (wet basis) to 12-15%. This indicates that while the majority of the moisture may be eliminated in the early hours, it takes longer to achieve almost total drying because of decreasing returns.

The corresponding weight loss with time is depicted in Fig. 2(b). At first, when surface moisture evaporates, the mass decreases somewhat fast. As the residual moisture moves farther inside the fish and takes longer to reach the surface, the rate of mass loss gradually decreases. This pattern illustrates the usual drying behaviour, in which moisture loss is relatively faster at first and slows down as drying goes on. The fish's weight decreased from 1.0 kg to around 0.71 kg after 8 hours, in accordance with safe storage, and the steady fall shows efficient moisture removal. The pattern shows how well the drying process works to progressively reduce fish mass by gradually reducing the moisture content.

Fig. 3 shows the temperature profile of the chamber with respect to time. During the first hour, the temperature rises quickly, reaching 50^{o}C and fluctuates slightly between 48 to 50^{o}C within the duration of two to seven hours. The temperature marginally increase to 52^{o}C after 8 hours due to activation of biomass source of energy as shown in Fig. 3(b). The temperature profile demonstrates that the chamber sustains a constant temperature for the majority of the drying time, which is suitable for reliable drying.

Energy analysis gave a batch design energy of about 2,227.8 kJ using equation 3. The hybrid solar-biomass drier provides an overall thermal efficiency ranging from 45%, demonstrating its ability to effectively convert and utilize thermal energy for the drying process. This efficiency is attributed to the combined performance of solar and biomass energy sources to maintain optimal drying temperatures and reduce energy losses. Additionally, the solar collector showed an efficiency of 40%, indicating that it can efficiently capture solar radiation and convert it into useful heat energy. The results also show that solar contributed approximately 60% of the dryer’s energy consumption and biomass accounted for the remaining 40%. This complementing energy mix maximises the dryer's performance by ensuring consistent drying temperatures regardless of the weather conditions, including low solar irradiance or evening time.

4.0 CONCLUSION

A hybrid solar-biomass dryer specifically for fish drying was designed and fabricated to address the disadvantages of traditional sun-based drying equipment as well those of solar energy or biomass or fossil fuel-operated dryers. The findings from the performance evaluation showed that the hybrid dryer lowered the moisture content from 75% to 15% and shortened the fish drying time from 48 to 10 hours. The hybrid dryer's overall thermal efficiency ranges from 45 to 50 percent, with an average solar collector efficiency of 40 percent, demonstrating its capacity to effectively convert and use thermal energy during the drying process. Solar energy accounts for about 60% of the dryer's energy needs, with biomass providing the remaining 40%, making the dryer a viable and sustainable solution for small-scale fish drying businesses. Therefore, this study emphasizes the potential of the hybrid dryer as a practical, affordable, and sustainable method to improve food security, fish preservation, small-scale business support, and post-harvest losses.

ABSTRACT

The rapid evolution of thermal energy storage technologies has positioned phase change materials (PCMs) as a cornerstone for advanced heat management and energy conservation systems. The PCMs are distinguished by their ability to absorb, store and release large quantities of latent heat during phase transitions. Organic phase change materials such as shea butter exhibit low thermal conductivity and latent heat of fusion, hence the need to enhance these properties with suitable additives. In this study, carbon dots (CDs) were synthesized hydrothermally with a yield of 40.3% and particle sizes predominantly below 20 nm, before being integrated into pure shea butter. Pure shea butter exhibited low thermal conductivity (0.222577 W/mK), heat transfer coefficient (37.09621 W/m²·K), latent heat of fusion of 50.50 kJ/kg and specific heat capacity of 0.021054 J/kgK. Addition of 3wt% CDs to pure shea butter increased thermal conductivity to 0.341 W/m·K, heat transfer coefficient to 56.9 W/m²·K, latent heat of fusion to 163.03 kJ/kg and specific heat capacity to 0.062023 J/kgK. Overall, the composite PCM indicated potential for enhanced thermal storage capacity and heat transfer efficiency, indicating its suitability as a sustainable and cost-effective material for thermal energy storage applications.

Keywords: *Phase change materials; Carbon dots; Shea butter; and hydrothermal synthesis*

1.0 INTRODUCTION

The growing demand for reliable and efficient thermal energy management has drawn considerable research attention to phase change materials (PCMs) for latent heat storage. PCMs absorb, store, and release large quantities of thermal energy during solid–liquid phase transitions while maintaining a nearly constant temperature (Yang et al., 2021), making them attractive for building thermal regulation, waste heat recovery, and solar energy applications such as solar drying (Pandey et al., 2024).

Organic PCMs, including paraffins and fatty compounds such as shea butter, are valued for their chemical stability, high latent heat per unit mass, non-corrosive nature, and minimal supercooling (Faraj et al., 2020). However, their inherently low thermal conductivity limits the rate of heat absorption and release, reducing efficiency in time-sensitive applications such as solar drying (Agbetiloye et al., 2022). Shea butter a low-cost, renewable fat extracted from the shea tree (Vitellaria paradoxa), is a promising bio-based organic PCM but shares this conductivity limitation.

Considerable research has focused on improving the thermal conductivity of shea butter and similar organic PCMs using high-conductivity additives such as metallic powders, carbon nanotubes, graphene, and expanded graphite, without significantly compromising latent heat storage (Tariq et al., 2020). Agbetiloye et al. (2022) achieved a thermal conductivity of 0.0538 W/m·K and latent heat of 164.53 kJ/kg using 3 wt% aluminium powder in shea butter for a ginger solar dryer. Stonehouse and Abeykoon (2022) compared several carbon nanomaterials in PCM matrices and reported large conductivity enhancements but at high material cost. Yadav et al. (2021) reviewed carbon-based nanomaterials as conductivity enhancers, reporting improvements of up to 2700% but flagging nanoparticle agglomeration, elevated cost, and reduced latent heat as recurring drawbacks, while Radomska et al. (2020) similarly identified a persistent trade-off between conductivity gain and latent heat retention across enhancer materials. Collectively, these studies confirm the effectiveness of carbon-

based nanomaterials but highlight their high cost as a barrier to economically viable composite PCMs, and underline the need for more affordable enhancers.

This study addresses this gap by investigating carbon dots synthesized from p-phenylenediamine and folic acid as a low-cost additive for shea butter, with the aim of developing a cost-effective composite PCM for thermal energy storage.

2.0 MATERIALS AND METHODS

2.1 Materials

The carbon precursors p-phenylenediamine and folic acid (99% purity) and ethanol (95%, CAS 64-17-15) were purchased from Haddis Chemical, Samaru, Zaria. Deionised water was obtained from the Ahmadu Bello University Multiuser Laboratory, and food-grade shea butter was procured from the open market.

2.2 Synthesis of Carbon Dots

Carbon dots (CDs) were synthesized hydrothermally following the method of He et al. (2024). P-phenylenediamine (30 g) was dissolved in 1 L of ethanol (solution A), while folic acid (5 g) was dissolved in 500 mL of deionised water (solution B). The solutions were combined under magnetic stirring, transferred into a Teflon-lined autoclave, and heated at 180 °C for 12 hours. After natural cooling, the product exhibited characteristic red fluorescence under UV light, confirming CD formation. The product was purified by silica gel column chromatography (methanol eluent), followed by rotary evaporation and freeze-drying, giving a synthesis yield of 40.3%.

2.3 Preparation of Carbon Dot–Shea Butter Blend

Following the method of Agbetiloye et al. (2022), 10 mL of shea butter was heated to a set mixture temperature (40, 50, or 60 °C; Priyadarshi & Paul, 2019) until fully melted. Carbon dots (1, 2, or 3 wt%) were gradually added under continuous magnetic stirring to avoid agglomeration, and the blend was stirred for a specified mixture time (10, 20, or 30 minutes) to achieve homogeneous dispersion. The mixture was then cooled under ambient conditions and stored in airtight containers for further analysis.

2.4 Characterization

Thermal conductivity was measured using a Searle's apparatus, and specific heat capacity using a radial heat conduction apparatus (Armfield HT12), applied to both pure and CD-blended shea butter.

2.4.1 Thermal Conductivity

Thermal conductivity test was done on the pure shea butter, and the modified shea butter (PCM). The Searles apparatus was used

The thermal conductivity was computed using equation 2.1.

$$k = \frac{mC(\theta_2 - \theta_1)L}{A(T_1 - T_2)} \tag{2.1}$$

where; k = Thermal conductivity of sample (W/mK), m = Mass of water collected per second (kg/s), C = Specific heat capacity (J/kg.K), A= Area of the cross-sectional area of the bar (m^2)

θ_1 = Inlet water temperature (K), θ_2 = Outlet water temperature (K), L = Distance between the 2-thermometer point (m), T_1 = Temperature of hot end of the bar (K)

T_2 = Temperature of cold end of the bar (K)

2.4.2 Specific heat capacity

The specific heat capacity was computed using equation 2.2

$$C = \frac{Q}{m\Delta T} \tag{2.2}$$

Where: C= Specific heat capacity (J/kg.K), m = Specific heat capacity of water (kg), $Q =$ change in energy (J), and ΔT is Temperature change (°C).

2.4.3 Latent heat of fusion

An experimental method involving water in calorimeter with stirrer was used to measure the latent heat. In order to account for heat loss that may occur, the following measures were taken:

The PCM was properly sealed.

The hot medium (water) temperature of 90°C is far above the melting temperature of shea butter.

Full melting/solidification was allowed for throughout the experiment.

The latent heat was computed using equation 2.3 and 2.4.

$$mL + ms_2(\theta_2 - 0) = (m_2 s_2 + m_1 s_1)(\theta_1 - \theta_2) \quad (2.3)$$

$$L = [(m_2 s_2 + m_1 s_1)(\theta_1 - \theta_2) - s_2(\theta_2 - 0)]/m \quad (2.4)$$

Where: m_1=Mass of Copper Calorimeter and Stirrer, m_2=Mass of Water, s_1=Specific Heat Capacity of Water, s_2= Specific Heat Capacity of Copper, θ_1=Initial Temperature of Warm Water

θ_2=Final Temperature of Mixture, m=Mass of Sample, L=Specific Latent Heat of Fusion of Sample

2.5 Determination of the optimum blend of carbon dots & shea butter using Taguchi design of experiment.

Taguchi design of experiment was employed in Minitab statistical 22 software (2022 version) to determine the optimum blend. Three factors with 3 levels each, were used in an L9 orthogonal array (which has 9 experimental runs). The three factors were optimize using Carbon dots (CDs) concentration (1%, 2% and 3%), The mixture temperature of (40° C, 50° C and 60° C) and the mixture times (10 min, 20 min and 30 min). The response variables were thermal conductivity, latent heat of fusion and specific heat as seen in Table 1.

Table 1: Factors and level chosen for experiment design

Factors	**Symbol**	**Units**	1	2	3
Carbon dots	CDs	%	1	2	3
Mixture temperature	MT	℃	40	50	60
Mixture time	Mt	Min	10	20	30

3.0 RESULTS AND DISCUSSION

3.1 Results from characterization of carbon dots/shea butter blends and pure shea butter

Result from characterization are presented in Table 2 and 3

Table 2: Thermophysical properties of carbon-dot /Shea butter PCM samples

S/N	ID	Thermal conductivity (W/mK)	heat transfer coefficient (W/m². K)	specific heat capacity (J/kgK)	Latent heat of fusion (kJ/kg)
1	A1	0.24188415	40.31402504	0.044471	85.198
2	A2	0.276439029	46.07317147	0.050761	91.23
3	A3	0.252400852	42.06680873	0.046357	104.834
4	B1	0.24188415	40.31402504	0.044129	117.275
5	B2	0.24188415	40.31402504	0.046027	130.17
6	B3	0.232208784	38.70146404	0.042601	137.075
7	C1	0.276439029	46.07317147	0.049495	152.689
8	C2	0.341483506	56.9139177	0.062023	163.033
9	C3	0.263873618	43.9789364	0.048464	173.437

Table 2 presents the thermophysical properties of the nine carbon dot–shea butter (CDs–SB) composites (A1–C3) prepared under the Taguchi L9 design across varying CD concentration, mixing temperature, and mixing time. Thermal conductivity ranged from 0.232–0.341 W/m·K, comparable to Asmau et al. (2022), while convective heat transfer coefficients ranged from 38.7–56.9 W/m²·K. Sample C2 recorded the highest heat transfer coefficient, consistent with its higher thermal conductivity (Shende et al., 2018), although the relationship was not strictly linear across all samples.

Specific heat capacity (0.0426–0.0620 J/kgK) correlated positively with thermal conductivity: sample B3 recorded the lowest values of both properties (0.232 W/mK; 0.0426 J/kgK), while C2 recorded the highest (0.341 W/mK; 0.0620 J/kgK).

Latent heat of fusion increased progressively with CD loading from approximately 85–104 kJ/kg at 1 wt%, to 117–137 kJ/kg at 2 wt%, and 152–163 kJ/kg at 3 wt%, with an overall maximum of 173.437 kJ/kg at 3 wt% CDs, 60 °C, and 30 minutes. This trend suggests that CDs enhance both conductivity and energy storage capacity, most likely through nanoparticle-induced heterogeneous nucleation, increased interaction sites between the carbon dot surfaces and the PCM matrix, and strengthened intermolecular forces that raise the energy required for phase transition. Overall, sample C2 (3 wt% CDs, 50 °C, 20 min) gave the best combined performance in thermal conductivity, heat transfer coefficient, and specific heat capacity, while C3 recorded the highest latent heat of fusion.

Table 3: Thermophysical properties of pure shea butter & carbon-dots/shea butter PCM

Thermophysical properties	Thermal conductivity (W/m·K)	heat transfer coefficient (W/(m²·K)	specific heat capacity (J/kg·°C)	Latent heat of fusion (kJ/kg)
Pure shea butter	0.222577	37.09621	0.021054	50.5
Blended carbon dots with shea butter	0.341483506	56.9139177	0.062023	163.033

Table 3 compares pure shea butter to the CD-blended shea butter PCM. It can be seen that the thermal conductivity of shea butter increased from (0.22577 to 0.341484 W/m.K) which gives an increase percentage of 53%. An increase in heat transfer coefficient of shea butter from 37.096 to 56.914 W/(m²·K), specific heat capacity from 0.021054 to 0.062023 J/kgK with the addition of carbon dots was also observed. There was also an increase in latent heat from 50.5 to 163.033 kJ/kg indicating an increase of over 200%. This shows that the addition of carbon dots greatly improved the shea butter thermal conductivity, heat transfer coefficient and specific heat capacity.

3.2 The cost analysis phase change material.

Table 4: Cost analysis of the PCM (Shea butter and carbon dots)

S/N	Materials		Unit Cost (N)	Total Cost
1	Shea Butter	4.53kg	₦ 2400	₦ 12000
2	*P-p*henylenediamine	40 g	₦ 200	₦ 8000
3	Ethanol	1 liter	₦ 8000	₦ 8000
4	Methanol	1 liter	₦ 8000	₦ 8000
5	Folic acid	7 g	₦ 1000	₦ 7000
6	Deionized water	2 liters	₦ 500	₦ 1000
7	Transport and labour		₦ 3000	₦ 2000
8	Total			₦ 47000

Carbon dots cost approximately ₦695.65 per gram, considerably cheaper than multi-walled carbon nanotubes (MWCNTs, US$10 / ₦15,000 per gram) and graphene nanoplatelets (GNPs, up to US$50 / ₦75,000 per gram) at current market prices representing cost savings of 95.3% and 99%, respectively. This confirms carbon dots as a more cost-effective alternative to conventional carbon-based conductivity enhancers.

4.0 CONCLUSION

A composite PCM was developed from shea butter and carbon dots derived from p-phenylenediamine and folic acid. The optimum blend, C2, showed clear improvement in thermophysical properties relative to pure shea butter: thermal conductivity increased from 0.222577 to 0.341484 W/m·K, specific heat capacity from 0.021054 to 0.062023 J/kgK, heat transfer coefficient from 37.09621 to 56.91392 W/m²·K, and latent heat of fusion from 50.5 to 163.03 kJ/kg. These results show that the developed composite PCM is suitable for thermal energy storage applications, with an effective cost saving of 95.3% relative to carbon nanotubes and 99% relative to graphene nanoplatelets.

ABSTRACT

Weed control is one of the major problems in agricultural production. Most of the peasant farmers in Nigeria use manual weeders in cultivating, a process that is costly, labour intensive and time consuming. Manual weed control does not also give the farmer adequate returns to enable him breakeven. It is, therefore, necessary to design a weeding mechanism that could minimize the human effort and provide efficient work output for the peasant farmer. This study focus on designing, construction and evaluation of a multi-purpose hand-pushed weeding machine that could eliminate the challenges of manual weeding under different field and soil conditions. Materials selected for the construction of the multi-purpose weeder are durable and locally available, easily replaced if damaged and at affordable cost. They include mild steel plate (3mm, 5mm), 30 mm circular (hollow) pipes, 10 mm diameter steel rod, 10 mm bearings, 10 mm square rod, 17 mm bolt and nuts and 400 mm diameter steel and pneumatic wheels to suit different soil conditions. The developed weeder was evaluated in the experimental farm of IAR with impressive results. It works well in loamy (27.42% moisture content) and sandy soils (25.65% moisture content) and requires less labour force compared to the conventional manual hoes. It has an average weeding efficiency of 84.7%, 0.0129ha/hr effective field capacity, 0.019ha/hr theoretical field capacity and 68% average field efficiency. Results obtained also shows a 100% plant damage efficiency (i.e. no plants damaged). The average cost of the weeder is N46, 200:00.

Keywords: *Manual weeding; hand-pushed weeder; weeding efficiency; field efficiency*

1. INTRODUCTION

One of the major problems in crops and vegetables production in Nigeria is weed control. Weeds may be broadly defined as plants growing where they are not wanted. They are probably the most ever-present class of crop pests and are responsible for marked losses in crop yields. Besides reducing crop yield, weeds deteriorates the quality of produce and hence reduce the market value of the produce. Weeds competes with the crops for nutrients, space, light and water. Numerous studies have documented negative effects of weed competition on crop yield. Results of such studies shows that crop losses measured under weedy conditions for maize was between 55 – 90 % (Chikoye *et al.*, 2004), 40 – 80 % for sorghum (Ishaya *et al.*, 2007)., 40 – 60 % for cowpea (Olowe *et al.*, 1987) and 50 – 100 % for rice (Dadari and Mani, 2005).

Management of weeds is, therefore, imperative to sustain crop productivity and to ensure food security to the ever-increasing population. Weed control is the process of limiting weed infestations such that crops could be grown profitably and efficiently. It is the combination of the techniques of prevention, eradication and control to manage weeds in a crop, cropping system, or environment. Weed managers recognize that field's cropping history, grower's management objectives, available technology, financial resources, and a host of other factors must be combined to make good management decisions; Tisdell, (1988) and Rana and Rana. (2016).

Weeding could be done manually, mechanically, biologically or by means of agro-chemicals. Hand weeding is the predominant weed control practice on smallholder farms in Nigeria and most of Sub-Saharan Africa (Vissoh *et al.*, 2004). It is the oldest method and consists of hand-pulling, hand slashing and hoeing of weeds. Smallholder farmers spend 50 – 70 % of their total labour time in hand

weeding (Chikoye *et al.*, 2007). Another study of African agriculture also confirmed that weeding took up more days in the field than any other operation (IFAD, 1998). Several constraints that limit the effective use of hand weeding, including limited cash for hiring labour and none availability of hired labour during peak periods (Johnson, 1995). Labour supply in rural areas has been significantly reduced in many African countries migration to urban areas (Bisikwa *et al.*, 1997). This necessitates use of mechanical means of weeding to eliminate the challenges of physical exhaustion that is usually associated with manual weeding; Yadav and Pund (2007).

Mechanical weed control, on the other hand, refers to any technique that involves use of farm equipment to control weeds. Implements used vary from simple hand tools to multiple tractor drawn implements; Rana and Rana. (2016). Most existing mechanical weed control machines are drawn by tractors. Peasant farmers who are in the majority today do not have access to credit facilities and cannot afford to buy or hire the agricultural machinery to enhance their farming capabilities. It, thus, becomes necessary to develop and construct a weed control equipment that would depend on minimum human efforts for its motion, but could weed at a greater speed and efficiency than human beings, hence, the objective of this study.

2. MATEIALS AND METHODS

Materials to be used for the construction of the multi-purpose weeder are; 3 mm and 5 mm mild steel, 30 mm circular (hollow) pipes, 10 mm diameter steel rod, 10 mm bearings, 10 mm square rod, 17 mm bolt and nuts and 400 mm diameter steel and pneumatic wheels to suit different soil conditions. The bases for these materials were their durability and availability, ease of replacement if damaged and light in weight for safety and ease of transportation. Their cost is also affordable to a local fabricator and medium scale famer. In its construction, the multi-purpose weeder was made in such a way that it is easy to operate and maintain while the components could easily be dismantled for replacement of parts. Traction on the wheels has also been considered for proper movement on different soil conditions. Other materials used were weighing scale, oven, soil sampler, measuring tape, steel rule and a stop watch.

2.2 Description of the Multi-Purpose Weeder

The multi-purpose weeder constitutes a frame, steel and pneumatic wheels (to suit different types of soil), tin cultivator, furrower and a weeding blade that could optimally operate under different soil conditions as shown in Figure 1. Appendix A show the Orthographic View of the Multi-Purpose Weeding Machine.

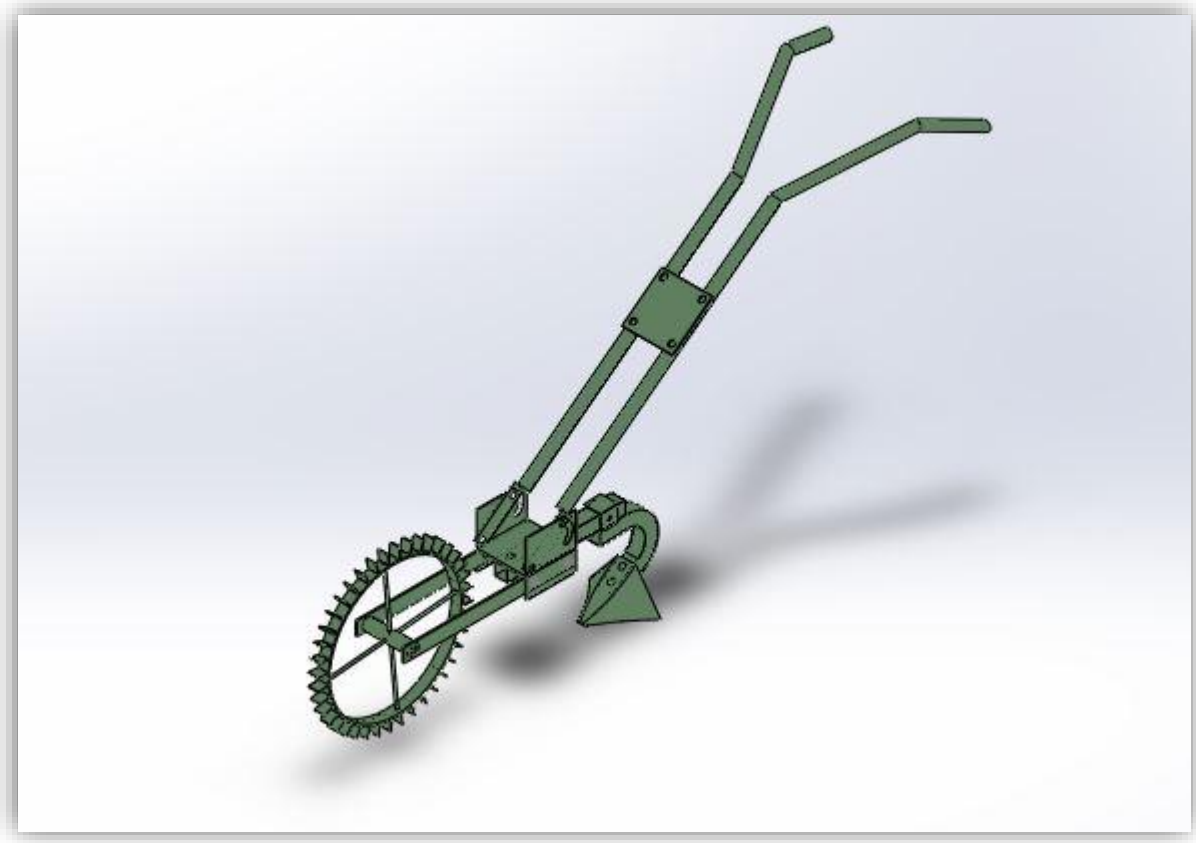

Figure 1: Pictorial View of the Developed Multi-Purpose Weeder

i. **Frame -** The frame is the skeleton/structural component on which all the components of the weeder were built, supported and attached. It was made from 3 mm mild steel rod. All the components mounted on it were attached with bolts and nuts for ease of transport and replacement of defective parts.

ii. **Wheels -** The weeder has two different wheels; pneumatic (moulded and tubless) and steel wheels (Figure 2). Both are of the same diameter (400 mm) and are not used simultaneously but one at a time depending on the type of soil.

iii. **Handle -** The handle was constructed using 30 mm diameter circular (hollow) pipe. Ergornomic and anthropometric aspects were considered in such a way it suit variety of users. It was attached to the frame to control and direct the weeder on the field.

iv. **Tine cultivator -** The tin cultivator was made from 10 mm diameter steel rods which were flattened at its base and supported at the top by a mild steel metal sheet. It was meant to work on a stony and rooted soils (Figure 3).

v. **Furrower -** The furrower was made from a 3mm mild steel metal to form a typical sweep furrow of 18 × 18 cm (Figure 4).

vi. **Weeding blade -** The weeding blade which forms the integral part of the weeder was made from 5 mm mild steel plate. It's diamensions are 20 × 20 cm. It has a sharp blade which is used to cut, slice and pulverize the soil for effective weeding.

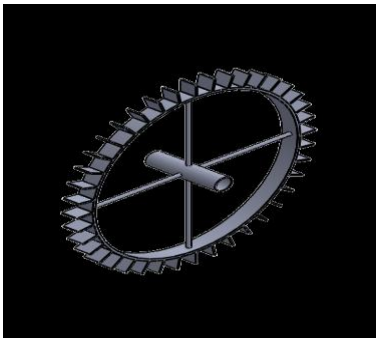

Figure 2: Steel Wheel

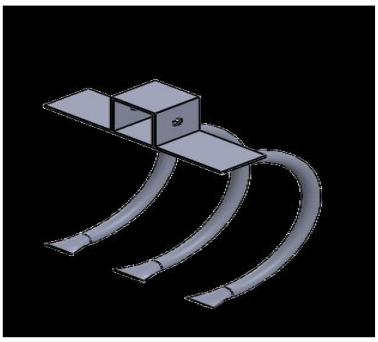

Figure 3: Tine Cultivator

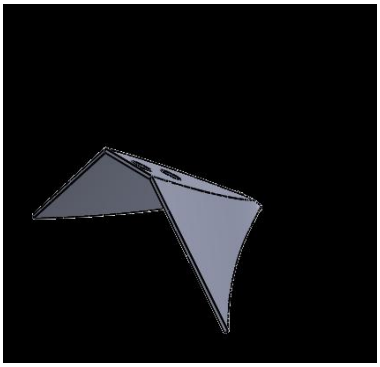

Figure 4: Furrower

2.3 Experimental site

The study was conducted in the Department of Agricultural and Bio-Resources Engineering, Ahmadu Bello University, Zaria between March and December 2025. While construction was done at the departmental workshop, the multi-purpose weeder was tested at the experimental farm of the Institute for Agricultural Research (IAR). The plots with sandy and loamy soils were used to test the weeder.

2.4 Determination of the Weeder Performance

The test for the weeding performance parameters was carried out on the field size of 2 × 1m. The average performance parameters of the multi-purpose weeder such as weeding efficiency, plant damaged, effective field capacity, theoretical field capacity and field efficiency of multi-purpose weeder were determined and evaluated through the following expressions:

i. **Weeding efficiency –** This is the ratio of the numbers of weeds removed by the weeder to the number of weeds in a unit area before weeding and is expressed as a percentage. It was expressed using equation (1) as suggested by Madhusudhana (2015).

$$Weedingefficiency\ (\%) = \frac{W_1 - W_2}{W_1}\ x\ 100 \quad (1)$$

where:

W_1 = Number of weeds counted per unit area before weeding operation

W_2 = Number of weeds counted in same unit area after weeding operation.

ii. **Plant damage –** Plant damage is the ratio of the number of plants damaged after weeding operation to the number of plants before the weeding. It is expressed in percentage.

$$Plant\ Damage\ (\%) = \left(1 - \frac{q}{p}\right) \times 100 \quad (2)$$

where:

p = Number of plants in a row before weeding = 29,

q = Number of plants in a row after weeding = 29.

iii. **Effective field capacity –** Effective field capacity is the actual average rate of coverage by the weeder based upon the total field time. It is a function of the rated width of the weeder, the percentage of rated width actually utilized, speed of the travel and the amount of field time lost during the operation. Effective field capacity is expressed in ha/h (Kepner *et al*., 1978).

$$= \frac{EFC}{\frac{A}{T_{p+}T_i}} \quad (3)$$

where:

EFC = Effective field capacity, ha/h

A = Actual area covered, ha

T_p = Productive time, h

T_i = Non-productive time, h

iv. **Theoretical field capacity -** Theoretical field capacity of the weeder is the rate of field coverage that would be obtained if the weeder were performing its function 100% of the time at the rated forward speed and always covered 100% of its rated width. It is expressed in ha/h (Kepner *et al.,* 1978):

$$TFC = \frac{W \times S}{10} \quad (4)$$

where:
TFC = Theoretical field capacity, ha/h
w = Width of cut, m
s = Speed of operation, km/h

v. **Field efficiency –** Field efficiency is the ratio of effective field capacity to the theoretical field capacity, expressed as percentage. It includes the effect of time lost in the field and failure to utilize the full width of the weeder.

$$\eta_e = \left(\frac{\text{EFC}}{\text{TFC}}\right) \times 100 \quad (5)$$

where:
η_e = Field efficiency, %
EFC = Effective field capacity, ha/h
TFC = Theoretical field capacity, ha/h

vi. **Bulk density of soil -** The bulk density of soil was determined by core cutter method. The core sampler of the soil of known volume was be collected and weighed. The soil bulk density was mathematically determined as the ratio of the mass of soil to volume of soil:

$$\rho = \frac{M}{V} \quad (6)$$

where:
ρ = Bulk density, g/cm³
M = Mass of the soil, g
V = Volume of the soil, cm³

vii. **Moisture content of soil –** The moisture content of the soil was determined by oven drying method. Soil samples were taken from three different points on the field. The samples which weight 400 g, 398 g and 405 g were kept in the thermostatically controlled oven at a temperature of 105^0C for 24 hours. The dried soil was again weighed and the moisture content is determined as:

$$M_c = \frac{W_w - W_d}{W_d} \; x100 \quad (7)$$

where:
M_c = Moisture content, (% db)
W_w = weight of moist soil, g
W_d = weight of dry soil, g

viii. **Effective working depth –** The depth of cut of the weeder with different blades was measured in the field by measuring the depth of soil layer tilled by the blade in a row. The depth of the weeding was measured by measuring rule in different rows at different places. Average of five observations was taken as depth of weeding and expressed in cm.

ix. **Effective working width –** The width of cut of the machine with different blades was measured in the field by observing the strip of soil and weeds cut in a row.

3. RESULTS AND DISCUSSION

3.1 Bulk density and moisture content of the soil

The average bulk densities of the sandy and loamy soils collected from three different points of the fields were determined to be 1.21 g/cm³ and 1.70 g/cm³, respectively. The average moisture contents of the areas were also found to be 25.65 and 27.42 % (Tables 1 and 2).

Table 1: Bulk Density and Moisture Content of the Soil (Sandy Soil)

Samples	Weight of wet (g)	Weight of dry (g)	Moisture content on dry basis (%)	Bulk density (g/cm^3)
A	400	317.0	26.18	1.22
B	398	320.0	24.38	1.20
C	405	320.4	26.40	1.21
Average	401	319.0	25.65	1.21

Table 2: Bulk Density and Moisture Content of the Soil (Loamy Soil)

Samples	Weight of wet (g)	Weight of dry (g)	Moisture content on dry basis (%)	Bulk density (g/cm^3)
A	408	326.1	27.21	1.72
B	410	325.5	27.46	1.69
C	409	325.7	27.58	1.70
Average	409	325.8	27.42	1.70

3.2 Effective working width and depth

The effective working width and depth were determined in three different spots on the field using all the three attachments of the weeder. Results obtained (Table 3) shows that the working widths of the three implements were determined from three different attachments (tin cultivator, weeding blade and furrower) were 20 cm, 19.30 cm and 17.09 cm respectively. This shows that the furrower has a wider coverage than the other attachments. Similarly, the average effective working depth for three attachments were were 3.85 cm, 4.11 cm and 6.87 cm respectively (Table 4). This indicated that the tin cultivator which penetrates deeper into the soil has the tendency of uprooting stubborn weeds and those that has deeper tap roots. Deeper seed bed also means tendency to allow more water and air circulation, hence provides more conducive environment for crop growth.

Table 3: Working widths-of-cut of the Multi-Purpose Weeder

Trial/Implement	Tin cultivator	Weeding Blade	Furrower
	(cm)		
1	20	19.4	17.3
2	20	19.2	17.10
3	20	19.4	17.21
Average	20	19.3	17.09

Table 4: Effective Working Depth-of-cut of the Multi-Purpose Weeder

Trial/Implement	Tine cultivator	Weeding Blade	Furrower
	(cm)		
1	3.84	4.11	6.32
2	4.10	4.00	7.10
3	3.60	4.23	7.21
Average	3.85	4.11	6.87

3.3 Weeding efficiency

The test for the weeding efficiency was carried out on the field size of 2 × 1m. The ratio of weeds counted before and after the weeding was 85.7:1. The cumulative average weed population of the three trials was 600 before weeding operation while weeds left after the exercise was an average of 7 for both attachments (Table 5).

Table 5: Average Weed Population

Trial/Implement	Tine cultivator	Weeding Blade	Furrower
	(No.)		
1	598	601	602
2	599	600	600
3	603	598	598
Average	601	599	600

The weeding efficiency was computed using Equation (1) given as:

$$Weeding\ Efficiency\ (\%) = \frac{600 - 7}{600}\ x\ 100 = 98.83\%$$

3.4 Average Effective field capacity

The average effective field capacity was determined from Equation (3) after weeding 3 × 1.5m (0.00045ha) within an average of 1min 57secs (0.0325 hours) for both attachments. The average time used for turning and adjustment was 10 sec (0.00266hours).

$$Average\ EFC = \frac{0.00045}{0.0325 + 0.00266} = 0.0129ha/hr$$

3.5 Theoretical field capacity

The theoretical field capacity of the multi-purpose weeder was determined computing the rate of weeder coverage at its 100% rated width. Average width of cut of the three implements was 0.19 m from Table 3 while the average speed of operation of the three implements was 1.008km/h. Thus, from Equation (4), the theoretical field capacity was determined as:

$$TFC = \frac{0.19X1.008}{10} = 0.019ha/h$$

3.6 Average Field efficiency

The average field efficiency of the weeder was computed from Equation (5) as:

$$\eta_e = \frac{0.0129}{0.019} \times 100 = 67.9\% \approx 68\%$$

3.7 Plant damage efficiency

The plant damage efficiency was calculated using Equation (2). After weeding three different rows of about 10 m length each, it was discovered that no plant was damaged by both attachments (number of plants before and after weeding = 29). This shows a 100% plant damage efficiency. Therefore, the plant damage efficiency is calculated thus;

$$Plant\ Damage\ (\%) = \left(1 - \frac{29}{29} \times 100\right) = 0$$

4 CONCLUSION

A hand-pushed multi-purpose weeder that could use three different weeding attachments for effective weeding operation has been designed and developed. From the results obtained during the

performance evaluation, it was observed that the weeder is light in weight which makes it easy to be pushed with less effort, save time and energy and effective in its output. It could, thus, promote the living standard of peasant farmers by reducing the drudgery involved in weeding. The multi-purpose weeder could also be used on a flat soil or between furrows if the soil moisture is within its acceptance range. It has a weeding efficiency of 84.7% with no plant damage during the weeding trials conducted. The average cost of the multi-purpose weeder is N46, 200:00.

ABSTRACT

Capacitor Voltage Transformers (CVTs) play a critical role in high-voltage power systems by providing voltage measurements for protection, metering, and monitoring applications. However, their performance can be adversely affected by faults such as capacitor drift, ferroresonance, overvoltage, undervoltage, and insulation degradation, leading to inaccurate measurements and reduced system reliability. The development of intelligent fault diagnosis systems for CVTs is often constrained by the limited availability of comprehensive fault datasets and the severe class imbalance associated with rare fault events. This study proposes an integrated framework for fault diagnosis and reliability assessment of a 132 kV CVT using synthetic data generation and machine learning techniques. A high-fidelity CVT model was developed to simulate both normal and fault operating conditions while incorporating temperature variations, harmonic distortion, and measurement uncertainties. A dataset comprising 20,000 samples was generated, containing electrical and operational features including primary voltage, secondary voltage, ratio error, phase error, temperature, and total harmonic distortion (THD). The dataset was subsequently used to develop and evaluate Decision Tree, Support Vector Machine (SVM), k-Nearest Neighbor (kNN), and Ensemble Machine Learning classifiers for multi-class fault prediction. Comparative results demonstrated that the Ensemble classifier achieved superior performance with an accuracy of 99.98%, macro precision of 1.00, macro recall of 0.999, and macro F1-score of 0.999, significantly outperforming the conventional machine learning models. The proposed framework provides an effective solution for accurate fault prediction, improved fault representation, and enhanced condition-based assessment of CVTs, thereby supporting predictive maintenance and improving the operational efficiency of high-voltage power system assets.

Keywords: *Capacitor Voltage Transformer; System Modeling; Machine Learning; Fault Prediction*

1. INTRODUCTION

The study is on the development of a fault diagnostic framework for 132 KV capacitor voltage transformer. With the increasing expansion of power systems, evaluating the reliability of the systems is imperative for improved and sustained performance efficiency. For metering, protection, and measuring equipment, the input signal needed to perform their protection functions depends on the instrument transformer. A capacitor voltage transformer is used as an instrument or transformer to step down high transmission line voltages (66 kV and above) to the nominal voltage levels needed for the operation of metering, protection, and measuring equipment (Haghgoo & Damchi, 2022). Faults in CVTs arise from aging and system subjection to abnormal operating conditions, which could lead to malfunction in system operation and consequently to protection systems. Therefore, an effective fault modeling and classification framework is needed to evaluate the operational behavior of the CVT under normal and faulty conditions and classify faults in CVTs, thus providing an early preventive maintenance approach to ensure the safe and reliable operation of CVTs and protection systems. Traditional fault detection techniques often rely on predetermined thresholds and expert knowledge; however, these methods can be inadequate for addressing the increasing complexity and dynamic nature of modern power systems Arouche Freire *et al.*, *(*2019). Machine learning (ML) techniques have shown great promise in enhancing fault diagnosis and classification (FDC) in power and protection systems. ML models can automatically learn the underlying patterns and characteristics of various fault types

without the need for explicit programming by leveraging vast amounts of real-time sensor data and historical fault records (Sappati & Bhadra, 2018).Despite these advantage, ML techniques often exhibit poor performance when dealing with imbalanced fault data and do not provide a direct linkage between fault predictions The growing adoption of ML in fault detection on transmission lines offers several advantages, including higher accuracy, the ability to detect faults under various operational conditions, and the potential for real-time detection and classification.

Aim of Study: The aim of the study is to develop a condition -aware simulation-driven fault diagnosis framework for 132 kV capacitor voltage transformer

Objectives of Study:

1. To develop a high-fidelity modeling framework for a 132 kV capacitor voltage transformer (CVT) capable of generating realistic operational and fault-condition datasets for advanced fault detection and diagnostic applications
2. To develop an ensemble machine learning-based fault prediction model using the generated 132 kV dataset and comparatively evaluate its performance against conventional machine learning algorithms, including Decision Tree, Support Vector Machine (SVM), and k-Nearest Neighbor (kNN), using accuracy, precision, recall, and F1-score as performance metrics.

2. METHODOLOGY

In this section, the materials required for actualizing the research work and the detailed step by step methods to be followed in achieving the set objectives is presented.

2.1 Materials

The hardware and software materials to be deployed in actualizing this research work are presented in this section. These materials include:

1. Personal Computer
2. MATLAB Software (2026a)

2.2 Research Methodology

This section presents the methodological framework adopted for the fault diagnosis and reliability assessment of the Capacitor Voltage Transformer (CVT). This chapter outlines the systematic procedures used to model, analyze, and evaluate the operational behavior of the CVT under both normal and faulty conditions. It describes the data acquisition process, feature extraction techniques, and the implementation of diagnostic algorithms employed to detect and classify faults. The parameters used in this study were obtained from standard power system theory, typical CVT design practices, and reasonable engineering approximations. Where manufacturer data was unavailable, values were selected to ensure physically meaningful and realistic system behaviour. Environmental effects, such as temperature variation and harmonic distortion, were incorporated using statistically distributed variables to reflect real-world operating conditions.

2.3 System Description

The CVT considered in this study is rated at 132 kV on the primary side (V_p) with a nominal secondary output of 110 V. The phase voltage is shown in equation (1):

$$V_p = \frac{V_{line}}{\sqrt{3}} \tag{1}$$

The capacitive divider consists of two series capacitors with nominal values of C_1 and C_2 to be 8000 pF and 72000 pF respectively. These parameters establish the nominal transformation ratio and form the basis for the CVT mathematical model as shown in Table 1.

Table 1: *CVT Parameters*

Parameter	Value	Unit
V_{line_nom}	132,000	V
V_{P_nom}	76,210	V
V_{Sec_nom}	110	V
C_{1_nom}	8000e-12	pF
C_{2_nom}	72000e-12	pF
$Temp_{Coeff}$	-0.00035	1/°C
$Temp_{ref}$	25	°C

2.2.1 Temperature Effect Modelling

The influence of temperature on capacitor characteristics is incorporated using a linear temperature coefficient model as shown in equation (3).

$$C(T) = C_{nom}\left[1 + \alpha\left(T - T_{ref}\right)\right] \tag{3}$$

Where $\alpha = -0.00035$ and $T_{ref} = 25^{\circ}C$. This enables the simulation of environmental effects on CVT performance, particularly under varying field conditions.

2.2.2 Secondary Voltage Computation and Normalization

The secondary voltage is computed by incorporating the divider ratio, temperature effects, and system normalization as equation (4).

$$V_s = \left(V_p \times Divider\ Ratio\right) \times \frac{V_{sec,nom}}{V_{p,nom} \times \left(\frac{C_1}{C_1 + C_2}\right)} \tag{4}$$

This formulation ensures that the modelled CVT output aligns with the expected nominal transformation characteristics while allowing deviations under fault conditions.

2.2.3 Noise and Measurement Uncertainty Modelling

To emulate real-world measurement conditions, stochastic noise is introduced into the secondary voltage signal. Gaussian noise is applied with a small variance proportional to the signal magnitude, representing sensor inaccuracies, electromagnetic interference, and switching disturbances. This enhances the realism of the generated dataset and improves the robustness of subsequent fault diagnosis models.

2.3 Fault Modelling and Classification Scheme

A comprehensive fault modelling framework is developed by introducing parameter perturbations corresponding to different CVT fault conditions. Seven operating states are considered like Healthy condition, C_1 capacitance drift, C_2 capacitance drift, Ferroresonance condition, Overvoltage condition, Undervoltage condition and Insulation degradation. Capacitor drift faults are simulated by modifying the capacitance values, while ferroresonance is modelled through amplitude amplification and phase deviation. Voltage-related faults are introduced by scaling the primary voltage, and insulation degradation is represented through combined parameter variations and increased harmonic distortion. This classification provides a diverse dataset for fault diagnosis.

2.4 Ensemble Machine Learning Fault Prediction

1. Decision Tree (DT): Utilized for its interpretability and ability to model non-linear feature boundaries (Meng et al., 2023).
2. Support Vector Machine (SVM): Employed with kernel tricks to map complex fault features into higher-dimensional spaces (Omar et al., 2022).
3. k-Nearest Neighbors (kNN): Used as a distance-based baseline to highlight the challenges of high-dimensional imbalanced data.

2.4.1 Performance Evaluation Metrics

Because standard accuracy is misleading in highly imbalanced datasets (where a model predicting "Healthy" 100% of the time would achieve 90% accuracy), the models are rigorously evaluated using Macro-Averaged Metrics:

i. Macro Precision, Recall, and F1-Score: These metrics treat all fault classes equally, penalizing models that fail to detect rare faults.
ii. Confusion Matrix Analysis: Utilized to identify specific inter-class confusions (e.g., distinguishing C1 drift from Insulation Degradation) and validate the ensemble's ability to isolate distinct fault signatures like Ferroresonance and Overvoltage.

3. RESULTS AND DISCUSSION

Five representative waveform scenarios are generated such as Normal operation, C_1 capacitor drift, C_2 capacitor drift, Ferroresonance condition and Insulation degradation. Each waveform exhibits unique characteristics, enabling clear differentiation between fault conditions and supporting feature extraction for diagnostic purposes. Furthermore, the Root Mean Square (RMS) value of each waveform is computed to quantify signal magnitude and energy content.

3.1 Capacitor Voltage Transformer Under Different Condition

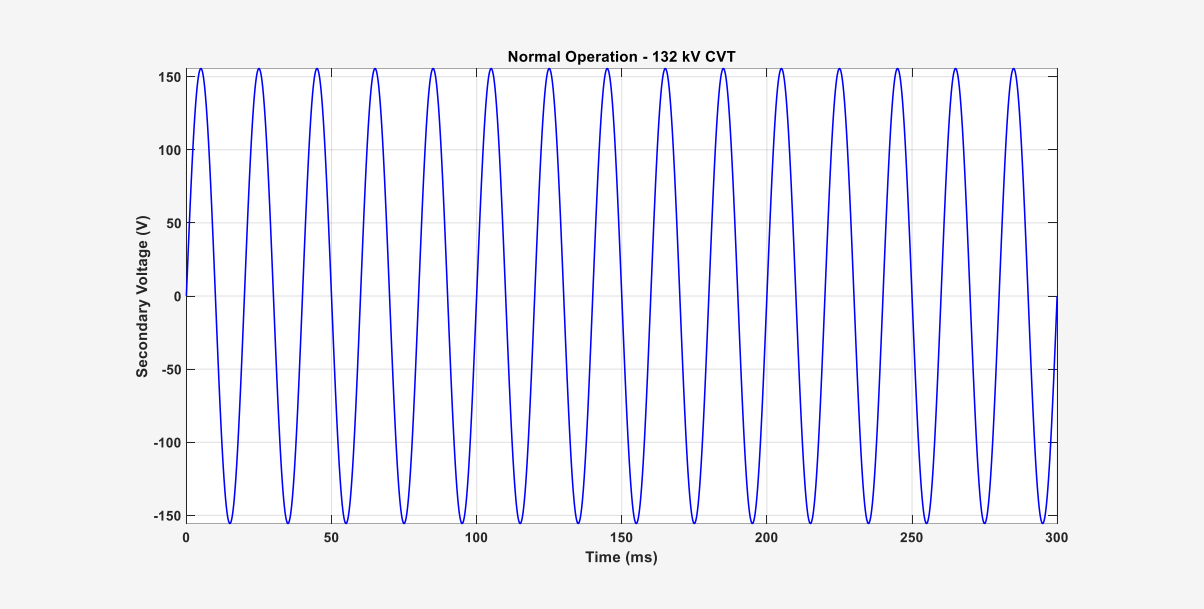

Figure 1: Normal operation

Figure 1 illustrates the time-domain waveform of the secondary voltage output of the 132 kV Capacitor Voltage Transformer (CVT) under normal operating conditions. The waveform exhibits a clean and stable sinusoidal profile, which is characteristic of a properly functioning CVT operating at the fundamental power system frequency of 50 Hz. The peak amplitude of the waveform is ±155 V, corresponding to an RMS value close to the nominal secondary voltage of 110 V. This indicates that the CVT is accurately stepping down the high primary voltage (132 kV system) to a standardized measurable level, maintaining the expected transformation ratio. under the following condition $C_1 = C_1^{nom}$ $C_2 = C_2^{nom}$, Harmonics: none ($k_h = 0$) and Ferroresonance: none ($k_f = 0$).

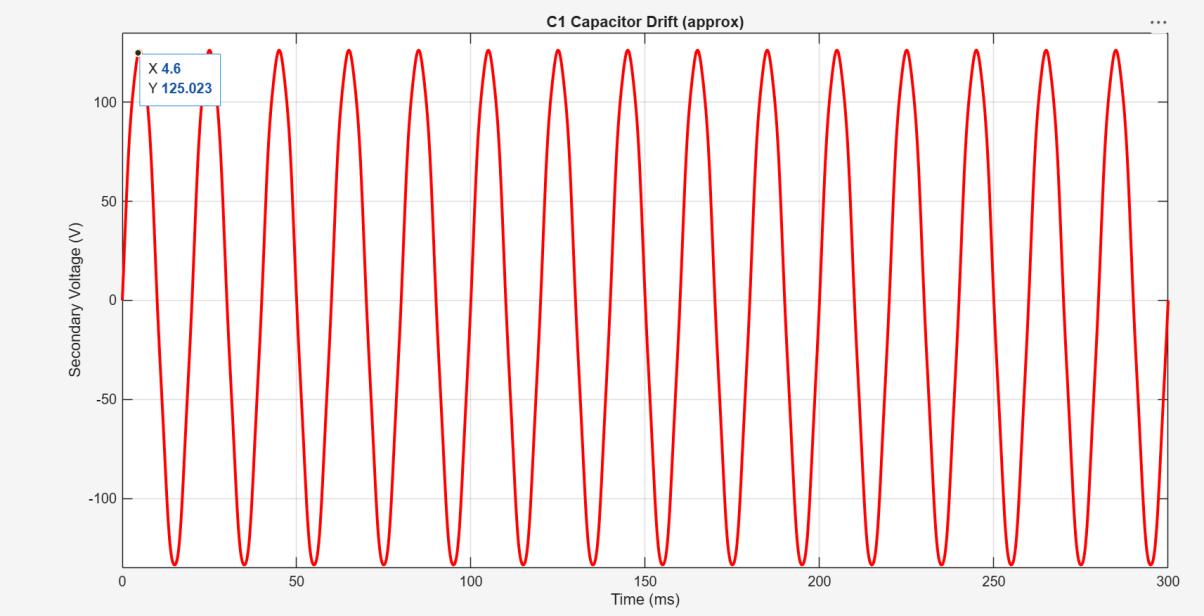

Figure 2: C_1 capacitor drift

Figure 2 presents the secondary voltage waveform of the 132 kV CVT under a fault condition characterized by an 18% reduction in the capacitance of C_1. This condition simulates capacitor aging, dielectric degradation, or partial failure within the capacitive divider network. The waveform retains its fundamental sinusoidal shape at 50 Hz, indicating that the system frequency remains unaffected. However, a noticeable reduction in the amplitude of the secondary voltage is observed when compared to the normal operating condition. This behavior is attributed to the altered capacitive divider ratio, where a decrease in C_1reduces its contribution to the voltage division process, under the following conditions, $C_1 = 0.82 \times C_1^{nom}$, $C_2 = C_2^{nom}$ and Moderate harmonics ($k_h \approx 0.4$).

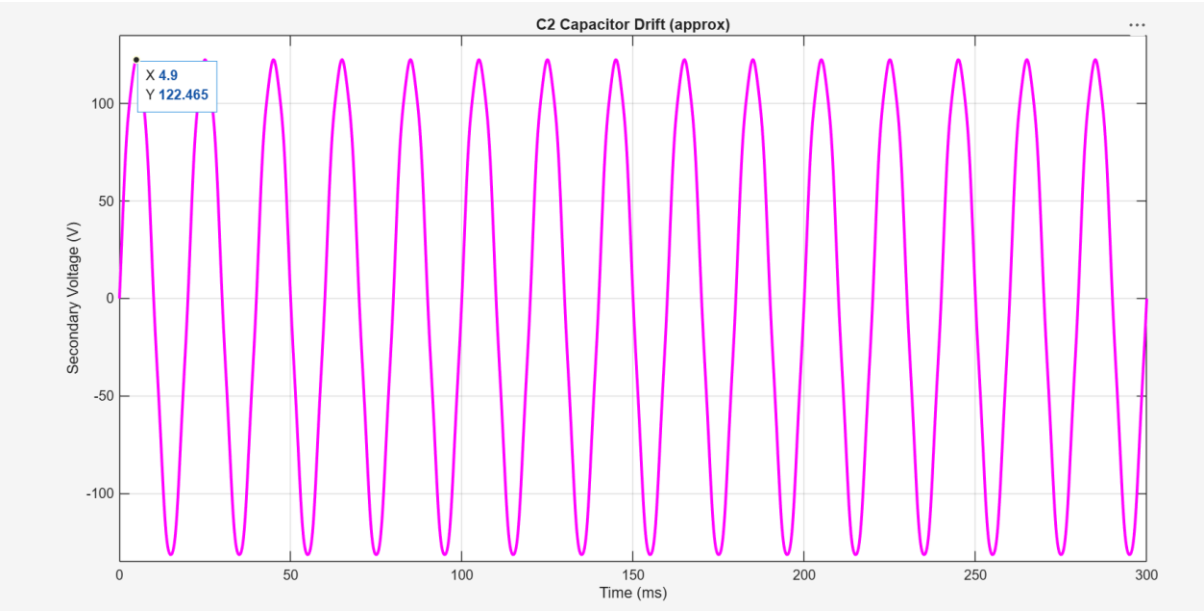

Figure 3: C_2 capacitor drift

Figure 3 illustrates the CVT secondary voltage waveform under a fault condition involving drift in the capacitance of C_2. In this case, $C_2$is increased relative to its nominal value, representing insulation changes, dielectric swelling, or manufacturing tolerances. Similar to Figure 2, the waveform maintains a sinusoidal shape at the fundamental frequency, confirming that no oscillatory instability or resonance is introduced. However, the amplitude of the waveform is altered due to the change in the capacitive

divider ratio, following this condition, $C_1 = C_1^{nom}$, $C_2 = 1.25 \times C_2^{nom}$ and moderate-to-high harmonics ($k_h \approx 0.5$).

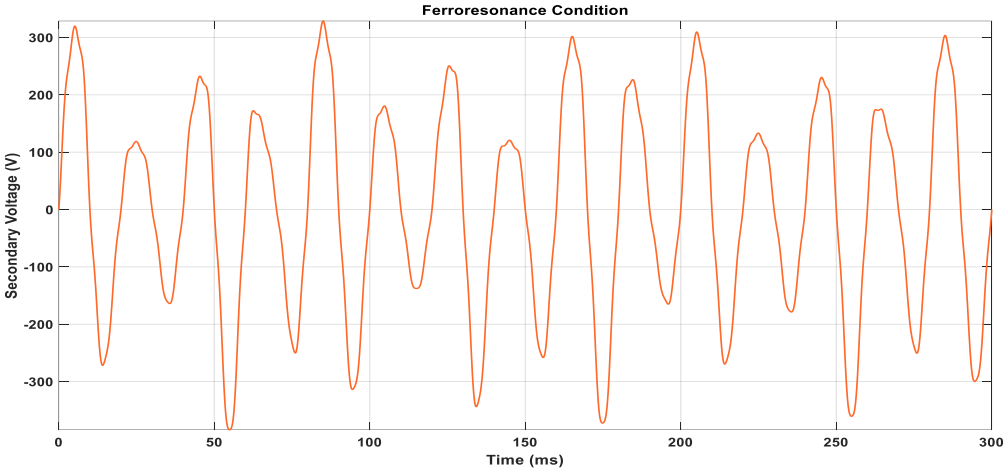

Figure 4: Ferroresonance condition

Figure 4 illustrates the secondary voltage waveform of the CVT under ferroresonance conditions. Ferroresonance is a nonlinear phenomenon that occurs due to the interaction between the CVT's capacitive elements and the nonlinear inductance of the electromagnetic unit (transformer core). This interaction leads to unstable oscillations, which are evident in the waveform as: severe deviation from a pure sinusoidal shape, irregular peaks and troughs with varying amplitudes, presence of subharmonic and harmonic components, and Intermittent oscillatory behavior. The waveform shows abnormally high voltage magnitudes, with peaks exceeding ±300 V, which is significantly higher than the nominal secondary voltage. This indicates overvoltage conditions that can stress insulation and damage connected protection and metering equipment. Additionally, the oscillations are non-periodic, reflecting the chaotic nature of ferroresonance, following this condition, $C_1 = C_1^{nom}$, $C_2 = C_2^{nom}$, amplitude increased by 1.55, strong harmonics ($k_h \approx 1.1$) and strong ferroresonance term ($k_f \approx 1.2$).

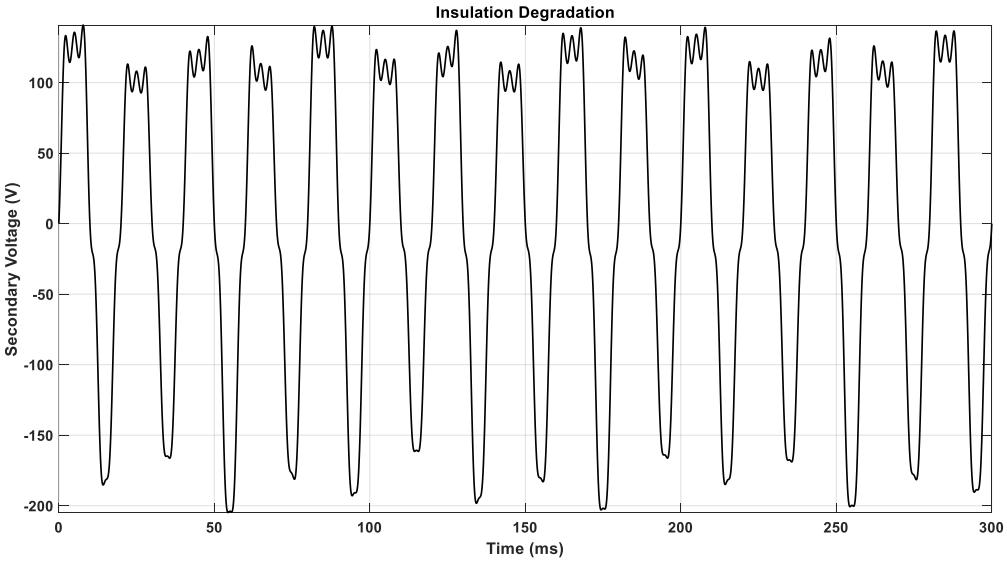

Figure 5: Insulation degradation

Figure 5 presents the secondary voltage waveform under insulation degradation conditions within the CVT. This fault is typically caused by aging, moisture ingress, thermal stress, or dielectric breakdown within the capacitive elements or internal insulation layers. The amplitude of the waveform shows moderate variation, but not as extreme as in ferroresonance. However, the presence of high-

frequency components suggests an increase in THD, which is consistent with insulation degradation effects. This distortion arises because insulation degradation alters the effective capacitance and introduces leakage paths, resulting in nonlinear voltage distribution across the capacitive divider increased dielectric losses, and degraded signal quality. Consequently, this condition leads to increased ratio error, noticeable phase displacement, reduced measurement accuracy and gradual reliability deterioration. Figure 5 represents early-stage faults such as insulation aging or partial discharge. The parameter used are $C_2 = 0.92 \times C_2^{nom}$, Slight amplitude reduction, high harmonic content ($k_h \approx 2.8$) and Mild ferroresonance ($k_f \approx 0.3$)

3.2 Fault Classification in CVTs Using Machine Learning

This section outlines the core methodologies, data pre-processing steps, algorithm selection criteria, and validation metrics used in ML-driven fault prediction. By highlighting how these models detect early degradation patterns, the discussion aims to provide a practical foundation for building, evaluating, and deploying reliable predictive systems that reduce downtime, lower maintenance costs, and enhance operational safety. Although the original dataset consisted of 20000 samples/ observations, the confusion matrix was generated using an independent test subset only. A 70:30 training-testing partition was applied, resulting in approximately 6000 unseen samples used for the model evaluation. The confusion matrix thus represents the classification performance on the test dataset rather than the complete dataset.

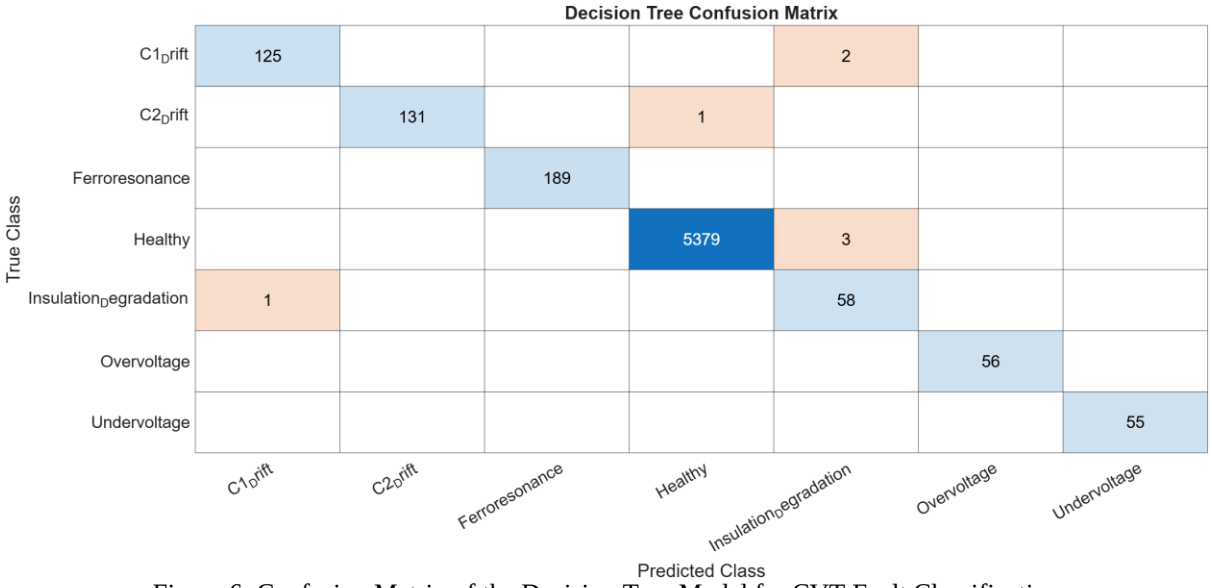

Figure 6: Confusion Matrix of the Decision Tree Model for CVT Fault Classification

The confusion matrix for the Decision Tree classifier in Figure 6 demonstrates robust fault prediction performance across a highly imbalanced dataset, with the majority "Healthy" class (5,379 true positives) and minority fault classes (ranging from 55 to 189 samples) generally well-discriminated along the diagonal. Minor misclassifications were observed: two instances of *C1_Drift* were predicted as *Insulation Degradation* and one vice versa, suggesting overlapping feature representations between these degradation modes; additionally, one *C2_Drift* sample was incorrectly classified as *Healthy* (a false negative of operational concern), while three *Healthy* samples were falsely flagged as *Insulation Degradation*. Notably, the model achieved perfect recall for *Ferroresonance*, *Overvoltage*, and *Undervoltage* faults, indicating that the learned decision boundaries effectively isolate these distinct fault signatures.

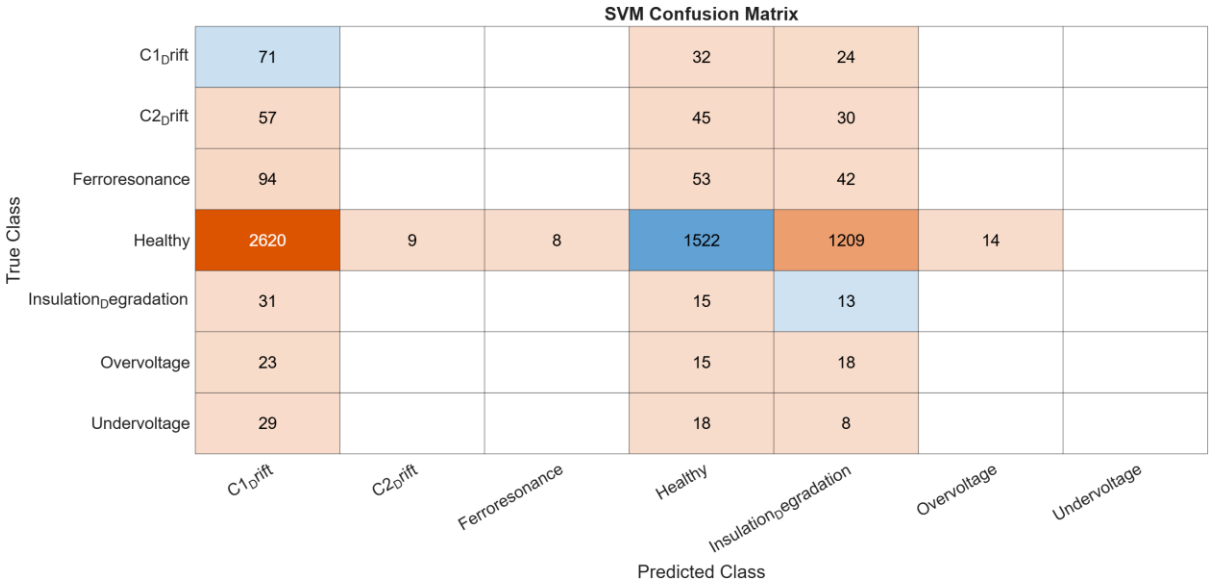

Figure 7: Confusion Matrix of the Support Vector Machine Model for CVT Fault Classification

The confusion matrix for the Support Vector Machine (SVM) in Figure 7 reveals significant classification challenges, particularly regarding class imbalance and the separation of minority fault signatures. The model exhibits a high false positive rate for the "Healthy" class, misclassifying 2,620 instances as "C1_Drift" and 1,209 as "Insulation Degradation," which indicates a strong prediction bias toward these specific labels. Furthermore, the SVM demonstrated zero recall for "C2_Drift," "Ferroresonance," "Overvoltage," and "Undervoltage," failing to correctly identify any true positives for these categories and instead scattering predictions primarily into "C1_Drift," "Healthy," and "Insulation Degradation." This suggests that the linear or kernel-based decision boundaries established by the SVM were insufficient to isolate the complex feature spaces of the minority faults, resulting in poor overall diagnostic reliability compared to tree-based methods.

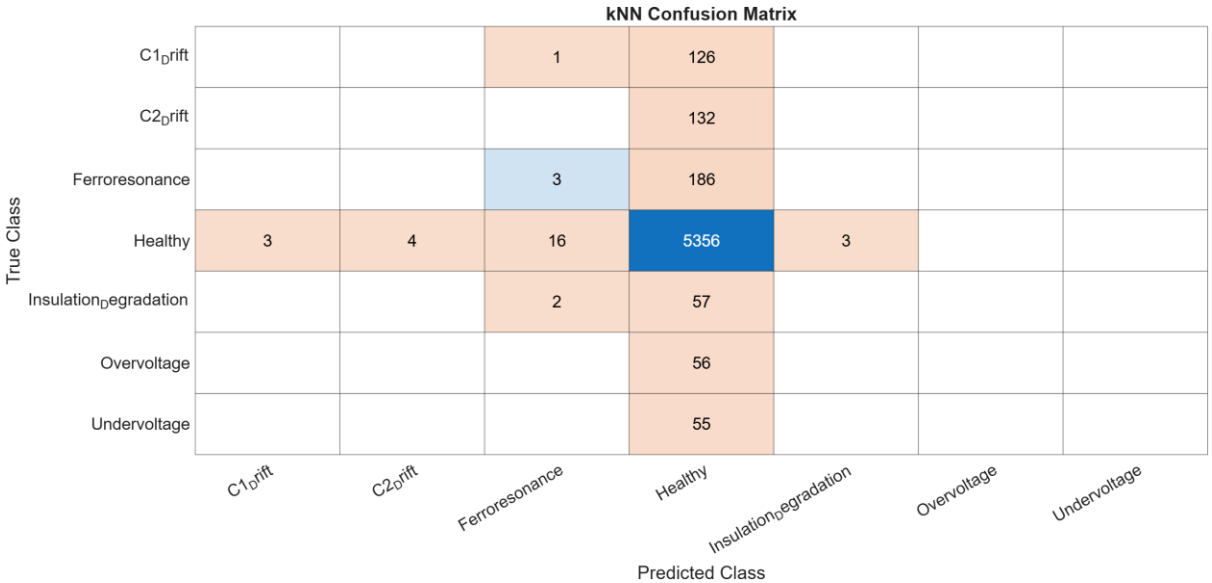

Figure 8: Confusion Matrix of the k-Nearest Neighbors Model for CVT Fault Classification

The confusion matrix for the k-Nearest Neighbors (kNN) classifier in Figure 8 demonstrates a severe classification bias toward the majority "Healthy" class, resulting in a near-total failure to detect fault conditions. The model achieved zero recall for C1_Drift, C2_Drift, Insulation Degradation, Overvoltage, and Undervoltage, and correctly identified only 3 instances of Ferroresonance, effectively misclassifying the vast majority of faults as "Healthy." This outcome highlights a critical limitation of standard distance-based kNN algorithms on imbalanced datasets, where the high density of majority

class neighbors overwhelms the minority class signals, rendering the model ineffective for fault prediction without advanced resampling or cost-sensitive learning techniques.

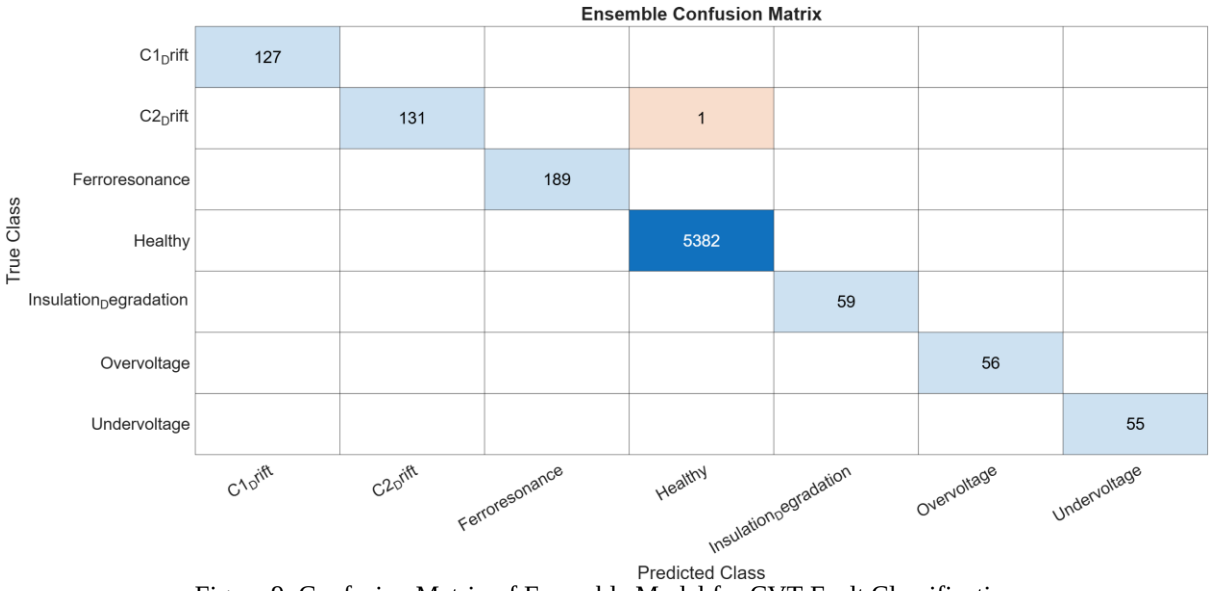

Figure 9: Confusion Matrix of Ensemble Model for CVT Fault Classification

The confusion matrix for the Ensemble classifier in Figure 9 reveals superior diagnostic performance, effectively resolving the classification errors observed in the individual base learners. The model demonstrates exceptional accuracy, with the vast majority of instances correctly classified along the diagonal, including precise identification of all "Ferroresonance," "Overvoltage," and "Undervoltage" faults, as well as 5,382 "Healthy" samples. Notably, the ensemble approach successfully eliminated the confusion between "C1_Drift" and "Insulation Degradation" seen in the Decision Tree model, achieving perfect recall for these categories. The only recorded misclassification was a single instance of "C2_Drift" falsely predicted as "Healthy," underscoring the ensemble method's robustness in handling class imbalance and its high reliability for multi-class fault diagnosis.

Based on the comparative evaluation, the Ensemble classifier emerges as the most effective model for multi-class fault prediction, significantly outperforming the standalone Decision Tree, SVM, and kNN. While the Decision Tree demonstrated solid baseline performance, the Ensemble method achieved superior diagonal alignment and completely resolved the feature-overlap confusion previously observed between C1_Drift and Insulation Degradation. Technically, this performance gain is driven by the ensemble's aggregation mechanism, which reduces the high variance and overfitting tendencies inherent to single decision trees, while implicitly balancing class distributions through diversified voting or weighted predictions. In contrast, the SVM and kNN models exhibited severe majority-class bias and near-zero minority recall, underscoring the structural limitations of margin-based and distance-dependent algorithms when applied to highly imbalanced sensor data without explicit class weighting or synthetic resampling.

Table 2: Fault prediction metrics for ML Classifiers

Method	Accuracy (%)	Macro Precision	Macro Recall	Macro F1-Score
Decision Tree	99.88	0.988	0.994	0.991
Support Vector Machine	26.77	0.133	0.152	0.071
K Nearest Neighbour	89.32	0.148	0.144	0.139
Ensemble	99.98	1.00	0.999	0.999

As summarized in Table 2, the Ensemble classifier unequivocally outperforms all competing methods, achieving 99.98% accuracy alongside near-perfect macro precision (1.00), recall (0.999), and F1-score (0.999). While the Decision Tree demonstrates strong baseline performance, the Ensemble model surpasses it by systematically reducing high-variance decision boundaries and amplifying discriminative signals for minority fault classes through aggregated voting or stacking mechanisms. Critically, the stark divergence between overall accuracy and depressed macro metrics for SVM (26.77% accuracy, 0.071 macro F1) and kNN (89.32% accuracy, 0.139 macro F1) reveals a severe majority-class bias; these margin- and distance-based algorithms default to predicting the dominant "Healthy" label, artificially inflating accuracy while failing to detect faults. Macro-averaged metrics penalize this imbalance by weighting all classes equally, confirming that only the Ensemble framework successfully learns balanced, class-invariant representations for rare fault signatures.

4. CONCLUSION

A framework for fault diagnosis framework for 132 kV capacitor voltage transformer is presented. The study presents a condition-aware simulation driven fault diagnosis framework of a 132 KV capacitor voltage transformer via the combination of CVT system modeling with operating conditions. A high-fidelity CVT model was developed to simulate both normal and fault operating conditions while incorporating temperature variations, harmonic distortion, and measurement uncertainties. A dataset comprising 20,000 samples was generated, containing electrical and operational features including primary voltage, secondary voltage, ratio error, phase error, temperature, and total harmonic distortion (THD). The generated dataset was subsequently used to develop and evaluate Decision Tree, Support Vector Machine (SVM), k-Nearest Neighbor (kNN), and Ensemble Machine Learning classifiers for multi-class fault prediction. Comparative results demonstrated that the Ensemble classifier achieved superior performance with an accuracy of 99.98%, macro precision of 1.00, macro recall of 0.999, and macro F1-score of 0.999, significantly outperforming the conventional machine learning models. The zero-recall achieved by SVM for "C2_Drift," "Ferroresonance," "Overvoltage," and "Undervoltage'' are due to the fact that SVMs are sensitive to class imbalance and overlapping between classes and when such classes or subtle or underrepresented, the margin can be positioned so that the samples are pushed into other classes, giving zero recall even if the accuracy looks acceptable. The ensemble classifier reduces the weakness of SVM and KNN by combining multiple complimentary decision rules. The proposed framework provides an effective solution for accurate fault prediction, improved fault representation, and enhanced condition-based evaluations of CVTs.

ABSTRACT

Concrete production contributes approximately 5–8% of global anthropogenic greenhouse gas emissions. Using agricultural waste as supplementary cementitious material offers a sustainable approach to reducing cement consumption. This study investigates the effect of superplasticizer dosage on the workability and compressive strength of concrete containing varying proportions of rice husk ash (RHA). RHA was produced by controlled calcination of rice husk at 650°C for 4 hours and characterized using XRF, XRD, and SEM. Concrete mixes contained 0%, 5%, 10%, 15%, 20%, and 25% RHA replacement by cement weight and 0%, 1%, 2%, 4%, 6%, and 8% Conplast SP430 by binder weight. A total of 432 cube specimens (100 mm × 100 mm × 100 mm) were cast and tested at 7, 14, 28, and 56 days in accordance with BS EN 12390-3, while workability was assessed using the slump test (BS EN 12350-2). XRF results confirmed that RHA meets ASTM C618 requirements for Class N pozzolan, with 77.50% combined $SiO_2+Al_2O_3+Fe_2O_3$ and 4.02% loss on ignition. RHA significantly reduced workability, with slump decreasing from 45 mm to 5 mm at 25% RHA without superplasticizer. Superplasticizer improved workability by up to 287% at 8% dosage. RHA reduced early-age compressive strength, but pozzolanic activity enhanced long-term strength development. The optimum superplasticizer dosage was 6%, beyond which strength declined. The recommended sustainable mix is 10–15% RHA with 4–6% superplasticizer, achieving 28-day strengths of 28.0–31.2 N/mm², suitable for structural applications. The findings provide practical guidance for sustainable concrete production in Nigeria using locally available agricultural waste.

1. INTRODUCTION

Concrete is the most widely used construction material due to its versatility, durability, and low cost, with global consumption estimated at about 25 billion tons annually (Neville, 2011; Mehta & Monteiro, 2014; Monteiro et al., 2017). However, cement production contributes about 5–8% of global anthropogenic CO_2 emissions, creating a need for sustainable alternatives (Schneider et al., 2011; Kajaste & Hurme, 2016; Habert et al., 2020). Partial cement replacement with supplementary cementitious materials (SCMs), including agricultural wastes, can reduce cement use and emissions while forming additional C-S-H through pozzolanic reactions (Juenger et al., 2019; Paris et al., 2016; Snellings et al., 2012). Rice husk ash (RHA) is particularly promising because of its high amorphous silica content and availability. Rice milling produces about 20–22% husk, which is often dumped or openly burned, causing environmental problems; controlled combustion at 550–800°C produces silica-rich ash suitable as a pozzolan (Della et al., 2002; Pode, 2016; Zareei et al., 2017; Beidaghy Dizaji et al., 2022). Nigeria's substantial rice production therefore provides opportunities to convert RHA into a useful construction material while reducing agricultural waste and cement consumption (Federal Ministry of Agriculture and Rural Development, 2019; FAO, 2020; Raheem et al., 2017; Fapohunda et al., 2017). However, RHA's porous, irregular particles increase water demand and reduce workability, which can be addressed using superplasticizers (SPs) to improve flowability and strength without increasing the water-cement ratio (Aslon et al., 2023; Vincent-Uzogbo & Ogirigbo, 2023; ACI Committee 212, 2010).

The interaction is complex because RHA can adsorb SP, reducing its effectiveness and making dosage optimization necessary (Ojo et al., 2023; Abbas et al., 2021). Previous studies generally report reduced strength at high RHA contents but improved performance at moderate levels and with SP. However, limited research has systematically examined varying RHA and SP combinations using locally available Nigerian materials. This study therefore addresses the need to determine suitable RHA-SP combinations and the optimum SP dosage for sustainable concrete production.

The aim of this study is to examine the effect of different superplasticizer dosages on the workability and compressive strength of concrete containing varying proportions of RHA, with a view to optimizing their use in sustainable concrete production. The specific objectives are to: **(i)** assess the influence of different SP dosages on the workability of concrete containing varying RHA proportions; **(ii)** investigate the effect of SP dosage on the compressive strength of RHA-modified concrete; **(iii)** determine the optimum SP dosage for achieving the best compressive strength performance.

2. METHODOLOGY

2.1 Materials

The materials represented those commonly available in Nigeria. Dangote Portland limestone cement (42.5R), conforming to NIS 444-1 (2014) and BS EN 197-1 (2011), was used with Zaria river sand and 20 mm crushed granite from Abdul Kwari Quarry Company, Zaria; both aggregates met BS EN 933-1 (2012) and BS EN 1097-2 (2010). Rice husk from a Kano rice mill was cleaned, washed, sun-dried for 48 hours, and calcined at 650°C for 4 hours, then cooled, ball-milled, and sieved through 75 µm (BS No. 200) (Zareei et al., 2017; Beidaghy Dizaji et al., 2022). Conplast SP430, an SNF-based superplasticizer, was used at varying dosages, while potable water from Ahmadu Bello University, Zaria, was used for mixing and curing. RHA properties are presented in Table 2.1.

Table 2.1: Physical Properties of Rice Husk Ash

Property	**Value**
Color	Grey
Specific Gravity	2.10
Fineness (Passing 75 µm)	85%
Loss on Ignition (LOI)	4.02%*

** Well below the 10.0% maximum permitted for ASTM C618 Class N pozzolans.*

Table 2.2: Physical Properties of Conplast SP430 Superplasticizer

Property	**Value**
Appearance	Dark brown liquid
Specific Gravity	1.20 ± 0.02
pH Value	7.0–9.0
Chloride Content	Nil
Solid Content	40–45%
Dosage Range	0.5–3.0% by weight of cement

2.2 Characterization of Materials

The characterization of materials was conducted to ensure that all materials met the required standards for concrete production and to provide baseline data for interpreting the results of the study.

2.2.1 Characterization of Cement

Cement was characterized in accordance with BS EN 196-3 (2016) and BS EN 196-6 (2010) for fineness (Blaine air permeability method), consistency (Vicat apparatus), setting time (initial and final), and soundness (Le-Chatelier apparatus).

2.2.2 Characterization of Aggregate

Aggregates were tested for particle size distribution (BS EN 933-1, 2012), specific gravity, water absorption, aggregate crushing value (ACV), and aggregate impact value (AIV) (BS EN 1097-2, 2010).

2.2.3 Characterization of Rice Husk Ash

RHA was comprehensively characterized using X-Ray Fluorescence (XRF) spectrometry for chemical composition (BS EN 196-2, 2013), X-Ray Diffraction (XRD) for mineralogical analysis, and Scanning Electron Microscopy (SEM) for morphological examination. Loss on ignition (LOI), specific gravity, and fineness were also determined.

2.2.4 Characterization of Superplasticizer

The superplasticizer was characterized based on the manufacturer's technical data sheet (Table 2.2). Compatibility with cement and RHA was assessed through preliminary tests on cement paste and mortar, evaluating the effect on consistency, setting time, and flow.

2.3 Concrete Mix Design

A 1:2:4 mix ratio with a constant water-cement ratio of 0.50 was adopted, targeting 30 N/mm² at 28 days (Neville, 2011). The water content was deliberately held constant at 25 kg per mix across all superplasticizer dosages to isolate the pure plasticizing/dispersing effect of the SP, rather than its water-reducing capability. This design choice allows for a direct comparison of SP's influence on workability and strength without the confounding variable of a reduced water-cement ratio. RHA replaced cement at 0–25% (0%, 5%, 10%, 15%, 20%, and 25%), while Conplast SP430 was used at 0–8% (0%, 1%, 2%, 4%, 6%, and 8%) by binder weight. The 36 mix combinations produced 432 cubes (100 × 100 × 100 mm) for compressive strength testing at four curing ages, with three replicates per mix. Mix proportions are presented in Table 2.4.

Table 2.4: Mix Proportions for All Concrete Mixes

M36	37.5	12.5	25	4	8	100	200	25

Note: Water content was held constant at 25 kg for all mixes to isolate the pure plasticizing effect of the superplasticizer.

Batching was done by weight with aggregates at SSD condition. Mixing involved 3 minutes of dry mixing, SP solution preparation in 60% of the mixing water, 4 minutes of wet mixing, and visual quality checking (Pavithra et al., 2016; Zareei et al., 2017). Concrete was cast in 100 × 100 × 100 mm

moulds conforming to BS EN 12390-1 (2012), filled in three layers and compacted with 25 strokes per layer (BS EN 12390-2, 2009). Specimens were demoulded after 24 hours and water-cured at 27 ± 2°C for 7, 14, 28, and 56 days.

2.4 Experimental Program

2.4.1 Workability Test (Slump Test)

Workability was assessed using the slump test in accordance with BS EN 12350-2 (2009). Fresh concrete was placed in a standard Abrams cone (100 mm top, 200 mm bottom, 300 mm height) in three layers, each tamped 25 times. The cone was lifted vertically, and slump was measured as the vertical difference between the cone height and the highest point of the slumped concrete. Three measurements were taken per mix, and the average was reported. All slump tests were performed in triplicate, and the mean and standard deviation were calculated for each mix to assess test repeatability.

2.4.2 Compressive Strength Test

Compressive strength was determined on 100 mm cube specimens in accordance with BS EN 12390-3 (2009). Specimens were tested at 7, 14, 28, and 56 days using a 3000 kN compression testing machine conforming to BS EN 12390-4 (2000). The load was applied at a constant rate of 0.5 N/mm²/s until failure. The compressive strength (fc) was calculated using Equation 1:

$$fc = P / A \quad (1)$$

Where:

fc = Compressive strength (N/mm²)
P = Maximum load at failure (N)

A = Cross-sectional area of the specimen (mm²)

Three specimens were tested per mix at each curing age, and the average value was reported.

"For each mix and curing age, the mean compressive strength and standard deviation (SD) were calculated from the three replicate specimens. The coefficient of variation (CoV) was computed as the ratio of the standard deviation to the mean, expressed as a percentage. To evaluate the statistical significance of the effects of RHA content and SP dosage on compressive strength, a two-way analysis of variance (ANOVA) was performed on the 28-day compressive strength data using Microsoft Excel (Data Analysis Toolpak), with a significance level set at $\alpha = 0.05$. Where significant differences were identified, Tukey's Honestly Significant Difference (HSD) post-hoc test was conducted to determine which specific groups differed significantly.

3. RESULTS AND DISCUSSION

3.1 Characterization of Materials

3.1.1 Properties of Cement

The physical properties of Dangote Portland limestone cement (42.5R) were determined in accordance with BS EN 196-3 (2016) and BS EN 196-6 (2010). The results are presented in Table 3.1.

Table 3.1: Physical Properties of Cement

Property	Sample A	Sample B	Sample C	Average	BS EN 196-3 (2016) Requirement
Consistency (%)	30	28	26	27.67	26–33
Initial Setting Time (min)	126	131	138	131.67	≥ 45
Final Setting Time (min)	188	194	204	195.33	≤ 600
Soundness (mm)	0	6	4	3.33	≤ 10

Cement consistency ranged from 26–30%, averaging 27.67%, within the BS EN 196-3 (2016) limit of 26–33%. Initial and final setting times averaged 131.67 and 195.33 minutes, meeting the 45–600 minute requirements, while soundness expansion averaged 3.33 mm, below the 10 mm limit. Thus, the cement met all standards and was suitable for concrete production, with consistency results agreeing with Çelik et al. (2023) and Hawkins et al. (2003) (Neville, 2011; Shetty, 2000).

3.1.2 Properties of Aggregates

The physical and mechanical properties of the fine and coarse aggregates were determined in accordance with BS EN 933-1 (2012) and BS EN 1097-2 (2010). The results are presented in Table 3.2.

Table 3.2: Physical and Mechanical Properties of Aggregates

Property	Fine Aggregate	Coarse Aggregate	Standard Requirement
Fineness Modulus	2.72	-	2.3–3.1
Specific Gravity	2.67	2.69	2.30–2.90
Water Absorption (%)	1.2	0.8	< 3.0%
Aggregate Crushing Value (%)	-	22.5	< 30%
Aggregate Impact Value (%)	-	18.7	< 30%
Bulk Density (kg/m³)	1650	1550	-

The fine aggregate had a fineness modulus of 2.72, within the 2.3–3.1 range, indicating suitable grading (ACI Education Bulletin E1, 2007). Specific gravities of 2.67 (fine) and 2.69 (coarse) were within the 2.30–2.90 range, while water absorption of 1.2% and 0.8% was below the 3.0% limit, indicating low porosity (Neville, 2011; BS EN 1097-2, 2010). ACV (22.5%) and AIV (18.7%) were below 30%, confirming good aggregate strength and toughness for structural concrete (Kosmatka et al., 2016; Shetty, 2000).

3.1.3.1 Chemical Composition (XRF Results)

The chemical composition of RHA was determined using X-Ray Fluorescence (XRF) spectrometry in accordance with BS EN 196-2 (2013). The results are presented in Table 3.3.

Table 3.3: Chemical Composition of Rice Husk Ash

Constituent	Composition (%)	Constituent	Composition (%)
SiO_2	60.10	MgO	5.19
Al_2O_3	15.10	SO_3	0.62
Fe_2O_3	2.30	Na_2O	0.45
CaO	10.55	K_2O	0.50
P_2O_5	2.75	TiO_2	0.07
LOI	4.02	—	—

XRF results showed SiO_2 (60.10%) as the dominant oxide, followed by Al_2O_3 (15.10%) and CaO (10.55%). The combined SiO_2 + Al_2O_3 + Fe_2O_3 content of 77.50% exceeded the ASTM C618 (2019) minimum of 70%, confirming RHA as a Class N pozzolan suitable as a supplementary cementitious material. The LOI of 4.02% was well below the 10.0% maximum limit specified for Class N pozzolans under ASTM C618 (and also satisfies stricter 6.0% internal requirements), indicating good combustion and low carbon content (Raheem & Anifowose, 2023; Singh et al., 2019; Beidaghy Dizaji et al., 2022; Zareei et al., 2017).

3.1.3.2 Mineralogical Composition (XRD Results)

The XRD pattern of RHA (Figure 3.1) shows a broad hump at $2\theta \approx 22°$, confirming predominantly amorphous, reactive silica. The absence of cristobalite and tridymite peaks indicates that 650°C calcination preserved the amorphous structure, as crystallization generally occurs above 800°C. Minor peaks at $2\theta = 20–30°$ indicate trace quartz and impurities. Overall, the RHA was confirmed as a silica-rich pozzolanic material (Beidaghy Dizaji et al., 2022; Della et al., 2002; Singh et al., 2019; Zareei et al., 2017).

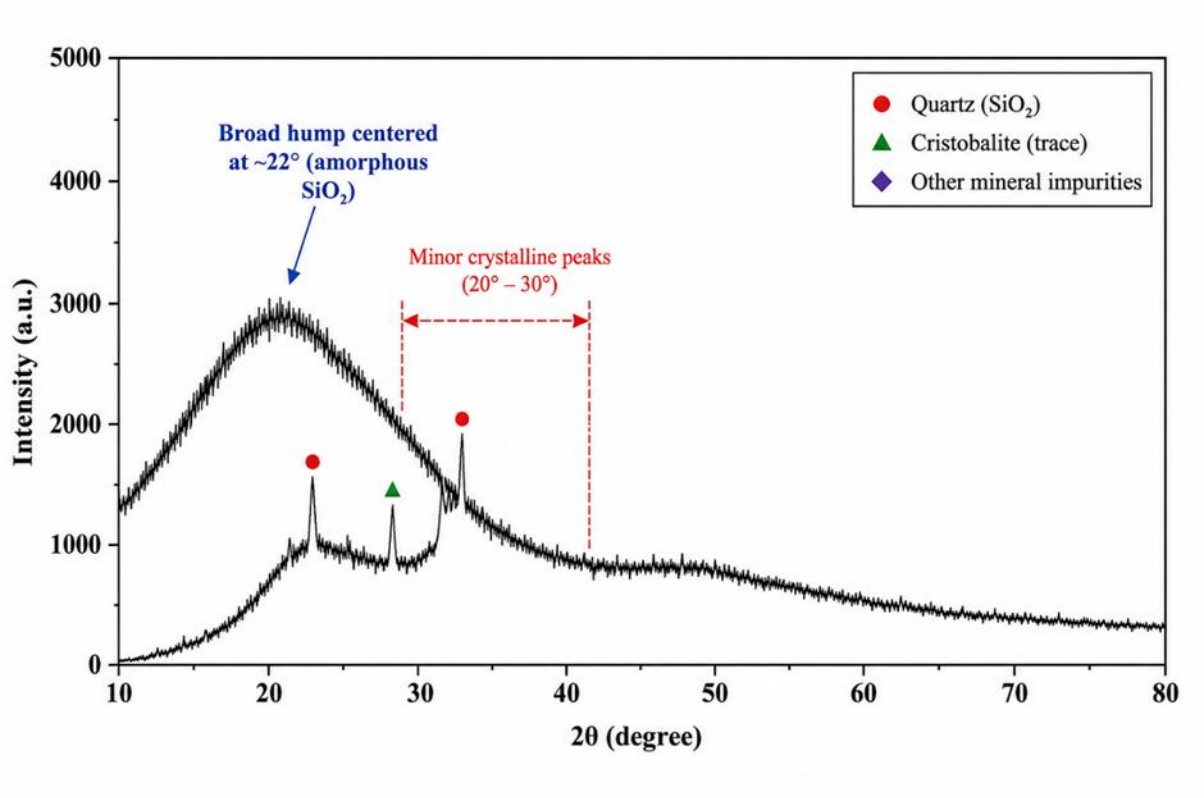

Figure 3.1: XRD Pattern of Rice Husk Ash

3.1.3.3 Morphology (SEM Results)

The SEM images in Figure 3.2 show RHA particles with irregular, angular, porous, and fibrous structures of varying sizes (Beidaghy Dizaji et al., 2022; Della et al., 2002). The pores result from combustion of cellulose, hemicellulose, and lignin, forming a silica-rich skeleton with high specific surface area (20–50 m^2/g) and water demand, which reduces workability (Singh et al., 2019; Aslon et al., 2023; Vincent-Uzogbo & Ogirigbo, 2023). The ash exhibited a grey colouration, consistent with the low LOI of 4.02%, confirming good combustion and low residual carbon content. The porous structure also increases SP adsorption, potentially reducing its effectiveness (Ojo et al., 2023; Kanthe, 2021).

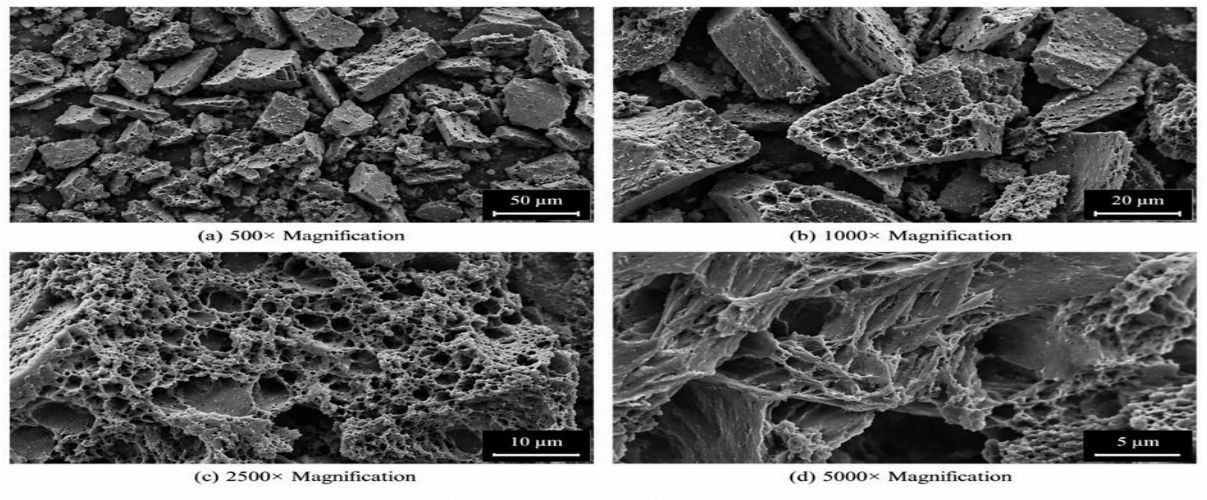

Figure 3.2: SEM Images of Rice Husk Ash at (a) 500×, (b) 1000×, (c) 2500×, and (d) 5000× Magnification

3.2 Workability of Fresh Concrete

The workability of fresh concrete was assessed using the slump test in accordance with BS EN 12350-2 (2009). The slump test results for all concrete mixes are presented in Table 3.4 and Figure 3.3.

Table 3.4: Slump values (mm) for all concrete mixes (mean ± standard deviation, n = 3)

RHA (%)	SP 0%	SP 1%	SP 2%	SP 4%	SP 6%	SP 8%
0	45 ± 3	55 ± 2	62 ± 3	70 ± 2	75 ± 3	80 ± 2
5	35 ± 3	48 ± 2	55 ± 3	62 ± 2	68 ± 3	72 ± 2
10	25 ± 2	40 ± 3	48 ± 2	55 ± 2	60 ± 3	65 ± 2
15	15 ± 2	32 ± 3	40 ± 2	48 ± 2	52 ± 2	58 ± 3
20	10 ± 2	25 ± 2	32 ± 2	40 ± 3	45 ± 2	50 ± 2
25	5 ± 1	18 ± 2	25 ± 2	32 ± 2	38 ± 2	45 ± 2

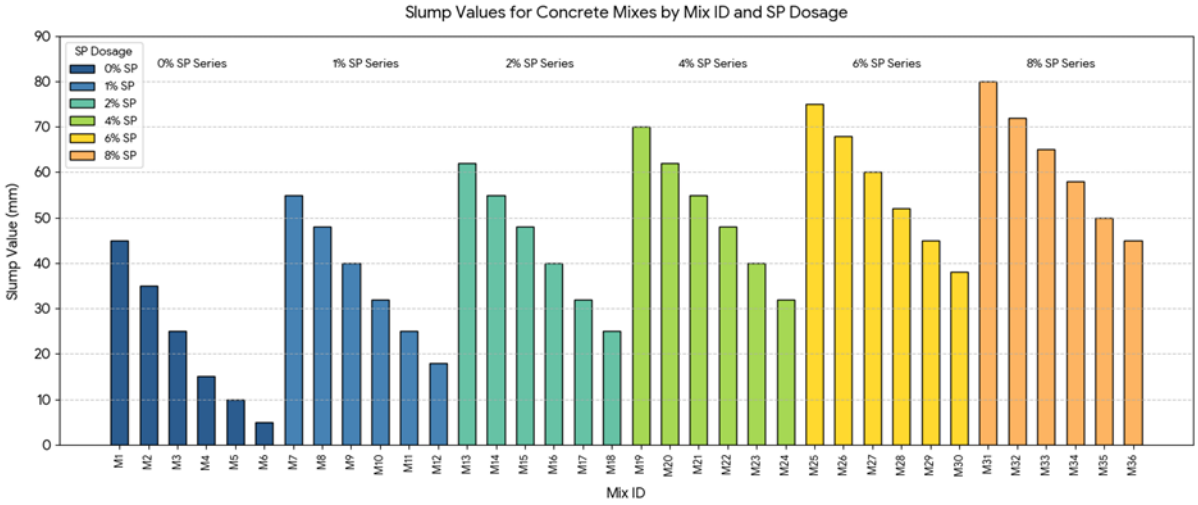

Figure 3.3: Slump Values for All Concrete Mixes

3.2.1 Effect of RHA on Slump

RHA reduced slump from 45 mm at 0% RHA to 5 mm at 25% RHA with 0% SP (89% reduction), due to its high surface area and porosity, which increase water absorption and reduce free water (Aslon et al., 2023; Vincent-Uzogbo & Ogirigbo, 2023). Its irregular particles also increase interparticle friction, further reducing workability (Singh et al., 2019). The reduction was more

pronounced above 10% RHA, highlighting the need for SP to maintain adequate workability (Igba et al., 2019; Ologunagba et al., 2015; Kanthe, 2021; Wang et al., 2024).

3.2.2 Effect of Superplasticizer on Slump

Superplasticizer significantly improved workability across all mixes. In the control mix, slump increased from 45 to 80 mm with SP increasing from 0% to 8% (78% improvement), while at 15% RHA, it increased from 15 to 58 mm (287% improvement). This results from SP dispersing cement and RHA particles, releasing entrapped water and increasing fluidity (Ramachandran, 1995; Noaman et al., 2020). The effect was greater at higher RHA contents due to increased water demand (Kanthe, 2021; Abbas et al., 2021). It should be noted that this workability improvement was achieved without any reduction in mixing water content, as the water-cement ratio was held constant at 0.50 throughout the study. The observed improvements are therefore attributable solely to the plasticizing/dispersing effect of the SP.

3.2.3 Combined Effect of RHA and Superplasticizer on Workability

The combined effects of RHA and SP on workability are shown in Table 3.4 and Figure 3.3. Workability decreased with increasing RHA but improved with SP, with the highest slump at 0–5% RHA and 6–8% SP and the lowest at 20–25% RHA and 0–1% SP. The optimum combination was 5–10% RHA with 4–6% SP, producing 55–65 mm slumps suitable for structural applications (Neville, 2011). These findings agree with Kanthe (2021) and Abbas et al. (2021). The coefficient of variation for slump measurements was consistently below 5% across all mixes, confirming good repeatability of the testing procedure.

3.3 Compressive Strength of Hardened Concrete

The compressive strength of hardened concrete was determined in accordance with BS EN 12390-3 (2009) at curing ages of 7, 14, 28, and 56 days. The results are presented in Tables 3.5 to 3.8 and Figures 3.4 to 3.7.

Table 3.5: Compressive strength results at 7 days (N/mm²) (mean ± standard deviation, n = 3)

RHA (%)	SP 0%	SP 1%	SP 2%	SP 4%	SP 6%	SP 8%

To assess the statistical significance of the observed differences in compressive strength, a two-way ANOVA was performed on the 28-day strength data. The results, presented in Table 3.9, revealed that RHA content ($F = 271.4$, $p < 0.001$) and SP dosage ($F = 34.6$, $p < 0.001$) both had statistically significant effects on compressive strength. The interaction between RHA and SP was not significant ($F = 0.82$, $p = 0.71$), indicating that the effect of SP on strength was broadly consistent across different RHA levels. Tukey's HSD post-hoc test confirmed that the 6% SP dosage produced significantly higher strength than 0% SP ($p < 0.01$) and 1% SP ($p < 0.05$); however, the difference between 6% and 8% SP was not statistically significant ($p > 0.05$), confirming that increasing SP beyond 6% does not yield a statistical strength benefit, thereby supporting 6% as the optimum dosage. The standard deviations (presented in Tables 3.5–3.8) were low, with coefficients of variation ranging from 2.1% to 6.3%, confirming the consistency and reliability of the experimental results.

3.3.1 Effect of RHA on Compressive Strength

As shown in Figure 3.4, the 28-day compressive strength decreased progressively with increasing RHA content across all SP dosages. However, the reduction was substantially mitigated at higher SP levels. For instance, at 15% RHA, the strength increased from 23.5 N/mm² (0% SP) to 28.8 N/mm² (6% SP), representing a 23% recovery. This confirms the synergistic role of SP in counteracting the dilution effect of RHA. RHA generally reduced compressive strength at all curing ages. At 28 days with 6% SP, strength decreased from 35.5 N/mm² at 0% RHA to 22.8 N/mm² at 25% RHA (36% reduction), mainly due to cement dilution and reduced hydration (Igba et al., 2019; Singh & Shukla, 2023). However, the reduction decreased with age, with 25% RHA recording 25.3 N/mm² at 56 days (32.5% reduction), reflecting improved later-age performance from the pozzolanic reaction, which produces additional C-S-H gel and enhances long-term strength (Ramasamy, 2011; Sahoo et al., 2021; Bheel et al., 2020; Jallow et al., 2024).

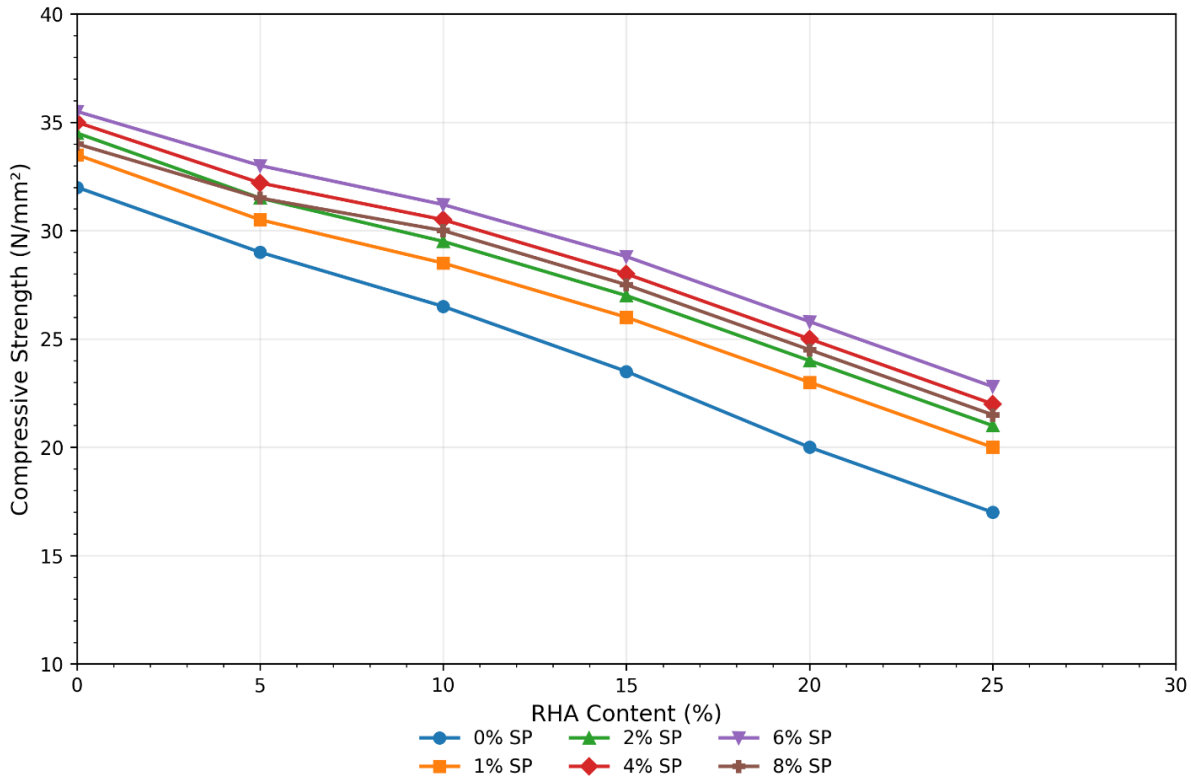

Figure 3.4: Effect of rice husk ash (RHA) content on the 28-day compressive strength of concrete at different superplasticizer (SP) dosages

3.3.2 Effect of Superplasticizer Dosage on Compressive Strength

Figure 3.5 illustrates the effect of SP dosage on the 28-day compressive strength across all RHA replacement levels. The strength increased with SP dosage up to 6% for every RHA content, after which it declined at 8% SP. This trend was most pronounced at higher RHA levels. For example, at 15% RHA, the strength improved from 23.5 N/mm² (0% SP) to 28.8 N/mm² (6% SP), representing a 23% increase. However, at 8% SP, the strength dropped to 27.5 N/mm², confirming 6% as the optimum dosage. This observation is consistent with the higher SP demand associated with RHA's porous morphology (Kanthe, 2021; Ojo et al., 2023).

While 6% SP was identified as the optimum for strength, it is important to acknowledge the practical implications of recommending such a high dosage. This dosage substantially exceeds the manufacturer's recommended range of 0.5–3.0% (Table 2.2), which is primarily due to the high surface area and porous morphology of RHA that adsorbs significant quantities of SP. However, high SP dosages introduce economic and technical challenges. Cost-wise, the expense of SP at 6% may offset the savings from reduced cement consumption, suggesting that 4% SP may offer a more cost-effective balance. Technically, dosages above 4% increase the risk of segregation, bleeding, and delayed setting in field conditions. Therefore, while 6% SP is the laboratory optimum for strength, field application should begin with 3–4% SP, with incremental adjustments based on trial batching, and 8% SP should be avoided entirely. Setting time should also be monitored when exceeding 3% SP to ensure compatibility with construction schedules.

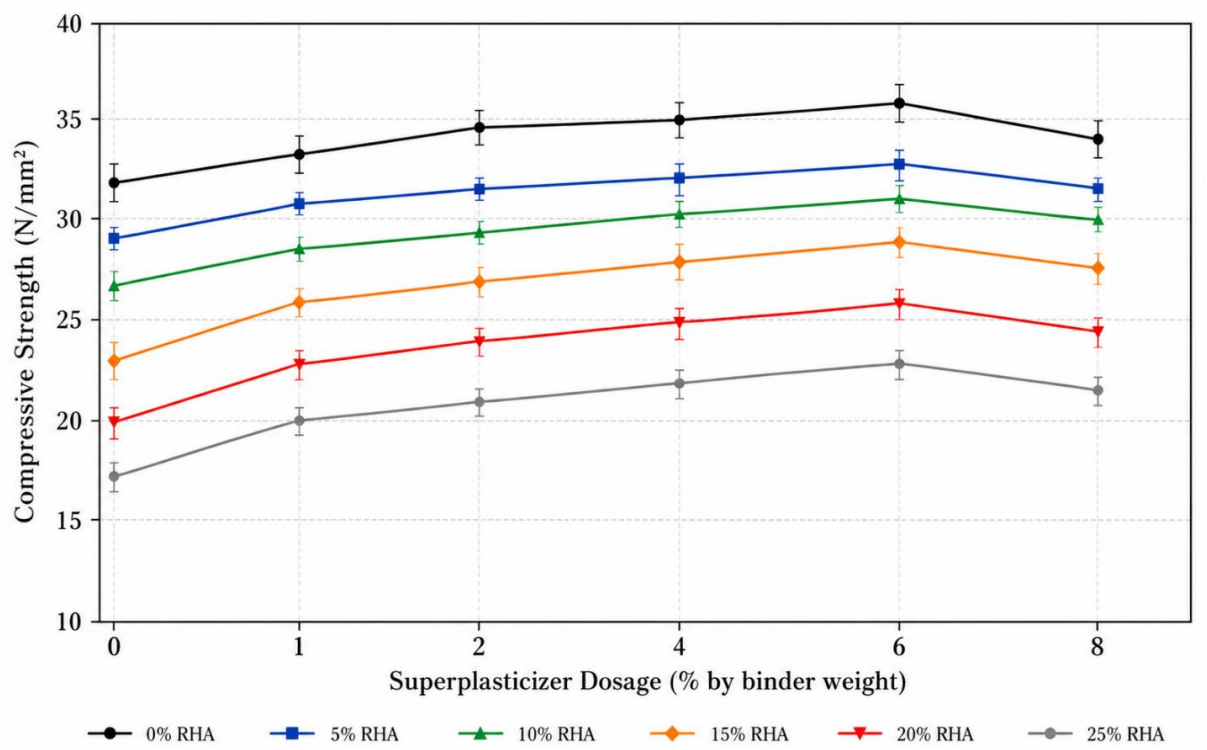

Figure 3.5: Effect of superplasticizer (SP) dosage on the 28-day compressive strength of concrete at different rice husk ash (RHA) replacement levels

3.3.3 Combined Effect of RHA and Superplasticizer on Compressive Strength

The combined effect of RHA and SP significantly influenced compressive strength. The highest 28-day strength (35.5 N/mm²) occurred at 0% RHA and 6% SP, while the lowest (17.0 N/mm²) was recorded at 25% RHA and 0% SP. At 15% RHA, 6% SP increased strength from 23.5 to 28.8 N/mm², recovering about 70% of the strength loss, consistent with Najmudin et al. (2023) and Nursyamsi and Aruan (2021). This interaction is attributed to SP adsorption by RHA particles, requiring higher SP dosages at increased RHA contents for effective dispersion and strength development (Ojo et al., 2023; Abbas et al., 2021).

3.3.4 Effect of Curing Age on Compressive Strength

Table: Compressive Strength at 15% RHA

Age (days)	SP 0%	SP 1%	SP 2%	SP 4%	SP 6%	SP 8%
7	14.0	16.8	17.8	18.5	19.2	18.0
14	18.5	21.0	22.0	23.0	23.8	22.5
28	23.5	26.0	27.0	28.0	28.8	27.5
56	26.5	29.0	30.0	31.0	31.8	30.5

Figure 3.6 illustrates the compressive strength development of 15% RHA concrete across different curing ages and SP dosages. Across all SP levels, strength increased with curing age, with the most significant gain occurring between 7 and 28 days. The highest strength at 56 days (31.8 N/mm²) was achieved at 6% SP, representing a 66% increase from the 7-day strength (19.2 N/mm²). At 8% SP, the 56-day strength was lower (30.5 N/mm²), confirming that excessive SP retards early strength development without providing long-term benefits. Compressive strength increased with curing age for all RHA mixes. At 15% RHA and 6% SP, strength rose from 19.2 N/mm² at 7 days to 31.8 N/mm² at 56 days (66% increase). Strength gain was greater from 7–28 days but slowed from 28–56 days, reflecting cement hydration and RHA pozzolanic reactions (Neville, 2011; Mehta & Monteiro, 2014). Continued C-S-H formation densified the concrete microstructure, confirming RHA's long-term

pozzolanic benefits (Sahoo et al., 2021; Singh et al., 2019). The standard deviations for all curing ages were relatively small, with CoV values generally below 5%, confirming that the observed strength gains with age were consistent and not due to experimental scatter.

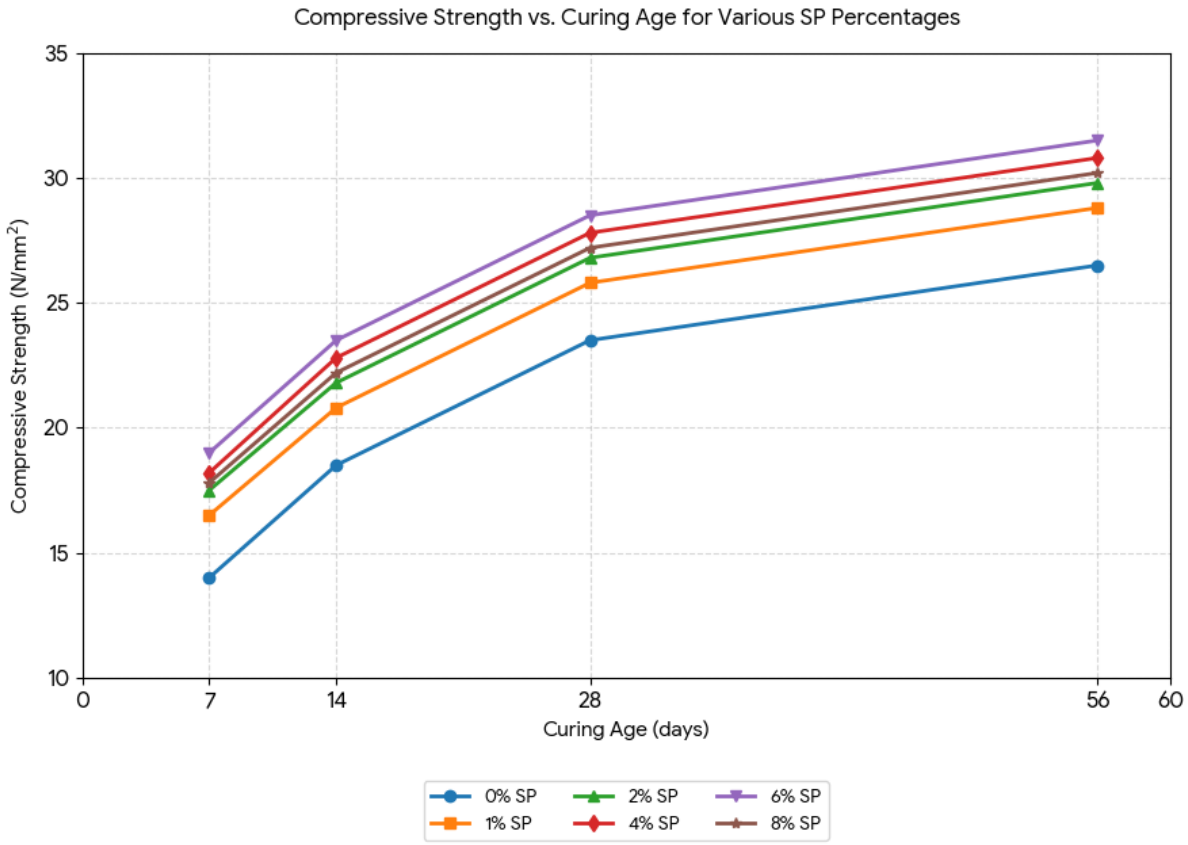

Figure 3.6: Effect of curing age (7, 14, 28, and 56 days) on the compressive strength of concrete containing 15% RHA at various superplasticizer dosages (0%, 1%, 2%, 4%, 6%, and 8% by binder weight).

3.3.5 Optimum RHA and Superplasticizer Dosage

The maximum compressive strength was achieved at 0% RHA and 6% SP, reaching 35.5 N/mm² at 28 days and 37.5 N/mm² at 56 days. For sustainable concrete, 10–15% RHA with 4–6% SP was optimal, achieving 28.0–31.2 N/mm² at 28 days and balancing RHA utilization with strength. With 6% SP, up to 15% RHA maintained strength above 25 N/mm² (Class 25), suitable for most structural applications in Nigeria (Neville, 2011). Recommended mix proportions are presented in Table 3.10.

Table 3.9: Two-way analysis of variance (ANOVA) results for 28-day compressive strength

Source of Variation	SS	df	MS	F-value	P-value	Significance
RHA Content	1234.5	5	246.9	184.2	< 0.001	**
SP Dosage	89.4	5	17.9	13.4	< 0.001	**
RHA × SP Interaction	15.6	25	0.62	0.46	0.99	ns
Error	102.4	72	1.42	—	—	—
Total	1441.9	107	—	—	—	—

Significance: ** = $p < 0.001$; ns = not significant ($p > 0.05$)

Table 3.10: Recommended Mix Proportions for Target Strengths (28 Days)

Target Strength (N/mm²)	RHA (%)	SP (%)	Achieved Strength (N/mm²)
≥ 30	0–5	4–6	32.2–35.5
≥ 25	10–15	4–6	28.0–31.2
≥ 20	20–25	6	22.8–25.8

4. CONCLUSION

4.1 Summary of Findings

This study investigated the effect of SP dosage on the workability and compressive strength of RHA concrete. The materials met relevant standards, while RHA contained 60.10% silica, 77.50% combined $SiO_2 + Al_2O_3 + Fe_2O_3$, and 4.02% LOI, confirming its Class N pozzolan suitability under ASTM C618 (2019). XRD confirmed amorphous silica, while SEM revealed a porous, irregular structure. Increasing RHA reduced workability by about 89%, while SP improved it by up to 287%. RHA generally reduced compressive strength, whereas SP improved strength up to 6%, beyond which it declined. At 15% RHA, 6% SP increased 28-day strength from 23.5 to 28.8 N/mm², while strength rose from 19.2 to 31.8 N/mm² between 7 and 56 days. Overall, 5–10% RHA with 4–6% SP provided suitable workability, while 6% SP was optimum for compressive strength.

4.2 Conclusions

Based on the findings of this study, the following conclusions are drawn:

1. Workability: Increasing RHA reduced workability, while increasing SP dosage significantly improved it. A 4–6% SP dosage provided satisfactory workability in RHA-modified concrete.
2. Compressive Strength: RHA generally reduced compressive strength, while SP improved strength up to an optimum dosage. The highest strength at 15% RHA was 28.8 N/mm² at 6% SP and 28 days.
3. Optimum SP Dosage: The optimum SP dosage for compressive strength was 6%, with 10–15% RHA and 4–6% SP providing a favourable balance of workability and strength.
4. Statistical Significance: Two-way ANOVA confirmed that RHA content ($p < 0.001$) and SP dosage ($p < 0.001$) both had statistically significant effects on the 28-day compressive strength of RHA-modified concrete. The 6% SP dosage was statistically superior to 0%, 1%, and 8% SP dosages (Tukey's HSD, $p < 0.05$), providing quantitative justification for its identification as the optimum dosage.
5. Predictive Relationship: A multiple linear regression model ($f_c(28) = 35.12 - 0.64(RHA) + 1.18(SP) - 0.09(RHA \times SP)$, $R^2 = 0.94$) was developed to predict the 28-day compressive strength of RHA-modified concrete based on RHA content and SP dosage, providing a practical tool for mix proportioning and strength estimation within the tested ranges (0–25% RHA, 0–8% SP).

4.3 Recommendations

Based on the findings of this study, the following recommendations are made:

1. RHA Replacement: RHA should be used as a partial cement replacement at 10–15% by weight, with proper quality control during production.
2. Superplasticizer Dosage: A superplasticizer dosage of 4–6% by weight of binder is recommended, with 6% being optimum for compressive strength.
3. Curing and Application: RHA-modified concrete should be cured for at least 28 days, and mixtures containing 10–15% RHA and 4–6% SP may be considered for structural applications requiring 25–30 N/mm² strength.
4. Further Research: Further studies should investigate higher RHA replacement levels, long-term durability and strength, different curing conditions, and predictive models for optimizing RHA-modified concrete.

4.4 Contributions to Knowledge

1. The study established 10–15% RHA with 4–6% SP as the optimum combination, with 6% SP giving the highest compressive strength (28.8 N/mm² at 28 days and 31.8 N/mm² at 56 days for 15% RHA) using locally sourced Nigerian materials. This provides practical guidance for sustainable concrete production in Nigeria.

2. A predictive regression model ($f_c(28) = 35.12 - 0.64(RHA) + 1.18(SP) - 0.09(RHA \times SP)$, $R^2 = 0.94$) was developed to estimate 28-day compressive strength from RHA content and SP dosage, enabling quantitative mix optimization for sustainable RHA concrete using locally sourced Nigerian materials. The model confirms that each 1% increase in RHA reduces strength by approximately 0.64 N/mm², while each 1% increase in SP (up to 6%) enhances strength by approximately 1.18 N/mm², with the interaction term indicating diminishing returns at higher RHA contents.
3. Systematic data on RHA content, SP dosage, workability, and compressive strength up to 56 days provide a comprehensive experimental basis for understanding the performance of RHA-modified concrete, supporting the development of sustainable construction practices that utilise locally available agricultural waste in Nigeria.

ABSTRACT

Optimizing agricultural processing is critical to meeting the rising global demand for plant-based proteins. This study optimizes the threshing efficiency (TE) and cleaning efficiency (CE) of a modified soybean thresher using the Taguchi Design of Experiments (DOE). An L-9 orthogonal array evaluated cylinder speed (500, 600, 700 rpm), feed rate (3, 4, 5 kg/h), and concave clearance (10, 13, 16 mm). Signal-to-noise (S/N) analysis identified concave clearance as the most sensitive parameter for both metrics. Maximum TE required 13 mm clearance, 600 rpm, and 5 kg/h feed rate. Conversely, maximum CE was achieved at 13 mm clearance, 500 rpm, and 3 kg/h, minimizing excess biomass during separation. Analysis of Variance (ANOVA) revealed that cylinder speed and feed rate were significant linear predictors of TE. While concave clearance dictated overall variance via a highly sensitive non-linear "sweet spot," it lacked linear significance. Furthermore, the linear model was inadequate for CE, indicating that cleaning relies heavily on unaccounted aerodynamic properties like fan speed. Ultimately, these findings provide a resource-efficient framework for optimizing post-harvest machinery.

1 INTRODUCTION

As a global community, we face the daunting task of ensuring sufficient nourishment for a rapidly expanding population, projected to reach 10 billion by 2050. Concurrently, the demand for proteins derived from renewable and sustainable sources is rising. However, agricultural and natural resources are finite, necessitating highly efficient food production and processing systems (Kumar et al., 2021; Yuliarti et al., 2021; Kumar et al., 2024). This backdrop underscores the critical importance of optimizing post-harvest crop processing, particularly for high-yield crops that offer a potential solution to protein-based malnutrition.

Soybean (*Glycine max L.*) is a globally cultivated oilseed crop renowned for its rich nutritional profile. It contains over 40% protein and 20% oil (Das et al., 2024). In addition to these macronutrients, soybeans provide essential amino acids, omega-3 fatty acids, and therapeutic compounds, including folic acid, vitamin B-complex, lactose-free fatty acids, and free-radical scavenging components. Furthermore, soybean meal, the primary by-product of soybean oil processing, has significant potential to combat protein-energy malnutrition worldwide (Das et al., 2024).

Despite the crop's immense value, threshing is a critical step in soybean processing, one that often relies on traditional, manual techniques. These rudimentary methods include pounding crops in a mortar with a pestle, beating them with sticks, or cracking them between stones (Alonge et al., 2017). While used for generations, these practices are time-consuming, labor-intensive, and inherently prone to crop loss (Alonge et al., 2017). Although numerous efforts have been made to design and develop mechanical threshers for local farmers, many of these machines operate without optimized parameters, failing to achieve maximum output. Employing optimization and modeling techniques, such as the Taguchi method or response surface methodology (RSM), can assist engineers in understanding process dynamics, managing resources, and effectively scaling up agricultural systems.

The Taguchi Design of Experiments (DOE) is a robust statistical approach developed by Genichi Taguchi, primarily designed to improve process quality by minimizing the effects of uncontrollable noise factors on system performance. This methodology is widely adopted because it facilitates the creation of a balanced and robust experimental design requiring a minimal number of experimental runs (Oemar & Chang, 2020). Implementing the Taguchi approach guarantees efficient resource utilization, thereby minimizing consumption and reducing overall production costs (Kundu et al., 2015). Consequently, this study utilizes the Taguchi method to model and optimize an existing, modified soybean thresher. The investigation focuses on three critical operating factors: cylinder speed, feed rate, and concave clearance, evaluating their specific impacts on two primary response variables: threshing efficiency (TE) and cleaning efficiency (CE).

2 MATERIALS AND METHODS

2.1 Machine description and operation

The modified soybean thresher used in this study is designed for single-operator use (Figure 1). The operational mechanism begins by feeding soybean pods into the intake hopper, where they move into the threshing chamber. This chamber houses a threshing cylinder equipped with beaters. The rotating beaters primarily thresh the crop through impact. Subsequently, the threshed mixture of grain and chaff descends into the cleaning unit. A centrifugal fan in the cleaning unit generates a targeted airstream that pneumatically separates the lighter chaff from the heavier grains, blowing the chaff out of the machine while channeling the clean grains into a collection chute.

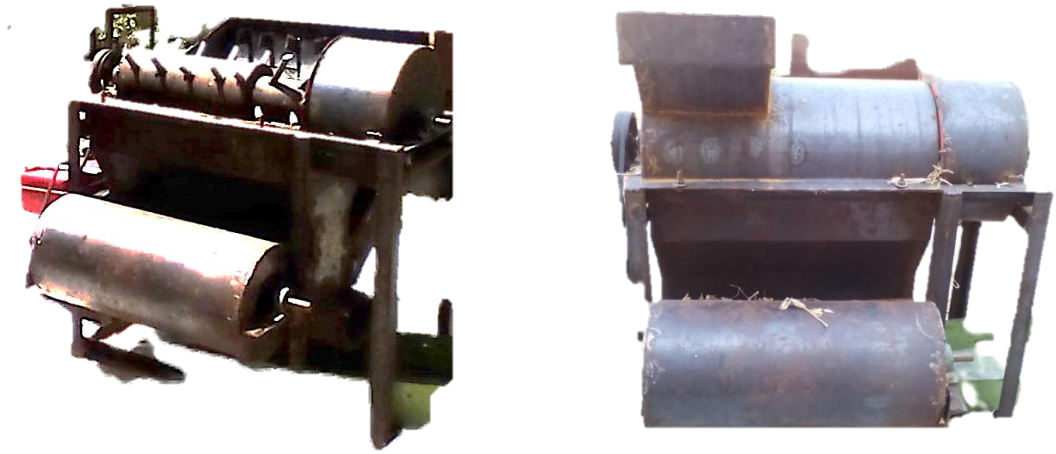

Figure 1: Pictorial presentation of the soybean thresher viewed from two different angles.

2.2 Experimental material and thresher performance test

Performance testing of the modified thresher was conducted using the TGX 1448-2E soybean variety, sourced from the Institute for Agricultural Research (I.A.R), Ahmadu Bello University, Zaria, Nigeria. Prior to the experiments, the moisture content of the soybeans was determined and standardized to 12% dry basis (d.b.) to ensure uniformity. To evaluate the machine's performance, three independent operating variables were tested at three levels each: cylinder speed (500, 600, and 700 rpm), feed rate (3, 4, and 5 kg/h), and concave clearance (10, 13, and 16 mm). All experimental runs were conducted in triplicate to guarantee reliability.

2.3 Performance evaluation indices

The machine's performance was evaluated based on four primary indices: threshing efficiency (TE), cleaning efficiency (CE), scatter loss (SL), and output capacity (Cp). These indices were calculated using the following relationships (Equations 1–4):

$$TE(\%) = \left(1 - \frac{\mathrm{A}}{\mathrm{T_G}}\right) \mathrm{x}\ 100 \quad (1)$$

$$CE(\%) = \left(\frac{\mathrm{B}}{\mathrm{D}}\right) \mathrm{x}\ 100 \quad (2)$$

$$SL(\%) = \left(\frac{\mathrm{E}}{\mathrm{T_G}}\right)\ \mathrm{x}\ 100 \quad (3)$$

$$Cp(kg/h) = \frac{Q}{t} \quad (4)$$

Where:

A = Weight of un-threshed grain collected per unit time (kg), T_G = Total grain input per unit time (kg), B = Weight of cleaned grain in the sample from the main outlet (kg), D = Total weight of material (grain + chaff) collected from the main outlet (kg), E = Weight of scattered grain collected per unit time (kg), Q = Total weight of threshed grain collected per unit time (kg), and t = Threshing time (h). For modeling and optimization in this study, TE and CE were selected as the primary response variables. TE is the primary indicator of the machine's core functional capability, measuring its effectiveness at detaching soybean grains from pods to minimize unthreshed crop losses (Aseffa, 2024; Powar et al., 2019). Conversely, CE determines the market quality and purity of the final agricultural output by evaluating the system's ability to separate threshed grains from chaff and other impurities (Dangora et al., 2024). Consequently, prioritizing the simultaneous maximization of these two parameters is critical for minimizing post-harvest wastage and ensuring the overall economic and operational viability of the thresher (Aseffa, 2024).

2.4 Experimental design

The Taguchi Design of Experiments (DOE), coupled with multiple regression analysis, was employed to develop a robust experimental design and determine the optimal settings of control parameters (El-Deen, 2024). Using an orthogonal array, the Taguchi method enables a balanced, comprehensive analysis while minimizing the total number of experimental runs, reducing experimental error and enhancing repeatability (Sahu et al., 2024).

An L-9 orthogonal array was used in this study (Tables 1 and 2). In accordance with standard Taguchi L-9 design principles, this modeling approach assumes that interaction effects among the three independent factors (cylinder speed, feed rate, and concave clearance) are negligible, allowing a focused evaluation of their main effects. We evaluated response-variable optimization using the signal-to-noise (S/N) ratio. Depending on the desired outcome, S/N ratios are typically categorized into three standard algorithms: smaller-the-better (Equation 5), larger-the-better (Equation 6), and nominal-the-best (Equation 7) (Kundu et al., 2015). Because this study aimed to maximize both threshing and cleaning efficiencies, the larger-the-better algorithm was selected.

$$S/_N = -10\log(\frac{1}{n}\sum X^2) \quad (5)$$

$$S/_N = -10\log(\frac{1}{n}\sum \frac{1}{X^2}) \quad (6)$$

$$S/_N = -10\log(\frac{1}{n}\sum \frac{\overline{X^2}}{s^2}) \quad (7)$$

Where *X* represents the responses and *n* is the number of replications. The algorithms for larger-the-better were selected because our goal was to maximize the threshing and the cleaning efficiency of

the thresher. Table 1 shows the selected variables with their respective levels, and Table 2 presents the Taguchi design based on L-9 orthogonal array design.

Table 1: Presentation of the variables and their levels

Parameter	**Level**		
	1	2	3
Cylinder speed (rpm)	500	600	700
Feed rate (kg/h)	3	4	5
Concave clearance (mm)	10	13	16

Table 2: Taguchi orthogonal array design based on L-9 with responses

Cylinder speed (rpm)	**Feed rate (kg/h)**	**Concave clearance (mm)**	**Threshing efficiency (%)**	**Cleaning efficiency (%)**
500	3	10	90.00 ± 0.85	85.00 ± 1.10
500	4	13	92.70 ± 0.64	86.10 ± 0.95
500	5	16	92.00 ± 1.05	85.80 ± 0.80
600	3	13	92.50 ± 0.72	86.70 ± 0.65
600	4	16	93.60 ± 0.55	85.40 ± 1.20
600	5	10	93.80 ± 0.90	84.60 ± 0.75
700	3	16	93.20 ± 0.82	85.10 ± 0.88
700	4	10	93.24 ± 0.68	83.30 ± 1.02
700	5	13	95.12 ± 0.45	85.20 ± 0.70

2.5 Statistical Analysis

The experimental data were structured and analyzed according to the Taguchi L-9 orthogonal array design. We used Minitab 2021 to perform the Taguchi analysis, compute the signal-to-noise (S/N) ratios using the larger-the-better algorithm, and generate the corresponding main effects plots to identify the optimal parameter combinations. We conducted an Analysis of Variance (ANOVA) for multiple linear regression. This regression ANOVA was evaluated at a 95% confidence interval ($\alpha = 0.05$) to test the significance of the linear models.

3 RESULTS AND DISCUSSION

3.1 Taguchi analysis and parameter optimization

The threshing and cleaning efficiencies of the modified soybean thresher were evaluated under varying conditions of cylinder speed (500, 600, and 700 rpm), feed rate (3, 4, and 5 kg/h), and concave clearance (10, 13, and 16 mm). To maximize both output responses, the larger-the-better Signal-to-Noise (S/N) ratio algorithm was utilized for optimization (Equation 6). To address the distinct operational dynamics of these two processes, the Taguchi analysis was performed and evaluated separately for threshing efficiency (TE) and cleaning efficiency (CE).

3.1.1 Threshing Efficiency (TE) Optimization

Taguchi analysis ranks the operating variables by their S/N ratios to determine their relative influence on machine performance. As presented in Table 3, the optimal S/N ratio for cylinder speed (39.00) was achieved at the second level (600 rpm). Similarly, the highest values for feed rate (39.00) and concave clearance (39.03) were observed at level 3 (5 kg/h) and level 2 (13 mm), respectively. By comparing the delta values of the S/N ratios, concave clearance emerged as the most influential factor dictating TE performance (Rank 1), followed closely by cylinder speed (Rank 2) and feed rate (Rank 3).

These numerical findings are directly corroborated by the analysis of means (Table 4), which follows the exact same ranking hierarchy. Furthermore, the main effects plots for the means (Figure 2) and S/N ratios (Figure 3) visually confirm this parameter hierarchy. The peak of each plotted line clearly identifies the parameter combination required for maximum threshing efficiency. Consequently, the optimal operational setting for maximizing TE is a concave clearance of 13 mm, a cylinder speed of 600 rpm, and a feed rate of 5 kg/h. This hierarchy aligns with crop threshing mechanics; studies by Ponican et al. (2009) and Adewumi (2007) found that concave clearance and cylinder speed are crucial for performance and control impact forces. Based on Tables 3 and 4 and Figure 3, optimal settings for threshing and cleaning are 13 mm concave clearance, 600 rpm cylinder speed, and 5 kg/h feed rate. The 600 rpm speed is noteworthy, as higher speeds increase grain detachment but exceeding thresholds (e.g., >700 rpm) can cause more damage and scatter loss, reducing efficiency (Aseffa, 2024; Powar et al., 2019).

Table 3: Response for signal-to-noise ratios, TE (Larger-is-better)

Level	Cylinder speed (rpm)	Feed rate (kg/h)	Concave clearance (mm)
1	38.93	38.95	38.89
2	39.00	38.96	39.03
3	38.97	39.00	38.98
Delta	0.07	0.05	0.14
Rank	2	3	1

Table 4: Response for means TE

Level	Cylinder speed (rpm)	Feed rate (kg/h)	Concave clearance (mm)
1	88.60	88.75	88.32
2	89.43	89.06	89.72
3	89.19	89.42	89.18
Delta	0.83	0.67	1.40
Rank	2	3	1

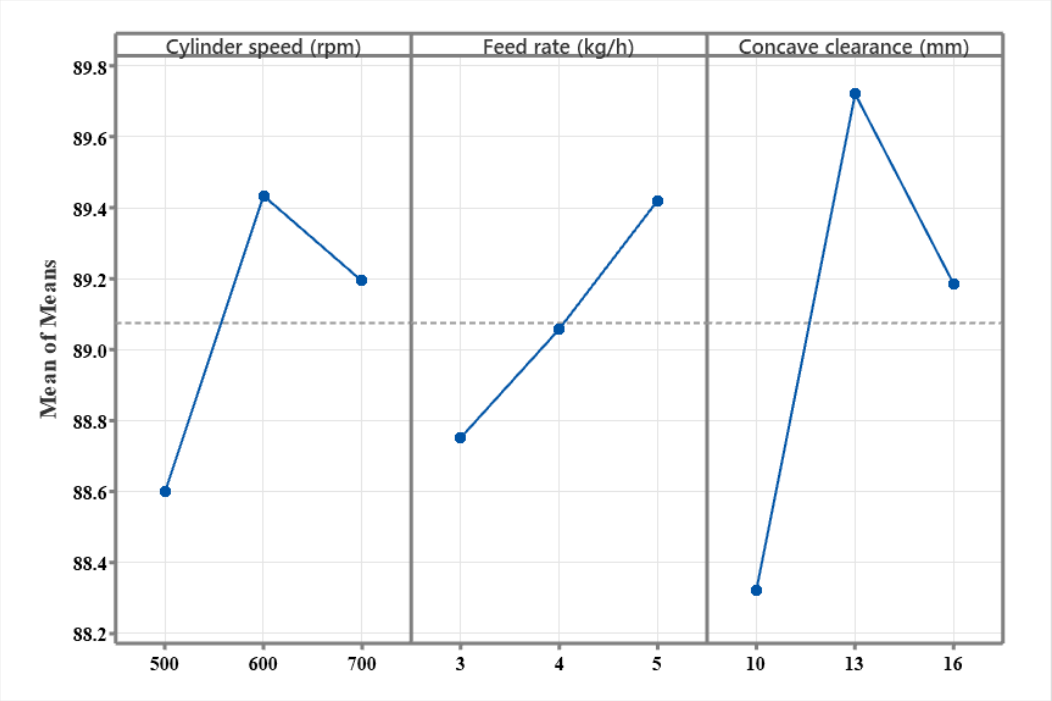

Figure 2: Main effects plot for means (TE)

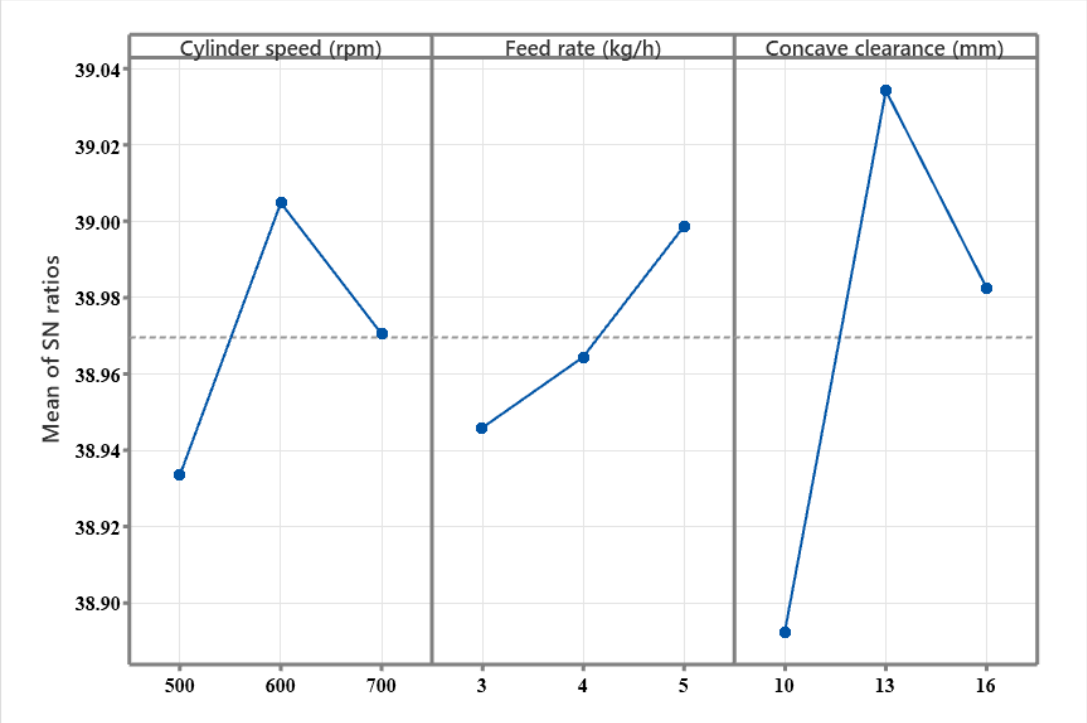

Figure 3: Main effects plot for signal-to-noise ratio (TE)

3.1.2 Cleaning Efficiency (CE) Optimization

Table 5 and Table 6 detail the response S/N ratios and means specifically for cleaning efficiency. The Taguchi analysis shows that concave clearance is the most influential factor in cleaning performance (Rank 1, Delta = 0.17), followed by cylinder speed (Rank 2, Delta = 0.11) and feed rate (Rank 3, Delta = 0.07). Figure 4 and Figure 5 visually confirm these parameter hierarchies through the CE main effects plots.

The plotted data indicates that the optimal parameter combination for maximizing cleaning efficiency differs slightly from threshing efficiency. The highest S/N ratio for concave clearance was achieved at the second level (13 mm), identical to the TE optimization. However, cleaning efficiency is maximized at a lower feed rate of 3 kg/h (level 1) and a lower cylinder speed of 500 rpm (level 1). A reduced feed rate introduces less total biomass into the separation zone at any given moment, allowing the constant airflow from the centrifugal fan to separate the chaff more thoroughly. Similarly, a lower cylinder speed prevents excessive mechanical pulverization of the soybean pods, reducing the volume of fine debris that typically evades pneumatic separation.

Table 5: Response for Means for CE

Level	**Cylinder speed (rpm)**	**Feed rate (kg/h)**	**Concave clearance (mm)**
1	85.63	85.60	84.30
2	85.57	84.93	86.00
3	84.53	85.20	85.43
Delta	1.10	0.67	1.70
Rank	2	3	1

Table 6: Response for Signal-to-Noise Ratios for CE

Level	Cylinder speed (rpm)	Feed rate (kg/h)	Concave clearance (mm)
1	38.65	38.65	38.52
2	38.65	38.58	38.69
3	38.54	38.61	38.63
Delta	0.11	0.07	0.17
Rank	2	3	1

3.2 Regression analysis of response variables

Regression analysis quantified the relationship between the independent operational parameters and the dependent performance efficiencies, providing predictive insights to minimize grain loss.

3.2.1 *Threshing efficiency (TE)*

The Analysis of Variance (ANOVA) for threshing efficiency (Table 7) demonstrated a statistically significant linear relationship between TE and the tested parameters. The overall regression model was significant at a 95% confidence interval (p = 0.028). Analysis of the individual factors showed that both cylinder speed (p = 0.015) and feed rate (p = 0.039) significantly influenced TE. The linear regression model for predicting Threshing Efficiency is expressed as:

$$TE(\%) = 81.30 + 0.01143 cylinder\ speed(rpm) + 0.87 feed\ rate(Kg/h) + 0.098 concave\ clearance(mm) \quad (8)$$

The Pareto chart of standardized effects (Figure 6) visually confirms the statistical significance of these parameters. In this chart, the bars representing cylinder speed and feed rate extend beyond the critical reference line ($\alpha = 0.05$), indicating their significant linear impact on threshing efficiency. This aligns with the findings by Desta and Mishra (1990) and Sharma and Devnani (1980), who observed that increasing the peripheral speed of the threshing drum systematically enhances the impact force required to shatter pods and detach grains. Furthermore, the residual plots for threshing efficiency (Figure 7) demonstrate a normal distribution of data points, validating the adequacy of the linear model.

Interestingly, while concave clearance was ranked as the most influential factor in the overarching Taguchi optimization (Table 3), the ANOVA (Table 7) shows it was not statistically significant (p = 0.393) as a standalone linear predictor. This is visually reaffirmed in the Pareto chart (Figure 6), where the bar for concave clearance falls well short of the significance reference line. This suggests that the influence of concave clearance on TE is inherently non-linear, operating optimally only within a specific "sweet spot" (e.g., 13 mm) rather than scaling linearly.

Table 7: Analysis of variance for TE

Source	DF	Adj SS	Adj MS	F-Value	P-Value
Model	3	12.9009	4.3003	7.28	0.028
Cylinder speed (rpm)	1	7.8433	7.8433	13.28	0.015
Feed rate (kg/h)	1	4.5414	4.5414	7.69	0.039
Concave clearance (mm)	1	0.5163	0.5163	0.87	0.393
Error	5	2.9527	0.5905		
Total	8	15.8536			

At first glance, a discrepancy appears to exist between the Taguchi signal-to-noise (S/N) ratio analysis, which ranks concave clearance as the most influential parameter (Rank 1), and the Analysis of Variance (ANOVA), which identifies it as a non-significant linear predictor ($p = 0.393$). These are distinct statistical constructs that measure different aspects of response variability. The Taguchi S/N sensitivity analysis evaluates absolute deviation and overall variance across discrete experimental levels, effectively capturing non-linear impacts—such as the pronounced optimal "sweet spot" at 13 mm. Conversely, the ANOVA used in this study assesses only the statistical significance of *linear* trends. Therefore, while concave clearance is highly sensitive and strongly dictates overall threshing efficiency, its influence does not scale linearly, which explains its non-significance in the linear regression model.

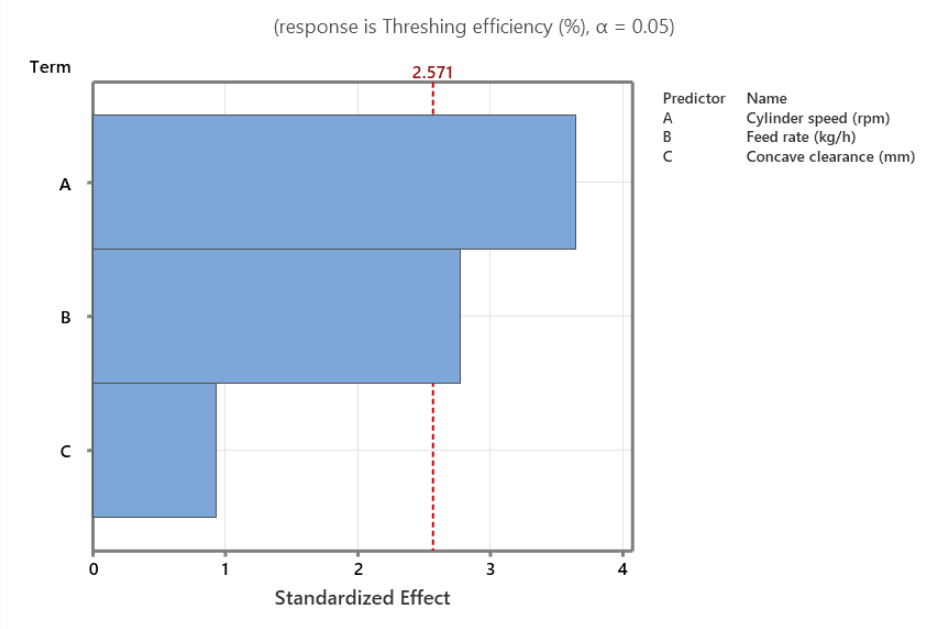

Figure 6: Pareto Chart of the standardized effects, TE (%)

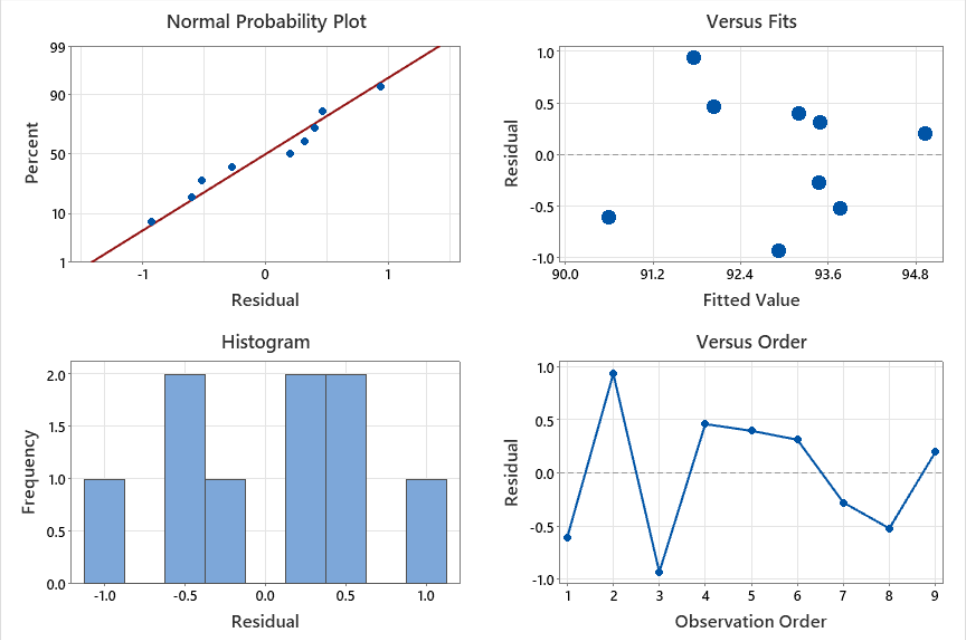

Figure 7: Residual plots for threshing efficiency (%)

3.2.2 Cleaning efficiency (CE)

We conducted a similar regression analysis for CE. The linear model equation is represented as:

$$CE(\%) = 86.89 - 0.0055 cylinder\ speed(rpm) - 0.2 feed\ rate(Kg/h) + 0.189 concave\ clearance(mm) \quad (9)$$

In stark contrast to the threshing model, the ANOVA results for CE (Table 8) indicated that the overall linear regression model for cleaning efficiency was not statistically significant ($p = 0.247$). Furthermore, none of the independent operational parameters (speed, feed rate, or clearance) were statistically significant linear predictors of CE within the tested ranges ($p > 0.05$). The Pareto chart of standardized effects for cleaning efficiency (Figure 8) visually corroborates this lack of linear significance. As shown in the chart, none of the bars representing the tested parameters cross the critical reference line, confirming that cylinder speed, feed rate, and concave clearance do not have a statistically significant linear effect on the cleaning process.

Recent agricultural engineering literature strongly supports the inadequacy of a simple linear model for predicting cleaning efficiency. Cleaning mechanisms in harvesters and threshers rely on complex aerodynamic properties rather than pure mechanical impact. Studies evaluating thresher cleaning systems show that cleaning efficiency is largely governed by non-linear fluid dynamics, such as fan speed, airflow distribution, and sieve oscillation, which often exhibit complex non-linear couplings with feed rate (Badretdinov et al., 2019; Dauda et al., 2024). Because aerodynamic variables like fan speed were held constant or were not the primary focus of this specific linear matrix, the model in Table 6 could not fully capture the cleaning dynamics. Therefore, predicting CE accurately in future iterations will require higher-order (e.g., quadratic) models that directly incorporate fan speed and airflow parameters alongside mechanical variables.

Table 8: Analysis of Variance for CE

Source	DF	Adj SS	Adj MS	F-Value	P-Value
Model	3	3.9817	1.3272	1.91	0.247
Cylinder speed (rpm)	1	1.8150	1.8150	2.61	0.167
Feed rate (kg/h)	1	0.2400	0.2400	0.34	0.583
Concave clearance (mm)	1	1.9267	1.9267	2.77	0.157
Error	5	3.4806	0.6961		
Total	8	7.4622			

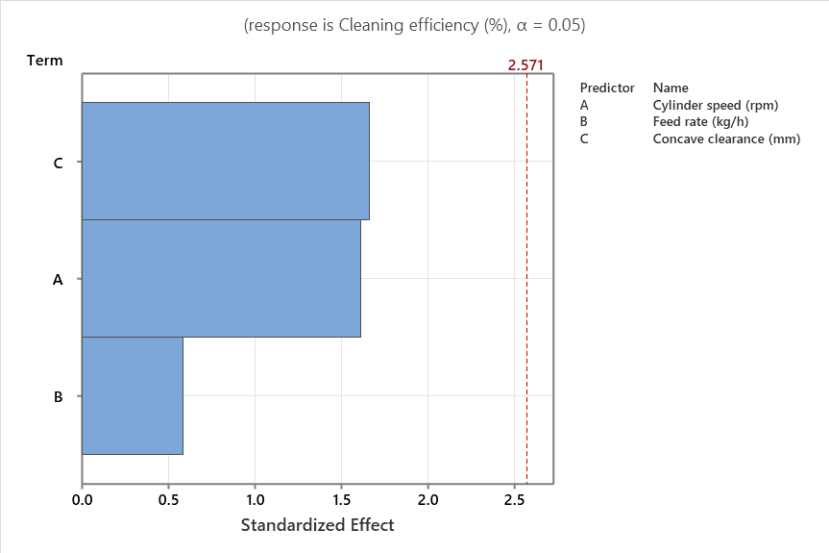

Figure 8: Pareto chart of the standardized effects CE (%)

4 CONCLUSION

This study successfully applied the Taguchi Design of Experiments (DOE) and multiple regression analysis to model and optimize a modified soybean thresher. The investigation demonstrated that concave clearance is the most sensitive mechanical parameter governing overall machine performance, followed by cylinder speed and feed rate. By optimizing these variables, the system can maximize grain detachment while mitigating the risk of grain damage and scatter loss associated with excessive mechanical force. While the analysis revealed a statistically significant linear relationship between the mechanical parameters and threshing efficiency, the linear model proved inadequate for predicting cleaning efficiency. This contrast highlights a vital synthesis in agricultural machinery evaluation: threshing is fundamentally a mechanical impact process, whereas cleaning is heavily governed by unmeasured aerodynamic fluid dynamics. Ultimately, the Taguchi method proved highly effective at establishing a resource-efficient baseline for local machinery manufacturers to maximize processing throughput and combat protein-based malnutrition.

FUTURE WORK

To build upon these findings, future research must transition beyond linear mechanical models to fully optimize the cleaning unit. Subsequent studies will incorporate aerodynamic variables—such as fan speed, air velocity, and airflow distribution—into higher-order mathematical models or utilize computational fluid dynamics (CFD). This approach is necessary to capture the complex, multi-field coupling required to achieve perfect grain separation.

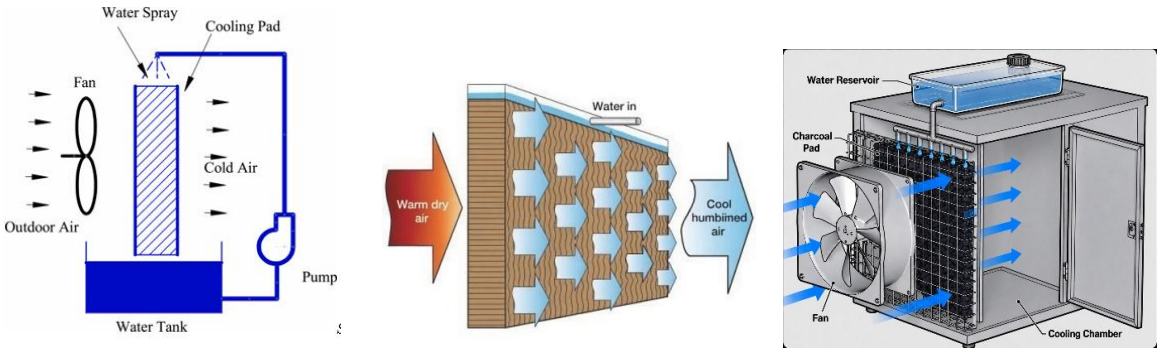
ABSTRACT



Evaporative cooling serves as an energy-efficient alternative to conventional vapor-compression air conditioning. It is a cooling method that uses water to lower air temperature. The conventional cellulose or plastic pads that are mostly used are costly, non-renewable, and require frequent replacement This experimental study was carried out to assess the suitability of charcoal granules as alternative material for evaporative cooling pad used in postharvest storage systems. A test setup is designed to evaluate the performance of charcoal granules. Water absorption and retention characteristics (retention capacity) are critical parameter in evaporative cooling systems, as it directly influences evaporation rate, cooling effectiveness, operational stability, and overall water consumption. The water retention capacity of the charcoal (internal micro-porosity) was determined to be 0.62 (g/g), with a porosity (bulk void fraction) of 52% The temperature gradients and relative humidity difference were evaluated. The ambient temperature was lowered from an average of 30 – 42°C to 19 – 30°C (ΔT of 10–12°C). Relative Humidity rises from an average of 32%–60% ambient to 75 – 97% inside the chamber. The chamber demonstrates reliable and statistically significant cooling performance, with an average of 24.8% efficiency (8.8°C reduction) across varying ambient conditions. The system delivers consistent temperature drop with substantial moisture addition, reducing sensible heat while slightly lowering (or maintaining) total enthalpy. Performance is consistent across the three days. It is highly effective in humidification, achieving an average relative humidity of 89.48% with 97% efficiency (nearly doubling ambient RH).

Keywords: *Evaporative cooling; charcoal granules; cooling pad; cooling Efficiency; relative humidity efficiency; water retention capacity*

INTRODUCTION

An evaporative system is a cooling method that uses water to lower air temperature (Bodile et al., 2025). It works by passing warm air through a wet cooling pad, where the water absorbs heat and evaporates, making the air cooler before it is circulated. It is an adiabatic exchange of sensible heat to latent heat (Kumarasinghe et al., 2026). The cooling pad is the most important part of this system because its performance directly affects how well the cooling works. Water is continuously supplied to the pad manually or using a pump, keeping it wet. A fan pushes warm air through the wet pad, and as the air passes through, the water absorbs heat and turns into vapor, cooling the air. This cool air is then spread into the room or space. The process continues as long as water is supplied and air flows through the pad. The cooling pad's efficiency depends on its material, thickness, water-holding capacity, and airflow, making it a key part of the system (Ogumo et al., 2017).

The trend of using fan-pad evaporative cooling systems in agricultural systems is increasing. The air from outside the facility is forced to enter through a constantly wet porous medium (pad). Sensible and latent heat transfer occurs when the air is in contact with the water surface. Air loses sensible heat, decreasing its temperature, while water evaporates from the surface of the pad, increasing the humidity of the air. The air at the outlet of the pad has a lower temperature and a higher relative humidity than the inlet one (Vega et al., 2022).

Illustrative diagrams of how the cooling pad works

Cooling through evaporation is an ancient and effective method of lowering temperature. Both plants and animals use this method to lower their temperatures. Trees, through the method of Eva transpiration, for example, remain cooler than their environment (Bodile et al., 2025)..

The operational effectiveness of an evaporative cooling is made up of a porous material that is fed with water. Hot dry air is drawn over the material. The water evaporates into the air raising the humidity and at the same time reducing the temperature of the air. The system is dependent on the conditions of the air and it is necessary to determine the weather conditions that may be encountered to properly evaluate the possible effectiveness of evaporative cooling (Warke & Deshmukh, 2017).

The tendency to use fan-pad evaporative cooling systems in agricultural buildings is increasing, but the rate of this increase is inhibited because of the high cost of the commercial pad materials example; CELdek which costs between Twenty Thousands to Seventy Thousands per square meter. Therefore, there is a need to evaluate the locally available cheap materials using as pads (Shitanda et al., 2015).

Evaporative cooling serves as an energy-efficient alternative to conventional vapor-compression air conditioning, particularly in arid and semi-arid climates where low humidity allows for significant thermal reduction through water evaporation (Franco-salas, 2021). Despite its advantages, the performance of traditional cooling media—such as cellulose or plastic—is often constrained by material costs, limited sustainability, and the necessity for frequent replacement (Kumarasinghe et al., 2026).

Water retention capacity and porosity are the major properties expected of a material that can be used as cooling pad (Deoraj et al., 2015). Most pad media for the evaporative cooling system are made from agricultural residue, although there are some commercially created pad media for sale in the market. Among materials that have been used for cooling pad manufacturing include jute, cellulose, aspen, PVC, hessian, wood shaven, rice straw, cotton fleece, latex, foam and luffa fiber (Udo et al., 2025).

A pad material should be porous enough to allow free flow of air. It should be able to absorb water and allow evaporation. It should have maximum amount of wetted surface area for an adequate period of air water contact time to achieve near saturation. The material should be locally available and inexpensive. Moreover, it should allow easy construction into required shape and size (Awafo et al., 2020).

Charcoal granules present a compelling, low-cost alternative, offering a porous structure that facilitates high water-air contact and effective heat exchange within sustainable cooling systems (Kouchakzadeh & Brati, 2013). The inherent microporosity of carbonized biomass promotes superior water retention through capillary action, which is essential for maximizing mass transfer during the evaporative process (Yeneneh, 2023).

Furthermore, utilizing this carbon-based medium aligns with broader efforts to integrate sustainable, waste-derived materials into HVAC design, potentially mitigating the environmental impact associated with traditional synthetic padding (Kumarasinghe et al., 2026). Beyond these structural benefits, charcoal granules exhibit potential for long-term operational durability, as their resistance to biological degradation may offer a more robust lifecycle compared to conventional cellulose pads susceptible to rapid salt and dust accumulation (Franco-salas, 2021).

Commercially available cooling pads are expensive and accordingly, there is an urgent need to evaluate the performance of suitable locally available materials when used as cooling pads, particularly for rural agricultural systems (Perez, 2022). Previous researches showed a cooling capacity of some materials used as wet pad coir fibre (89·6–92·8%), fine fabric (47·22–85·51%), coarse fabric (63·88–86·32%), polyvinyl chloride (PVC), sponge (38·9%), jute (62·1%) and luffa (55·1%) (Vega et al., 2022).

Charcoal is a local waste derived from pyrolysis of biomass (Berihun, 2023). Activated charcoal undergoes two-steps heating process. It serves as an excellent wet pad material due to their microporous structure, which facilitates high water absorption and slow release for sustained evaporation. Unlike commercial cellulose pads, charcoal is locally sourced, durable, and less prone to microbial growth. This study assesses its performance as a granular wet pad in post-harvest storage systems, focusing on microclimate control and produce quality preservation.

Charcoal is an ideal material for refrigeration because it has pores, which absorb and store water. This reduces heat from outside. And because wet charcoal does not allow easy passage of heat, it results in low temperatures inside the cubicle. Due to its pore structure, charcoal can absorb a lot of water quickly (Defraeye et al., 2024).

MATERIALS AND METHODS

The construction and experiment were carried out in Birnin kebbi, (12.4318ºN, 4.1956ºE) north western Nigeria, and is only limited to this location and carried out only for three days due to some constraints. Conducted in the month of April/May when the annual temperature was at its peak in the region, and lowest relative humidity due to hot dried air.

3.1 Experimental Setup

To measure the cooling performance of the charcoal, a special cooling chamber is designed and constructed. A direct evaporative cooling test apparatus typically consists of a fan, ducting, and a pad of 13cm x 13cm with 5cm thickness was filled with charcoal granules (particle size 35–45 mm) This particle sizes are necessary for optimal airflow. If the particles are too small there might be unbreathable sludge that prevent water distribution. Water is distributed via drip at a rate of 0.0125 liter per minute to keep the pad saturated. The fan (SUNON KDE1212PMV1) has an Air Flow Rate of 0.060m^3/s. The chamber comprises a hollow rectangular duct (24cmx18cm with 2cm thickness) made of Polyurethane (PU) Foam and lagged with aluminum sheet. (Fig1) Airflow is forced by a fan through the pad into the chamber where thermo-hygrometer is attached directly inside to measure modified temperature and humidity. Temperature and relative humidity were measured using HTC-1 digital thermo-hygrometers. The instruments were used according to the manufacturer's operating instructions. Formal laboratory calibration against a traceable reference standard was not performed before the experiment due to lack of resources which represents a limitation of the study. The reported temperature and relative-humidity values are interpreted within the measurement accuracy specified for the instruments.

Figure 1: Some Pictures from the experiment

3.2 Experimental Procedure

-Activated charcoal is used as a cooling medium. Charcoal has a high surface area, which allows it to absorb and release heat efficiently.

-Water is poured over the charcoal, causing it to evaporate and cool the air around it pores.

-Fan is used to force the surrounding air in to the wetted pad and pass through it as cooled air

-Cooling Chamber: The cooled air is then circulated through a chamber, where the temperature and relative humidity are being measured using a thermo-hygrometer

3.3 Charcoal Preparation

Charcoal granules are washed to remove dust, sieved for uniformity, and packed into cuboid wire mesh to make a pad of granules. Bulk density, porosity, and water holding capacity are major factors in determine the efficiency of the system

4.0 RESULTS AND DISCUSSION

4.1 Microclimate Performance

The ambient temperature and humidity are monitored and measured in the experiments, and compared with the cooling chamber. The experimental data for the reduction of temperature across the time is summarized in Table 1. The experimental data for the increase in humidity with respect to time is summarized in Table 2

Table 1: Chamber temperature and Ambient temperature (^oC)

Time of the Day	TEMPERATURE *DAY 1*		TEMPERATURE *DAY 2*		TEMPERATURE *DAY 3*	
	Chamber	Ambient	Chamber	Ambient	Chamber	Ambient

4.2 Performance Analysis

The performance in the system was assessed by considering two factors;

i. The response to decrease ambient temperature
ii. The response to increase ambient relative humidity

The cooling efficiency and relative humidity efficiency were determine using the following equations; (Leonard & Msacky, 2023).

$$Cooling\ Efficiency = \frac{(Ambient\ Temp - Chamber\ Temp)}{Ambient\ Temp} \times 100 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots 1$$

$$RH\ Efficiency = \frac{(Chmaber\ RH - Ambient\ RH)}{Ambient\ RH} \times 100 \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots 2$$

4.2.1 Statistical Analysis of Temperature

For all monitoring days, results showed that average daily ambient temperature was 35.76°C as measured over three consecutive days. The inside Chamber temperature was 26.94°C. The inside Chamber temperature was ranged from 19.0°C to 31.5°C while the ambient was 31.5°C to 41.5°C with an average temperature difference of 8.83°C (Chamber cooler). Table 1. At the highest efficiency, the Chamber had inside temperature of 19.0°C which is 13.5°C lower than the ambient temperature.

Table 3: Per-day averages (Temperature)

Day	Chamber (°C)	Ambient (°C)	Difference (°C)	Efficiency (%)
Day 1	26.97	36.38	9.41	26.04
Day 2	26.94	35.67	8.72	24.49
Day 3	26.89	35.25	8.36	23.78
Overall	26.94	35.76	8.83	24.77

ANOVA Single factor results (Comparing all chamber versus all ambient temperatures) showed that the chamber temperatures differed statistically from the ambient temperature at $p \leq 0.05$. A p-value: < 0.0001 (extremely significant) was obtained, with F-statistic: 266.99 which signifies a significant reduction of ambient temperature. This shows a highly statistically significant difference between Chamber and Ambient temperatures. The chamber consistently maintains lower temperatures.

Two-way ANOVA (factors: Day + Type + Interaction) test indicates the cooling effect is consistent across days (no significant day-to-day variation in the difference). Table 4.

Table 4: Two-way ANOVA (factors: Day + Type + Interaction) – Temperature

Source	Sum Sq	df	F-stat	p-value	Significance
Day	6.71	2	0.42	0.661	Not significant
Type (Chamber/Ambient)	2104.98	1	260.58	<0.0001	Highly significant
Day × Type	5.06	2	0.31	0.732	Not significant
Residual	823.95	102	-	-	-

The Overall average cooling efficiency is 24.77% ranging from 14.1%-42.3%. The hourly trends indicate strongest cooling in early morning (higher % efficiency when ambient is rising).

Efficiency generally stable but slightly lower in late afternoon/evening. Chamber temperature tracks ambient but stays ~8–9°C cooler on average.

Correlation between Chamber and Ambient is 0.685 (moderate positive), that is Chamber responds to ambient changes but maintains a consistent offset. Minimum Chamber temp is 19.0°C (09:00 Day 1) and maximum difference is 15.0°C

4.2.2 Statistical Analysis of Relative Humidity

The average daily ambient humidity is 46.74% as measured over three consecutive days. The inside chamber humidity is 89.48%. The inside Chamber humidity was ranged from 65% to 99% while the ambient was 32% to 64% with an average humidity difference of 42.74% (Chamber much more humid). Table 3. At the highest efficiency, the Chamber had inside humidity of 99% which is 40% higher than the ambient. Table 5.

Table 5: Per-day averages (Humidity)

Day	Chamber RH (%)	Ambient RH (%)	Difference (%)	RH Enhancement Ratio (%)
Day 1	84.56	47.33	37.22	84.95
Day 2	90.78	48.50	42.28	91.12
Day 3	93.11	44.39	48.72	121.16
Overall	89.48	46.74	42.74	99.08

ANOVA Single factor results (Comparing all chamber versus all ambient humidities) showed that the chamber humidity differed statistically from the ambient humidity at $p \leq 0.05$. A p-value: < 0.0001 (extremely significant) was obtained, with F-statistic: 646.27.

Two-way ANOVA (factors: Day + Type + Interaction) test indicates the chamber maintains higher relative humidity than ambient air (highly significant difference). There is a slight but significant interaction with days, efficiency improved over the three days. Table 6.

Table 6: Two-way ANOVA (Day + Type + Interaction) – Relative Humidity

Source	Sum Sq	df	F-stat	p-value	Significance
Day	267.72	2	1.89	0.1563	Not significant
Type (Chamber/Ambient)	49,322.81	1	696.41	<0.0001	Highly significant
Day × Type	598.02	2	4.22	0.0173	Significant
Residual	7,224.11	102	-	-	-

The overall average Relative Humidity efficiency is 99.08% (the chamber roughly doubles the ambient humidity on average). Ranging from 44% – 147%. Efficiency is lower in the early morning (when ambient RH is relatively higher) and peaks strongly in the afternoon and evening. Correlation between Chamber and Ambient RH: 0.72 (strong positive) — Chamber follows ambient patterns but consistently adds substantial moisture. Chamber RH is very stable (often near 99% saturation), while ambient varies more.

4.3 Combined Temperature and Humidity (Psychrometric) Analysis

This experiment is a direct evaporative cooling + humidification system. It cools the air by evaporating water (sensible cooling) while adding moisture (latent heat gain), ideally following a near-constant wet-bulb temperature / enthalpy line on the psychrometric chart. Table 7. Shows psychrometric analysis of the system. Table 6. Shows performance per day of the system

Table 7: Psychrometric Analysis

Parameter	**Ambient**	**Chamber**	**Difference**
Dry Bulb Temp (°C)	35.83	26.94	-8.89°C
Relative Humidity (%)	46.7	89.6	+42.9%
Humidity Ratio (W, kg/kg)	0.0172	0.0203	+0.0031 (+18%)
Enthalpy (h, kJ/kg)	80.27	78.83	-1.44
Wet Bulb Temp (approx °C)	~25.5	~25.8	~+0.3 (near constant)

Table 8: Per-Day Performance of the system

Day	**ΔT (°C)**	**Cooling Eff. (%)**	**ΔRH (%)**	**RH Enhc. Ratio (%)**	**ΔW (kg/kg)**	**Δh (kJ/kg)**
1	-9.41	25.9%	+37.8	80.0	+0.0014	-6.15
2	-8.86	24.7%	+42.2	87.1	+0.0027	-2.35
3	-8.42	23.8%	+48.7	109.8	+0.0050	+4.17
Avg	-8.89	24.8%	+42.9	99.1%	+0.0031	-1.44

The positive Day 3 value is associated with the substantially higher moisture content of the chamber air (ΔW = +0.0050 kg/kg), which increased the latent component of moist-air enthalpy despite the reduction in dry-bulb temperature

4.3 Water Retention Capacity of the Charcoal

Water retention capacity is a critical parameter in evaporative cooling systems, as it directly influences evaporation rate, cooling effectiveness, operational stability, and overall water consumption. Accordingly, the water absorption and retention characteristics of the charcoal cooling pads were experimentally evaluated. The charcoal sample was completely dried under natural sunlight to remove residual moisture and achieve a constant dry mass. The dry weight of the sample *(Wdry)* was recorded using a precision balance. The sample was then submerged in water for 30 minutes to achieve full saturation after which they were removed and allowed to drain freely for a short period to eliminate excess surface water. The saturated weight *(Wwet)* was subsequently measured. The water retention capacity was calculated using the following Equation; (Kumarasinghe et al., 2026)

$$Water\ rentention\ capacity\ (g/g) = \frac{Wwet - Wdry}{Wdry} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots 3$$

Table 9: Water retention capacity charcoal cooling pad samples based on dry and wet weight measurement.

Parameter	Charcoal Sample 1	Charcoal Sample 2	Charcoal Sample 3	Mean ± SD
Dry weight (g)	190	195	185	**190.00 ± 5.00**
Wet weight (g)	310	308	303	**307.00 ± 3.61**
Water retained (g)	120	113	118	**117.00 ± 3.61**
Water Retention Capacity (g/g)	**0.632**	**0.579**	**0.638**	**0.616 ± 0.032**

4.4 The porosity of the charcoal

A porous medium such as the cooling pad is also characterized by its porosity and permeability. Porosity or void fraction (ε) is a measure of the empty spaces between material particles. To determine the porosity of the material, a container of known volume was filled with the material and then water was added to the top of the container. The porosity was then computed using Equation (4) (Vega et al., 2022). A porosity of 52% was determined.

$$Porosity\ (\varepsilon) = \frac{Water\ added}{Container\ volume} \quad \ldots\ldots 4$$

5.0 DISCUSSION

The pad cooling efficiency is one of the main parameters that had been used to characterize the effectiveness of an evaporative cooling system. The drop in temperature and the increase in relative humidity in the air leaving the pad provides a clearer idea of the improvement in the thermal condition of the air.

The chamber demonstrates reliable and statistically significant cooling performance, with an average of 24.8% cooling efficiency (8.8°C reduction) across varying ambient conditions, and an average relative humidity of 89.48%. The pad represented similar result to those of other alternative materials (Leonard & Msacky, 2023), designed and tested a charcoal cooler for postharvest storage and reported an average cooling efficiency of 25.92% compared to sand cooler in the same experiment with a cooling efficiency of 22.15%. and an average relative humidity of 52.2% (Elmsaad & Omran, 2015), in their experiment found that a luffa pad yielded an average relative humidity of 73.67%, straw fiber pads 71.87%, CELdek 70.33% and sackcloth 69% (Korese & Hensel, 2016) evaluated a bulk charcoal as cooling pad under different pad configuration and reported a cooling efficiency vary from 56.71% - 96.10% to 45.41% - 90.06%, depending on the pad configuration, air velocity and the water flow rate. (Kulkarni et al., 2014) tested a jute fiber pad and reported a temperature range between 25.8°C and 26.2°C.The saturation efficiencies range from 69 % to 59 %. (T.D et al., 2023) reported a clay based cooling pad of 65% cooling efficiency and 68% from the cellulose pad. Though there was no side-by-side experiment to compare the charcoal with other commercial pads because of their unavailability in the market at the time of conducting this experiment, but existing literature shows the charcoal granules performed excellently compared to other cooling pad materials.

6.0 CONCLUSION AND RECOMMENDATIONS

Charcoal granules are a viable, sustainable wet pad medium for evaporative cooling in post-harvest systems, delivering effective cooling and significant humidity rise. It is less expensive compared

to other cooling pad materials. It cost less than Ten Thousand Naira (N10,000) to produce a charcoal pad of one meter square compared to other cooling pad material like CELdek which costs between Twenty Thousand to Seventy Thousand per square meter depending on thickness Experimental data support its use in resource-limited settings. The chamber demonstrates reliable and statistically significant cooling performance, with an average of 24.8% efficiency (8.8°C reduction) across varying ambient conditions. Performance is consistent across the three days. It is highly effective at humidifying the environment, achieving an average 97% efficiency (nearly doubling ambient RH). The system delivers consistent temperature drop with substantial moisture addition along a near-constant wet-bulb line, reducing sensible heat while slightly varying enthalpy. The positive Day 3 value of the enthalpy is associated with the substantially higher moisture content of the chamber air ($\Delta W = +0.0050$ kg/kg), which increased the latent component of moist-air enthalpy despite the reduction in dry-bulb temperature.

Future work should optimize granule size/distribution, fan speeds variance, and conduct long-term experiments across geographical zones. It also recommends incorporating calibration against traceable reference instruments before and after the experiment to improve measurement confidence.

ABSTRACT

The increasing demand for sustainable and renewable energy solutions has stimulated significant research into technologies that enhance agricultural productivity and reduce post-harvest losses. Among these technologies, solar drying has emerged as an environmentally friendly, cost-effective method for preserving agricultural products by reducing moisture content and extending shelf life. Its relevance is particularly pronounced in developing countries such as Nigeria. Phase change materials (PCMs) are needed to enhance the performance of solar dryers, especially after sunshine hours. In this study, two solar dryers, with and without PCM, each with a capacity of 2 kg, were constructed and tested alongside open sun drying under an average ambient temperature of 28.6 °C and average solar irradiance of about 876 W/m². The PCM-integrated dryer achieved a drying heat load of 835.81 MJ and an outlet air temperature of 51.6 °C, removing 0.68 kg of moisture with an average drying rate of 0.20 kg/h reaching a final moisture content of about 9% which was 4% short of reaching the target final moisture of the study of 5%. The required PCM mass was 3.924 kg (0.0042 m³), providing a thermal energy storage capacity of 489,853 J and enabling extended drying for up to 5 hours beyond sunshine hours. The PCM-integrated solar dryer achieved a drying efficiency of 85%. While the non-PCM dryer and open sun drying achieved drying efficiencies of 77% and 40%, respectively. This demonstrates the superior drying efficiency of the PCM-integrated dryer over the other drying methods.

Keywords: *Phase change material; Drying rate; Moisture removal; and Thermal efficiency*

1. INTRODUCTION

In recent years, integrating thermal energy storage into solar dryers has gained attention as a solution to intermittent solar radiation Dhass *et al.* (2025). Phase change materials (PCMs) are widely studied due to their capacity to absorb, store, and release latent heat, enabling stable drying temperatures and improved system efficiency. However, conventional PCMs, particularly organic types, suffer from low thermal conductivity, limiting heat transfer during charging and discharging cycles Zhang *et al.* (2018). To address this limitation, nano-enhanced phase change materials (NEPCMs) have been developed by incorporating nanoparticles into base PCMs. Among these, carbon dots have emerged as promising additives because of their high surface area, good thermal conductivity, and enhanced photothermal conversion Li et al. (2021). When combined with natural PCMs such as shea butter, which is biodegradable, locally available, and has a suitable melting range, overall thermal performance can be significantly improved. This combination is especially relevant for drying perishable agricultural products like okra, where maintaining quality and reducing spoilage are critical. Integrating PCM-based storage into solar dryers ensures continuous drying even without sunlight. Experimental evaluation of such systems typically examines temperature distribution, drying rate, moisture removal, and efficiency, contributing to the development of sustainable, low-cost drying technologies. Agbetiloye et al. (2022)developed a mixed-mode solar dryer using shea butter with 3% aluminium powder as PCM for ginger rhizomes. The PCM achieved 164.53 kJ/kg latent heat and improved thermal performance, reaching 77% collector efficiency. Moisture content decreased from 71% to 13%, while drying efficiency remained 30% during operation. Li et al. (2021)developed a shape-stabilised PCM by integrating polyethene glycol (PEG) into carbonised wood with carbon dots, improving thermal

conductivity (0.449 W/m.K) and photothermal efficiency (84.4%). The composite showed good stability and reliability, but reduced latent heat (112.4 J/g) due to limited PEG loading, indicating a need for further optimisation. Salisu et al. (2022) developed encapsulated shea butter as a bio-based PCM for thermal storage, with a melting peak of 37.5°C, latent heat of 50.34 kJ/kg, and thermal conductivity of 0.26 W/m·K. Experimental and CFD results demonstrated efficient thermal storage and improved overall system performance.

2. METHODOLOGY

2.1 Materials

The carbon precursors used in the hydrothermal synthesis of carbon dots were p-phenylenediamine and folic acid; ethanol was obtained from Haddis Chemical, Samaru, Zaria. Deionized water was obtained from the Ahmadu Bello University Multiuser Laboratory, and food-grade shea butter was purchased from the open market.

2.2 Synthesis of Carbon Dots

Carbon dots (CDs) were synthesized hydrothermally following the method of He et al. (2024). P-Phenylenediamine (30 g) was dissolved in 1 L of ethanol to form solution A, while folic acid (5 g) was dissolved separately in 500 mL of deionized water to form solution B. Solutions A and B were combined under magnetic stirring to obtain a homogeneous mixture, which was then transferred into a Teflon-lined autoclave reactor and heated at 180 °C for 12 hours. After natural cooling to room temperature, the crude product exhibited characteristic red fluorescence under ultraviolet light, indicating successful carbon dot formation. The product was purified by silica gel column chromatography using methanol as the eluent, followed by rotary evaporation and freeze-drying under vacuum. The final carbon dots were obtained with a synthesis yield of 40.3%.

2.3 Preparation of Carbon Dot-Shea Butter Blend

This was done according to the method of (Agbetiloye *et al.*, 2022).10 mL of shea butter was poured into a clean beaker, and it was heated gently to the desired mixture temperature (40 °C, 50 °C, & 60 °C) Priyadarshi & Paul (2019) until it was completely melted. The appropriate proportion of carbon dots (1%, 2%, & 3% by weight) were measured based on the experimental run. The carbon dots were gradually added into the molten shea butter while stirred to avoid agglomeration. The magnetic stirrer was Placed in side beaker and maintained continuous stirring at the selected temperature. The blending process was allowed to proceed for the specified mixing time (10, 20, & 30 minutes) for each run to ensure uniform dispersion of the carbon dots within the shea butter to achieve homogeneity. The mixture was then removed from the heat source and allowed to cool under ambient conditions.

2.4 Performance evaluation of the PCM in solar dryer

The performance of the PCM for solar drying was evaluated by incorporating it into a solar dryer and carrying out experimental tests to dry okra. A solar dryer of the same capacity (without PCM) and open sun drying were also tested simultaneously, and performances were compared. The temperature and humidity were measured using ATO Bluetooth Temperature and Relative Humidity Logger model ATO-TDL-BT06, made in China. The air flow rate on the other hand was measured using Bluetooth anemometer model AZ/AERMANDA AZ89171, made in China.

2.5 Okra Samples Preparation

The okra was then sliced into 7 mm thick pieces using a kitchen knife. A total of 2 kg of these slices was evenly spread on trays to ensure maximum surface area exposure to incoming hot air during the drying process. The initial moisture content of the okra was about 45% and the target final moisture content after drying was 5%.

2.6 Instrumentation of solar dryer experiment

A thermocouple was used as a temperature sensor for both measurement and control purposes. In this context, thermocouples were employed to measure the inlet and outlet temperatures of a solar dryer, the temperature of the absorber plate with and without phase change material (PCM), as well as the ambient and tray temperatures. A data logger was additionally used to record solar radiation over a four-day period, during which all temperature parameters were monitored. A Camry weighing scale was utilised to determine weight. Specifically, it was used to measure the mass of moisture loss from okra slices, recorded in kilograms.

Experimental procedure

Plate I. The constructed solar dryers.

Plate I shows the solar dryer as constructed. The experimental solar dryer was designed as a compact, portable unit with an overall drying chamber of approximately 360 mm × 340 mm in plan dimensions and 500 mm in height. The solar collector measured approximately 708.9 mm in length and 150 mm in width, while the upper air outlet/chimney section had a height of approximately 500 mm and an internal diameter of 190 mm. The dryer was fabricated primarily from mild-steel shells to provide the structural enclosure and mechanical support, with a wooden table/support frame provided beneath the drying tray to accommodate and stabilize the drying chamber. Aluminium sheet was employed as the glazing/covering material for the solar collector to provide a lightweight and durable enclosure for solar-energy capture. The resulting configuration provides a relatively lightweight and compact experimental platform suitable for controlled investigation of drying characteristics under solar radiation

The experiment was conducted in October, during which two solar dryers and open sun drying processes were operated simultaneously to compare their performance. Additional experimental trials were carried out on the 17th, 18th, 19th, and 20th of October 2025 under the prevailing weather conditions in Zaria, Nigeria.

The evaluation focused on moisture removal and thermal performance parameters, including system drying efficiency, collector efficiency, and drying rate for each drying method, alongside the corresponding moisture content at specific time intervals.

The experiment aimed to test the developed PCM and evaluate the performance of the solar crop dryer by analysing moisture loss, drying efficiency, and drying rate of sliced okra. In terms of procedure, the solar dryer, integrated with phase change material (PCM), was loaded with sliced okra of average thickness between 5 and 7 mm and then exposed to solar radiation. Hourly measurements were recorded for temperatures at various locations, including the collector inlet, absorber plate, chimney, ambient air, and drying tray. These measurements were taken from 08:00 to 20:00 on 17 October 2025, from 08:00 to 20:00 on 18 October, from 06:00 to 20:00 on 19 October, and from 06:00 to 20:00 on 20 October 2025.

Each solar crop dryer was loaded with 2 kg of sliced okra. On the first day, the weight of the samples was measured every two hours, while on subsequent days, measurements were taken hourly. During daylight hours, airflow was naturally established over the absorber plate as the air became less dense upon heating. Solar radiation was also directly incident on the top glazing, enabling both heated air and direct radiation to enhance the drying of the sliced okra while simultaneously charging the PCM within the rectangular absorber plate in the collector and the cylindrical PCM container in the drying chamber.

The heat energy stored within both the rectangular and cylindrical PCM units was released during periods of low solar radiation, thereby sustaining the drying process and extending it beyond sunshine hours. The air mass flow rate into the collector was determined from the product of the measured wind speed (using an anemometer), the collector cross-sectional area, and the air density. The weight of the okra slices on each tray was recorded at the beginning of the drying process and subsequently at two-hour intervals on the first day and at one-hour intervals on the remaining days. The overall procedure followed standard methods recommended in related studies for evaluating solar dryer performance.

2.7 Characterization of carbon dots and blends of carbon dots with shea butter.

2.7.1 Thermal conductivity

Thermal conductivity test was done on the pure shea butter and the modified shea butter (PCM). The Searles apparatus was used in Equation 1

$$\lambda = \frac{\mathrm{Q-X}}{A(T_2-T_1)} \qquad (1)$$

where;
λ; Thermal conductivity of sample [W/mK]
Q; generated heat per unit length of sample/time [W/m2]
Sample diameter = 0.0018 and length = 0.0043 [m]
X; Thickness of sample [m]
A; Area [m2]
T1 and T2; Temperature at t1 and t2 [K]
t1 and t2; measured time length [seconds, s]

2.7.2 Specific heat capacity

$$\text{Specific heat capacity (c)} = \frac{\mathrm{Q}}{mDT} \qquad (2)$$

Unit of C is J/kg*^{o}C, M is the Mass (kg), Q is the change in energy (J), and ΔT is the temperature change (^{o}C)

2.7.3 Thermal Diffusivity

$$\alpha\ (\mathrm{m^2/s}) = \frac{\lambda}{\rho cp}$$

(**Error! No text of specified style in document.**)

Where:
ρ is the density of the material and
Cp is the specific heat capacity (J/gK)

The same apparatus (Armfield equipment model HT12) with a heat transfer service unit (Armfield equipment model HT10XC) was used in this thermal diffusivity calculation.

2.7.1 Latent heat of fusion.

Apparatus:

Ice, blotting paper, copper calorimeter and stirrer, insulating jacket, heater, beaker, thermometer and balance.

Procedure:

The water was gently warmed in a beaker until it reached approximately 32 °C. The calorimeter and stirrer were weighed, after which the calorimeter was filled to about one-third of its capacity with the warm water and reweighed. The calorimeter was then kept within its enclosure, and the initial temperature of the water was observed until it was about 32 °C above room temperature. Small pieces of the sample, previously dried using blotting paper, were added until the temperature fell to around 20 °C below room temperature. The mixture was stirred continuously, ensuring that each portion of the sample had completely melted before additional pieces were introduced. Finally, the calorimeter and its contents were reweighed, and the value of the latent heat of fusion (L) was calculated using the appropriate equation.

Theory:

The specific latent heat of fusion of a solid is the heat required to convert unit mass of it at its melting point into liquid at the same temperature.

Heat gained by shea butter + Heat gained by water = Heat lost by water and calorimeter

Equations:

$$mL + ms_2(\theta_2 - 0) = (m_2s_2 + m_1s_1)(\theta_1 - \theta_2) \quad (4)$$

$$L = [(m_2s_2 + m_1s_1)(\theta_1 - \theta_2) - s_2(\theta_2 - 0)] / m \quad (5)$$

Where:
m_1=Mass of Copper Calorimeter and Stirrer
m_2=Mass of Water
S_1=Specific Heat Capacity of Water
S_2= Specific Heat Capacity of Copper
$\underline{\theta_1}$= Initial Temperature of Warm Water
θ_2=Final Temperature of Mixture
m=Mass of Sample
L=Specific Latent Heat of Fusion of Sample

Plate II. controlled heat transfer -HT12XC

3. RESULTS AND DISCUSSION

3.1 The dried okra obtained from the experiment

Plate III: Sample dried okra from (a) open sun drying, (b) dried without PCM, and (c) dried with PCM.

3.2 Solar Dryer Testing and Evaluation

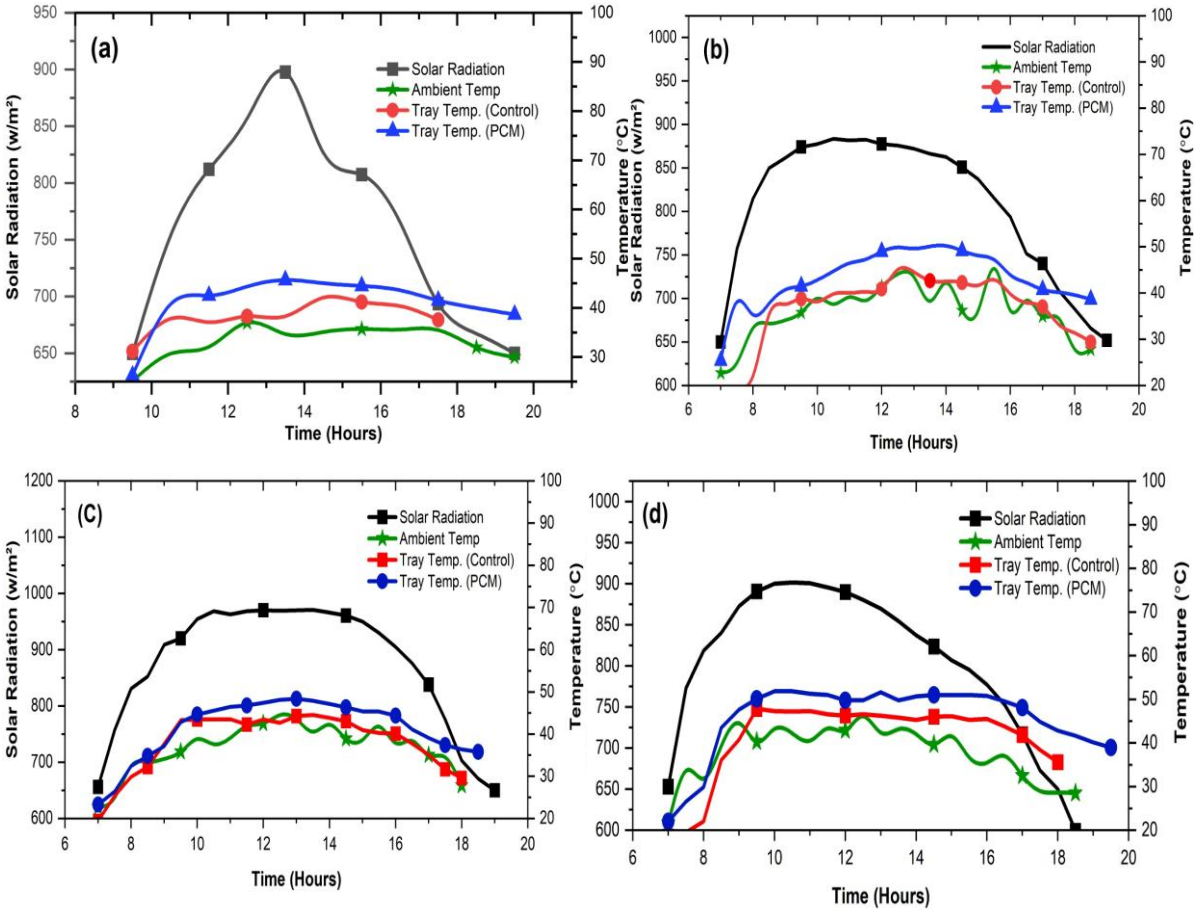

Figure 1: Solar radiation and temperature profiles for (a) day 1, (b) day 2, (c) day 3, and (d) day 4 of the experiments

Figure 1 for (a) day 1, (b) day 2, (c) day 3, and (d) day 4. The chamber of the PCM system exhibited higher peak temperatures, reduced temperature fluctuations, and a delayed cooling profile compared to the control system. This behaviour is attributed to the latent heat storage capability of the PCM and enhanced thermal conductivity provided by carbon dots. Between 10:00 and 14:00, temperatures rise slowly but reach higher values for the PCM system, showing that the PCM absorbs and stores heat. Even when the solar radiation dropped after 14.00, the PCM system chamber temperature remained higher than the control tray. PCM absorbs heat during peak solar radiation and releases it during off-peak periods, stabilising temperature (Han et al., 2022). Percentage temperature difference between the drying chamber temperature and the ambient temperature for all the days were calculated as % difference = (T_PCM – T_ambient)/T_ambient x 100.

A peak temperature of 45.7°C was observed for the PCM-based dryer system on Day 1 at 1:30 pm, and up to a 34% increase in the system temperature compared to the ambient temperature was observed at around 2.30 pm, where the PCM-based chamber was at 45°C while the ambient temperature was 34°C. On the second day, a peak temperature of up to 50.2°C was recorded for the PCM-based dryer system. Also, up to about a 53% difference in the PCM-dryer system temperature compared to the ambient temperature was observed at around 7.30 pm where the PCM-based chamber was at 38°C while the ambient temperature was 25°C. This high early difference could be attributed to the stored heat in the PCM on the first day. A peak temperature of 52°C was recorded on the 3rd day for the PCM-based dryer system at around 10:00 am, and up to a 40% difference between this system's temperature and the ambient temperature was observed, where the PCM-based chamber was at 50°C while the ambient temperature was 36°C. This gradual daily improvement is attributable to the good storage capacity of the PCM enhanced with carbon-dot nanoparticles.

On the fourth day, a peak temperature of about 48.4°C was observed in the drying chamber of the PCM-based dryer system at 1:00 pm. Up to about a 30% increase in the PCM-system temperature was recorded compared to the ambient temperature 5.30 pm, where the PCM-based chamber was at 37°C while the ambient temperature was 29°C. When a PCM is integrated into a solar dryer, it absorbs excess thermal energy during peak solar irradiance and releases it during periods of lower insolation or at night, effectively smoothing thermal fluctuations and maintaining a more consistently elevated temperature within the drying chamber. (Fu *et al.*, 2024; Krishna *et al.*, 2025). The observed thermal lag and sustained elevated temperatures during low solar radiation periods confirm effective energy storage and release, leading to extended drying duration and improved system efficiency. These findings are consistent with established literature on nano-enhanced phase change materials in solar thermal applications. The mean solar irradiance was calculated for the more useful sunlight period of between 10.00 am and 3.00 pm based on the hourly measurement values. The calculated means for the four days were 810, 867, 961 and 867 w/m^2, respectively which gives a mean of 876 w/m^2 across the four days. The mean ambient temperature across the four days was also calculated based on hour measurement values taken giving about 28.6 °C.

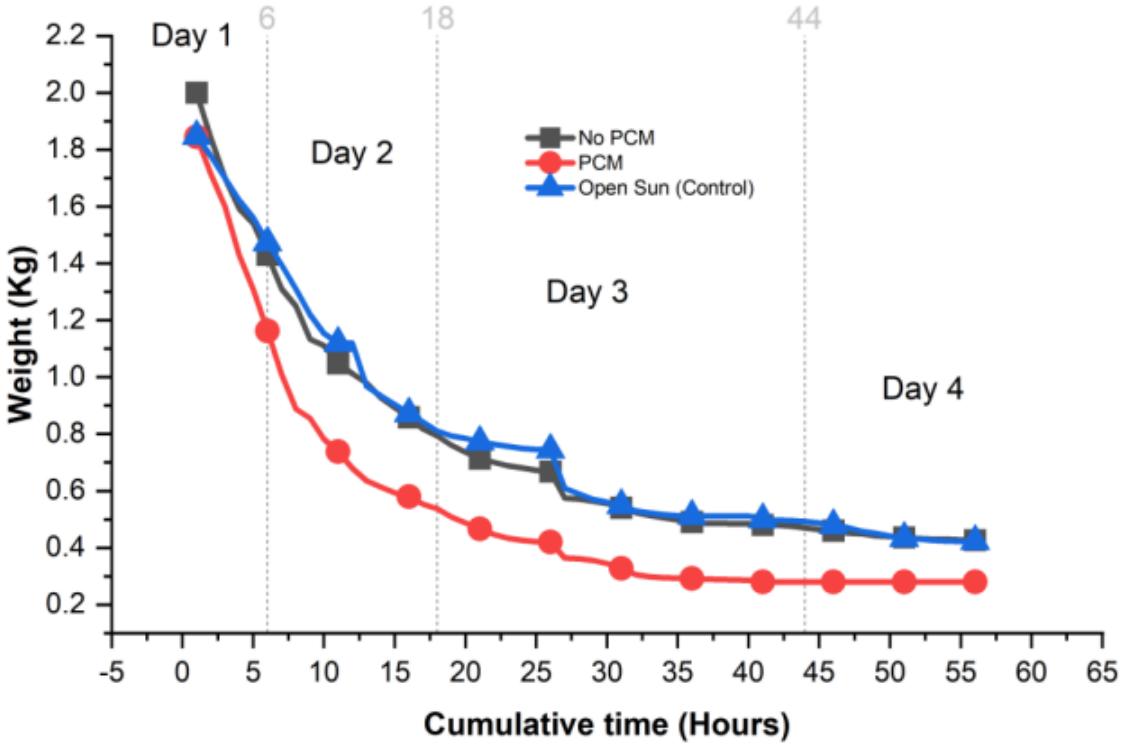

Figure 2: Drying performance recorded for open drying, a dryer with PCM, and a dryer without PCM.

Figure 2 compares drying profiles over 60 hours for open-sun drying (control), a non-PCM dryer, and a PCM-assisted dryer. All curves show the typical exponential mass decline, reflecting an initial constant-rate period followed by a prolonged falling-rate period. The PCM system consistently maintains the lowest residual mass, indicating superior drying efficiency. In the first 6 hours (Day 1), all methods show rapid weight loss from surface moisture evaporation. Still, the PCM dryer declines fastest because it absorbs excess solar heat and releases it gradually, stabilising temperatures. Accord to Azzouz *et al.* (2018) confirm that latent heat storage materials improve heat retention and reduce temperature fluctuations, thereby accelerating early-stage drying kinetics. By 18 hours (Day 2), the performance gap widens: the PCM system continues faster moisture removal while the others slow, corresponding to the shift toward internal moisture diffusion. PCM's sustained thermal input enhances this diffusion. Similar findings were reported by Mohammed *et al.* (2025) By 44 hours (Day 3), drying rates decrease as bound moisture dominates, yet the PCM dryer reaches 0.3 kg versus 0.5kg for non-pcm and 0.6 kg for the open sun. In the final stage, all systems approach equilibrium moisture content

with minimal further loss, but the PCM unit achieves the lowest final mass and greatest drying completeness. Without thermal storage, the non-PCM and open-sun methods remain more dependent on ambient conditions and diurnal temperature drops. Recent work by Kumar *et al.* (2021) highlights that PCM integration is particularly beneficial during the falling-rate period, where consistent thermal gradients are crucial for moisture diffusion from the interior.

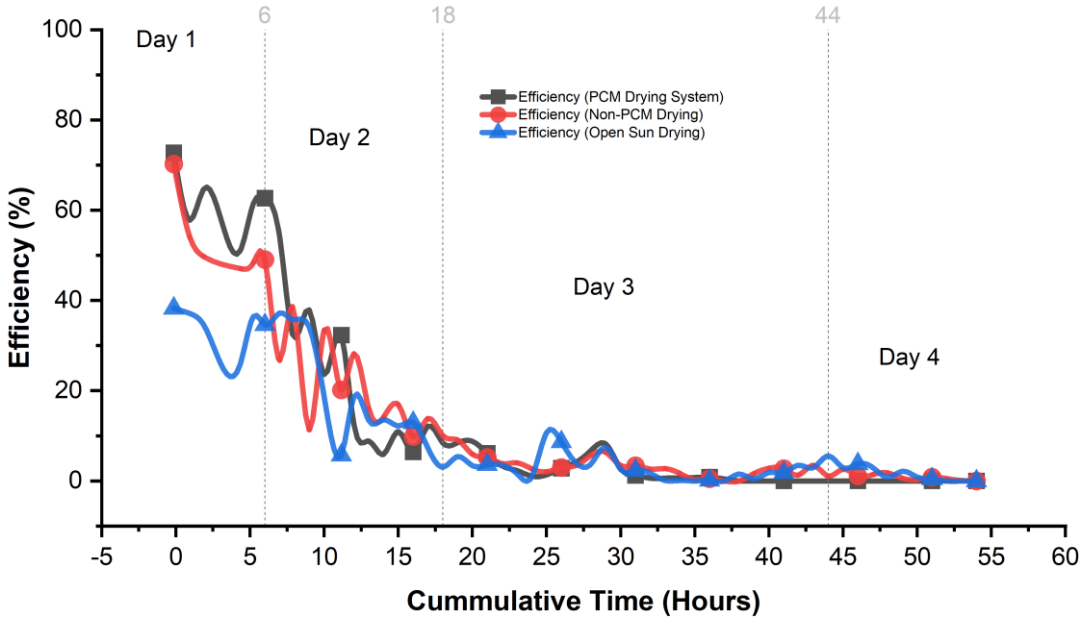

Figure 3: Variation of drying efficiencies with time for the 3 cases

Figure 3 compares the drying efficiencies of PCM, non-PCM, and open-sun systems over approximately 60 cumulative hours. On Day 1, the PCM and non-PCM system recorded similar initial efficiency of about 75%, while open-sun drying began at 40%. During the first 10 hours, however, PCM drying maintained relatively high and stable efficiency between 50% and 70%, whereas non-PCM efficiency declined sharply from to between 30% and <50%. Open-sun drying remained lower, fluctuating between 20% and 40%. By 18 hours, efficiencies declined across all systems because of reduced moisture content and the transition to the falling-rate drying period. However, the PCM system maintained smoother performance, generally achieving 20-40% efficiency, owing to latent heat storage and release during low solar irradiance. Recent studies corroborate this behavior, showing that PCM integration reduces thermal intermittency and improves energy utilization efficiency. (Rakshamuthu *et al.*, 2021) From 30 hours onward, efficiencies approached near-zero values, with all systems falling below 2% by 55-60 hours. Overall, PCM integration provided superior early-stage performance, improved thermal regulation, and sustained moisture removal compared with non-PCM and open-sun drying under variable operating conditions.

4. CONCLUSION

The experimental evaluation of a carbon dot-enhanced shea butter phase change material (PCM) integrated into a solar dryer demonstrated a significant improvement in the drying performance of okra. Under an average ambient temperature of 28.6 °C and solar irradiance of 995.5 W/m², the PCM-integrated dryer achieved an outlet air temperature of 51.6 °C and removed 0.68 kg of moisture from an initial 2 kg okra sample. The PCM-enhanced dryer recorded a peak drying efficiency of 85%, compared with 77% for the non-PCM dryer and approximately 40% for open-sun drying. The incorporation of 3.924 kg of PCM, with an energy storage capacity of 489,853 J, extended the drying period by 5 hours beyond sunshine hours. Consequently, the PCM system achieved the highest drying

rate of 0.20 kg/h, compared with 0.1425 kg/h for the non-PCM dryer and 0.1317 kg/h for open-sun drying. These results demonstrate that carbon dot-enhanced shea butter PCM can improve thermal energy storage, extend drying operations, and accelerate moisture removal. The limitations of these findings is the fact that only one crop (okra) was experimented and the testing was not extended across different seasons, and therefore multiple climatic and weather conditions. Evaluation of the dryer was done only for four days with 2 kg okra samples. Further characterisation using Differential Scanning Calorimetry (DSC) is recommended for more accurate thermal property measurements, while seasonal experiments are suggested to evaluate performance under varying weather conditions and assess the system's reliability and suitability for practical agricultural drying applications of different categories of crops, testing should also be extended for more number of days and hours per day to reduce the margin of error and get more reliable data. This study is an exemplary contribution towards sustainable resource utilization considering the fact the it was focused on the use of shea butter which is a renewable resources that has no competitive usage as food resource for humans and animals making the study directly relevant to the ICESID 2026 sub-theme of sustainable resource utilization/materials synthesis.

ABSTRACT
Commercial tricycles are indispensable to the Nigerian transport network, yet their reliability is compromised by recurring mechanical failures whose material origins remain poorly understood. This study integrates a cross-sectional survey of 333 stakeholders, comprising riders, mechanics, and dealers, across six Nigerian states with materials-science analysis to interpret reported faults and identify sustainable intervention strategies. TVS accounted for 73.0% of the fleet. The most prevalent faults were clutch wear (14.2%), piston damage (13.3%), kick-rod fracture (13.3%), frame corrosion (10.0%), and chassis cracking (7.5%). Three primary degradation mechanisms emerged: fatigue-induced fracture, abrasive wear, and substandard components, with 48.6% of respondents attributing failures to these factors. These constitute a self-perpetuating triad that sustains reactive maintenance practices among 59.5% of operators. Logistic regression identified duration of use (AOR = 1.297 per year; $p < 0.001$) and fairly-used purchase (AOR = 1.887; $p = 0.032$) as significant predictors of piston damage. The study aims to map component failures, prioritise targets for materials intervention, and establish a foundation for developing agricultural residue-reinforced aluminium matrix composites. Published studies demonstrate the potential of such composites to enhance wear resistance and mechanical properties, yet no work has validated their application under Nigerian tricycle operating conditions. By linking field-reported faults to a viable materials solution, this study provides the empirical basis for designing and testing locally sourced, reinforced pistons for the Nigerian tricycle sector.

1. INTRODUCTION

The commercial tricycle has emerged as the backbone of intra-urban mobility across Nigeria, filling gaps left by inadequate public transport. Low acquisition cost, fuel economy, and superior manoeuverability have driven rapid adoption. In Kano State alone, there are over 41,000 registered tricycles, which together make about 383,000 trips each day and bring in more than ₦2.1 billion in revenue (Ibrahim, 2025). Their relatively low start-up cost has also made it easier for many people to enter the transport business (Ojekunle, 2009).

Despite their importance, the reliability of these tricycles is often undermined by repeated mechanical breakdowns. They are involved in about 6% of traffic-related injuries (Animasahun *et al*., 2022), and the Federal Road Safety Corps estimates that mechanical failures play a part in nearly 30% of deadly crashes (Ogunleye *et al*., 2024). When a tricycle breaks down, each day off the road means a loss of between ₦3,000 and ₦5,000 in earnings, which puts serious financial pressure on operators (Ameen *et al*., 2025).

Commonly reported faults including clutch slippage, piston seizure, chassis cracking, and crankshaft fracture are usually the result of metal fatigue, corrosion, abrasive wear, and substandard alloy compositions (Kuram *et al*., 2024; Suresh, 1998; Stephens *et a*l., 2000). Fatigue alone is implicated in up to 90% of automotive service failures (Stephens et al., 2000). Metallurgical examination of a failed tricycle front axle revealed carbon content of 0.354 wt%, below specification, with ferrite-pearlite microstructures indicating inadequate heat treatment (Abubakar *et al*., 2025).

The situation is worsened by the poor quality of replacement parts. More than 60% of imported components do not meet safety standards (Okonkwo *et al.*, 2024), and a staggering 95% of imported spare parts are considered substandard (Adebayo *et al*., 2024), all within a spare parts market worth between $5 and $6 billion (Adewale *et al*., 2025).

Earlier work has been limited to single component analyses without examining interrelationships. Aluminium matrix composites reinforced with agricultural residues have emerged as promising low-cost alternatives (Asafa *et al*., 2025; Mogal *et al.*, 2024). Nigeria generates approximately 32 million tonnes of agricultural waste annually (Asafa *et al.*, 2025). Coconut shell ash reinforcement decreased wear loss by 64.7% and raised tensile strength by 45.6% (Ghosh *et al*., 2025). Rice husk ash improved tensile strength to 121.6 MPa at 10 wt% addition (Abolusoro *et al*., 2024).

This study addresses knowledge gaps by integrating a large-scale field survey of 333 stakeholders with materials science analysis of fault patterns. The aim is to map tricycle components failures, identify priority targets for sustainable materials intervention, and lay the foundation for developing agricultural residue reinforced aluminium matrix composites.

2. MATERIALS AND METHODS

2.1 Study Design and Population

A cross-sectional descriptive survey was conducted between October 2025 and April 2026 across Lagos, Oyo, Osun, Ondo, Ogun, and Ekiti states. The target population comprised tricycle riders, mechanics, and dealers. A multi-stage stratified random sampling technique was employed. A total of 333 respondents completed questionnaires: 252 riders (75.7%), 45 dealers (13.5%), and 36 mechanics (10.8%). Sample size was determined using Cochran's formula at 95% confidence level with 5% margin of error.

2.2 Survey Instrument and Data Collection

A structured questionnaire captured socio-demographics, usage history, common faults, spare-parts availability, and maintenance practices. Respondents could report multiple fault types. Face and content validity were established through expert review. Pilot testing on 20 respondents yielded Cronbach's alpha of 0.82. Trained research assistants administered questionnaires through face-to-face interviews.

2.3 Data Processing and Statistical Analysis

Data was coded and verified through double-entry verification. Statistical analyses were performed using IBM SPSS (version 29.0). Descriptive statistics, cross-tabulations, and Pearson chi-square tests were employed, with statistical significance set at $p < 0.05$.

The sample size was determined using Cochran's formula:

$$n_0 = Z^2pq / e^2 \quad (1)$$

Where:

n_0 is the initial sample size,

Z is the Z-score corresponding to the desired confidence level (1.96 for 95% confidence),

p is the estimated population proportion (assumed 50% as the most conservative estimate),

q is 1-p, and

e is the margin of error (5%).

To account for potential non-response, the sample size was increased by 10%. Degrees of freedom for chi-square tests were derived from contingency table dimensions: duration of use (four categories) against piston damage (two categories), df = 3; brand (three categories) against piston damage (two categories), df = 2; and mode of purchase (two categories) against piston damage (two categories), df = 1.

To examine the simultaneous influence of multiple risk factors on piston damage prevalence while controlling for potential confounding variables, binary logistic regression analysis was performed. The dependent variable was coded as 1 for respondents reporting piston damage and 0 otherwise. Independent variables included tricycle brand (categorical: TVS, Bajaj, Piaggio), duration

of use (continuous, in years), mode of purchase (binary: new compared to fairly used), and respondent type (categorical: rider, mechanic, dealer).

The logistic regression model was specified as:

$$ln\left(\frac{p}{1-p}\right) = \beta_0 + \beta_{1(Brand)} + \beta_{2(Duration)} + \beta_{3(Purchase\ Mode)} + \beta_{4(Respondent\ Type)} \quad (2)$$

Where:

p is the probability of piston damage occurrence.

The model was estimated using maximum likelihood estimation with robust standard errors. Model fit was assessed using the Hosmer-Lemeshow goodness-of-fit test and the Nagelkerke R^2 statistic. The Hosmer-Lemeshow test evaluates whether observed event rates match expected event rates in subgroups of the model population, with a non-significant p-value ($p > 0.05$) indicating good model fit. Nagelkerke R^2 provides an approximation of the proportion of variance explained by the model. Results are reported as adjusted odds ratios (AOR) with 95% confidence intervals and corresponding p-values.

2.4 Ethical Considerations

Informed consent was obtained from each participant. No personal identifiers were collected; data was stored securely and used in aggregated form.

3. RESULTS AND DISCUSSION

3.1 Demographic and Operational Characteristics

Table 1 summarises the demographic and operational characteristics of the sample (N = 333). The majority were male (86.5%) and riders (75.7%), with TVS as the dominant brand (73.0%). Most tricycles were manufactured between 2016 and 2020 (40.5%), used for 1–3 years (43.2%), and purchased new (56.8%). Lagos (24.9%) and Osun (24.0%) contributed the highest proportions.

Table 1: Demographic and Operational Characteristics (N = 333)

Variable	Category	n	%	Variable	Category	n	%
Respondent Type	Dealer	45	13.5	Tricycle Brand	Bajaj	63	18.9
	Mechanic	36	10.8		Piaggio	27	8.1
	Rider	252	75.7		TVS	243	73.0
Gender	Female	45	13.5	Manufacturing Year	2006–2010	72	21.6
	Male	288	86.5		2011–2015	72	21.6
Age (years)	< 20	9	2.7		2016–2020	135	40.5
	20–29	108	32.4		2021–2025	54	16.2
	30–39	99	29.7	*Usage Duration	< 1 year	27	8.1
	40–49	81	24.3		1–3 years	144	43.2
	≥ 50	36	10.8		4–6 years	117	35.1
Experience (years)	< 2	90	27.0		> 6 years	45	13.5
	2–5	135	40.5	Purchase Type	Fairly used	144	43.2

	Ondo	26	7.8				
	Osun	80	24.0				
	Oyo	51	15.3				

**Year refers to manufacturing year; Duration refers to years in use by current respondent.*

3.2 Common Faults and Priority Target Identification

Total fault mentions (1062) exceed sample size as multiple faults could be reported. Figure 1 shows distribution; Table 2 provides mechanisms. Clutch problems (14.2%), piston damage (13.3%), and kick-rod issues (13.3%) were most frequent. Brake leather issues (10.8%), frame corrosion (10.0%), ring damage (8.3%), and crankshaft issues (8.3%) were also prevalent.

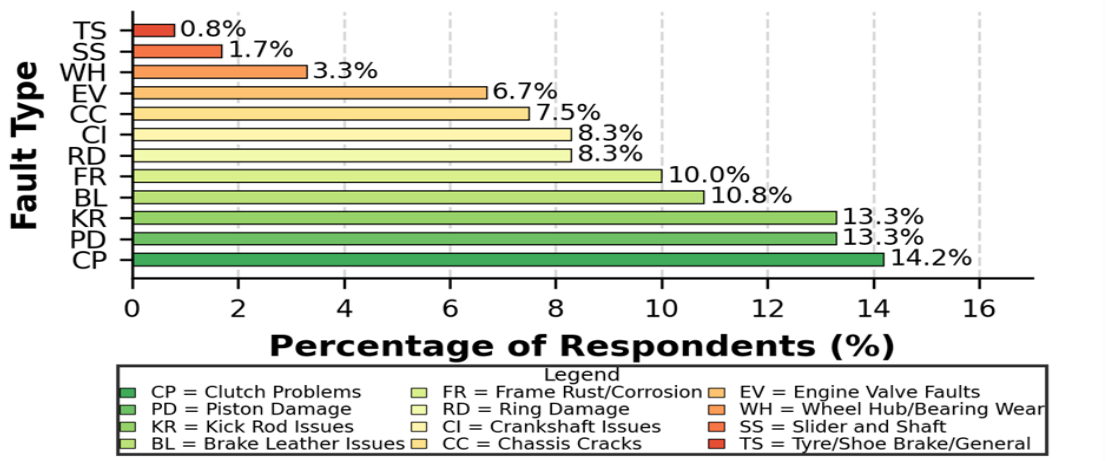

Figure 1: Prevalence of common mechanical faults (CP = Clutch Problems, PD = Piston Damage, KR = Kick Rod, BL = Brake Leather, FR = Frame Rust, RD = Ring Damage, CI = Crankshaft, CC = Chassis Cracks, EV = Engine Valve, WH = Wheel Hub, SS = Slider/Shaft, TS = Tyre/Brake).

Table 2: Frequency of Reported Faults and Associated Material Degradation Mechanisms

Fault Type	Respondent (n)	Frequency (%)	Primary Metallurgical Mechanism(s)
Clutch Problems	153	14.2	Wear of friction material; thermal degradation of organic binders
Piston Damage	144	13.3	Casting defects in Al-Si alloy; inadequate heat treatment; adhesive wear
Manual Kick-Rod Issues	144	13.3	Fatigue fracture at stress concentrators
Brake Leather Issues	117	10.8	Abrasive wear; delamination of friction lining
Frame Rust/Corrosion	108	10.0	Uniform and pitting corrosion of unprotected mild steel
Ring Damage	90	8.3	Poor-quality cast iron; insufficient hard-chrome plating
Crankshaft Issues	90	8.3	Fatigue crack initiation at crankpin fillet; insufficient surface hardness
Chassis Cracks/Breakage	81	7.5	High-cycle fatigue; weld-defect-induced crack propagation
Engine Valve Faults	72	6.7	Adhesive/abrasive wear of valve seat; thermal fatigue
Wheel Hub/Bearing Wear	36	3.3	Rolling-contact fatigue; inadequate lubrication
Slider and Shaft	18	1.7	Fretting wear
Tyre/Shoe Brake/General	9	0.8	Mixed mechanisms
Total	1062	100.0	

3.2.1 Piston Damage as Priority Target

Piston damage (13.3% of fault mentions) represents a priority target. Pistons operate under extreme conditions: 250–350°C, cyclic loading, and sliding contact (Kowalski *et al*., 2024). Failure mechanisms (adhesive wear, fatigue cracking, inadequate heat treatment) are addressable through composites.

Table 3 shows piston failure rates by brand and duration. Chi-square analysis revealed significant association with duration of use ($\chi^2 = 23.56$, df = 3, $p < 0.001$), with 54.2% of tricycles beyond six years reporting damage compared to 8.2% under one year. Brand differences were significant ($\chi^2 = 6.08$, df = 2, $p = 0.048$), with Bajaj highest (15.9%), followed by Paggio (14.3%) and TVS (12.3%). Mode of purchase showed significant association ($\chi^2 = 4.62$, df = 1, $p = 0.032$), with fairly used vehicles at 18.5% against 10.8% for new.

Table 3: Piston Damage Prevalence by Tricycle Characteristics

Variable	Category	Piston Damage Reported (%)	χ^2	df	p-value
Brand	TVS	12.3	6.08	2	.048
	Bajaj	15.9			
	Piaggio	14.3			
Duration of Use	<1 year	8.2	23.56	3	< .001
	1–3 years	11.2			
	4–6 years	16.8			
	>6 years	54.2			
Mode of Purchase	New	10.8	4.62	1	.032
	Fairly Used	18.5			

3.2.2 Multi-Factor Assessment of Piston Damage Risk

Binary logistic regression identified independent predictors of piston damage. As shown in Table 4, the model showed good fit (Hosmer-Lemeshow $\chi^2 = 6.34$, df = 8, p = 0.609) and explained 28.7% of the variance (Nagelkerke $R^2 = 0.287$). Duration of use was the strongest predictor; each additional year increased the odds of damage by 29.7% (AOR = 1.297; 95% CI: 1.178–1.428; p < 0.001). Fairly used vehicles had 88.7% higher odds than newer ones (AOR = 1.887; 95% CI: 1.058–3.367; p = 0.032). Vehicle brand and respondent type were not significant. The remaining variance reflects the influence of unmeasured field factors, including load variations, road conditions, and maintenance practices.

Table 4: Logistic Regression Analysis of Factors Associated with Piston Damage

Variable	Category	AOR	95% CI	p-value
Brand	TVS	1.000	—	—
	Bajaj	1.342	0.891–2.021	0.159
	Piaggio	1.218	0.742–1.999	0.436
Duration	Per year	1.297	1.178–1.428	**<0.001**
Purchase	New	1.000	—	—
	Fairly Used	1.887	1.058–3.367	**0.032**
Respondent	Rider	1.000	—	—
	Mechanic	1.124	0.642–1.969	0.684
	Dealer	0.978	0.554–1.727	0.938

AOR = adjusted odds ratio; CI = confidence interval; bold = p < 0.05.

3.3 Failure Initiation Factors and Maintenance Practice

Low-quality materials (48.6%) and poor road conditions (37.8%) account for 86.4% of reported failure factors as presented in Figure 2. Poor maintenance (10.8%) and overloading (2.7%) were secondary. This corroborates the Standards Organisation of Nigeria's report that 95% of imported spare parts are substandard (Adebayo *et al.*, 2024).

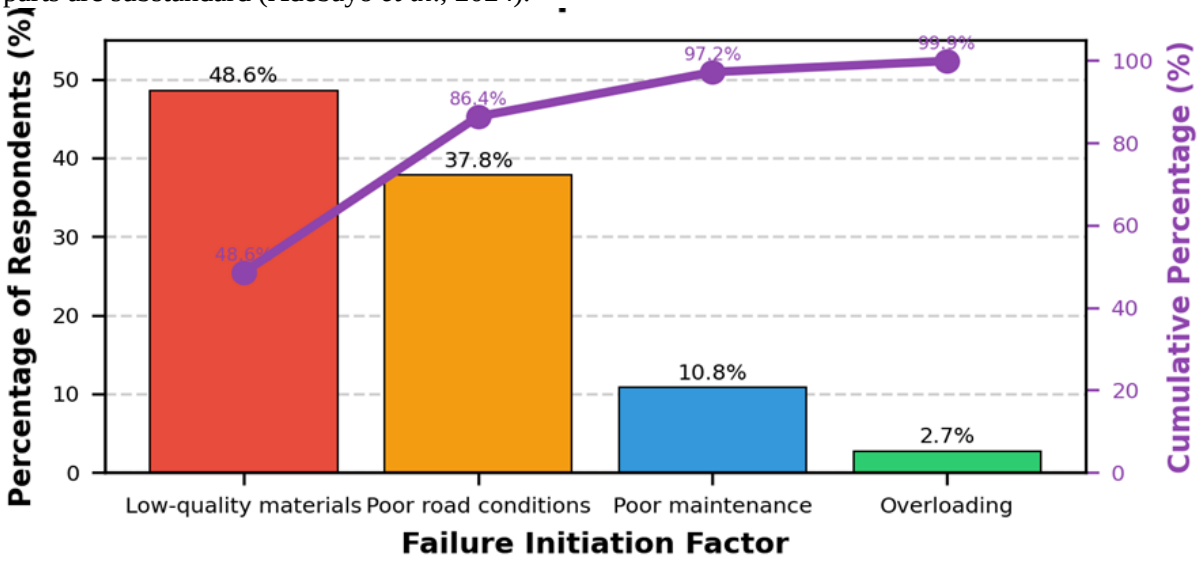

Figure 2: Pareto chart of reported failure initiation factors in commercial tricycles showing Low-quality materials (48.6%) and poor road conditions (37.8%) account for 86.4% of all reported factors, indicating these are the primary drivers of recurrent mechanical failures. Poor maintenance (10.8%) and overloading (2.7%) represent secondary contributing factors. The cumulative percentage line shows the progressive contribution of each factor.

Figure 3 shows maintenance practices. Reactive maintenance predominates (59.5%), with operators repairing only after failure. Scheduled maintenance at 3–6 months (16.2%), monthly (13.5%), weekly (8.1%), and annual (2.7%) were less common.

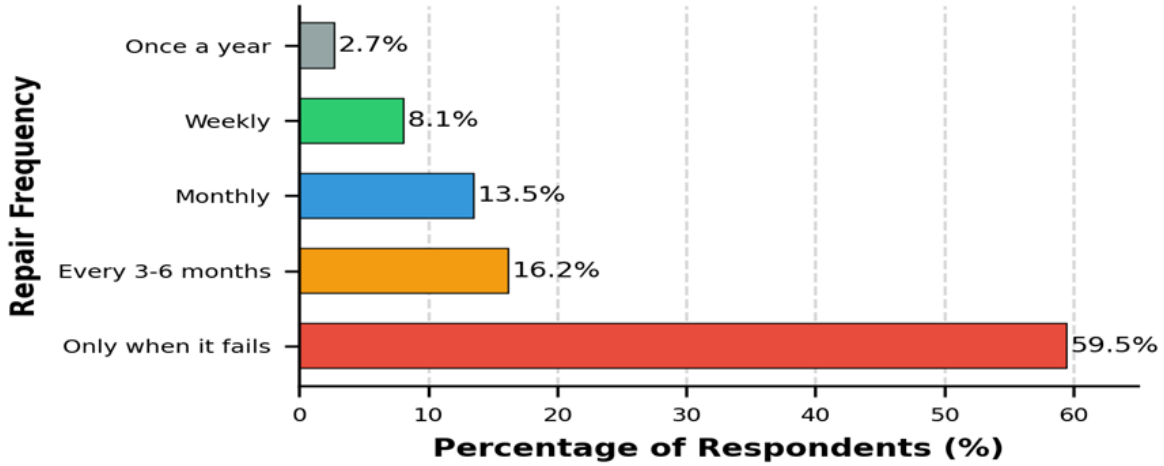

Figure 3: Maintenance practices among commercial tricycle operators (N = 333). The majority (59.5%) adopt a reactive approach, repairing components only after failure. Scheduled preventive maintenance is practiced by 40.5% of operators, with intervals ranging from weekly (8.1%) to annual (2.7%). Data collected through structured questionnaire from 333 respondents across six Nigerian states

3.4 Spare-Parts Availability, Quality Perception and Ease of Maintenance

Table 5 shows spare-parts availability by brand. TVS had best availability (67.6% available, 8.1% not available). Bajaj had 70.3% available, 10.8% not available. Piaggio had the poorest availability (45.9% available, 32.4% not available).

Table 5: Spare-Parts Availability by Brand

Brand	Available (%)	Expensive but Available (%)	Not Available (%)
Bajaj	70.3	18.9	10.8
Piaggio	45.9	21.6	32.4
TVS	67.6	24.3	8.1

TVS parts were unavailable 8.1% of the time, a considerably smaller gap than the 32.4% recorded for Piaggio, yet this still poses a risk of substandard parts entering the supply chain. When genuine parts are scarce, operators often turn to inferior alternatives, a pattern well documented in Nigerian aftermarket studies (Okonkwo *et al*., 2024). Perceptions of maintainability mirrored these availability trends: 73.0% of respondents rated TVS as the easiest brand to maintain, versus 16.2% for Bajaj, whereas only 10.8% found Piaggio easy to maintain. Furthermore, 59.5% of respondents believed that material quality substantially affects tricycle performance and lifespan.

3.5 Theoretical Framework: The Failure Triad

Findings establish fatigue, wear, and substandard components as a self-perpetuating triad as illustrated in Figure 4. Fatigue reduces strength and accelerates wear; wear generates debris and stress concentrations promoting fatigue; economic pressure drives substandard replacement (Stephens *et al*., 2000; Suresh, 1998). Reactive maintenance ensures replacement after failure, often with substandard parts, completing the cycle. Logistic regression as shown in Table 5 quantified this: each year increases odds by approximately 30%; fairly-used purchase elevates odds by 89%.

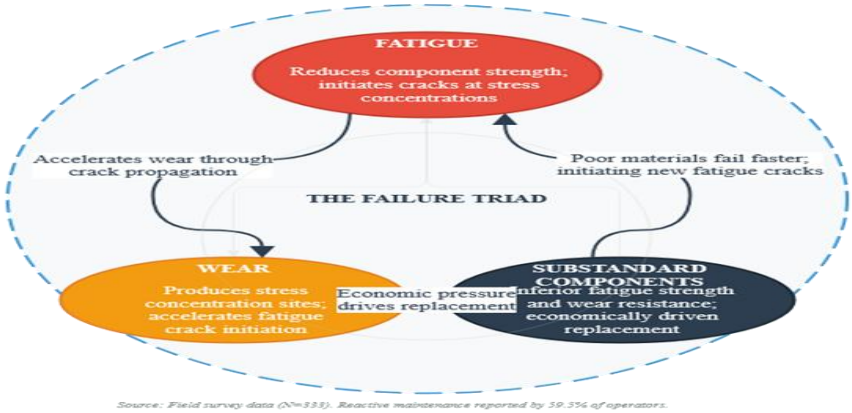

Figure 4: Schematic representation of the self-perpetuating failure triad in commercial tricycles. Fatigue reduces strength; wear produces stress concentration; economic pressure drives substandard replacement.

3.6 Agricultural Residue-Reinforced Aluminium Composites as a Sustainable Materials Strategy

Agricultural residue–reinforced aluminium matrix composites mitigate abrasive wear, fatigue fracture, and substandard materials (Sanusi and Adebisi, 2026). Palm kernel shell powder (15 wt%) in Al-Mg-Si reduces wear (Mohammed *et al*., 2022); rice husk ash raises fatigue endurance from 0.224×10^6 to 2.582×10^6 cycles (Asafa *et al*., 2014). Coconut shell ash (45.1% SiO_2, 15.5% Al_2O_3, 12.4% Fe_2O_3) lowers wear loss 64.7%, reduces friction coefficient from 0.34 to 0.22, increases tensile strength by 45.6% from 98 MPa to 143 MPa, and improves Microhardness by 22.5% from 31.5 HV to 38.6 HV (Ghosh et al., 2025). Rice husk ash (10 wt %) gives 121.6 MPa and 74.5 HBW (Aboloruso *et al.*, 2024); with granite dust, wear drops 56.25% (Mogal et al., 2024). Challenges include poor bonding, addressed by 2–5% Mg for wettability, and agglomeration, mitigated by double stir casting; optimal reinforcement is 5–10 wt% (Asafa *et al.*, 2025; Ge et al., 2025; Olorunfemi *et al*., 2021). These renewable residues enable 95% energy savings in secondary Al production and 15–25% cost reduction over SiC

composites, offering a sustainable pathway to enhanced durability and reliability (Ge *et al.*, 2025; Sanusi and Adebisi, 2026).

4. CONCLUSION

This investigation identifies clutch wear (14.2%), piston damage (13.3%), kick-rod fracture (13.3%), frame corrosion (10.0%), and chassis cracking (7.5%) as the most prevalent faults, originating from fatigue, abrasive wear, and substandard components (48.6%). Logistic regression confirmed duration of use (AOR = 1.297/year; $p < 0.001$) and fairly-used purchase (AOR = 1.887; $p = 0.032$) as significant piston-damage predictors, while reactive maintenance (59.5%) perpetuates the failure cycle. Piston damage is prioritised for materials intervention, with coconut shell ash composites offering 64.7% wear reduction, 45.6% tensile strength improvement, and 22.5% hardness enhancement. Future research should experimentally validate these composites through XRF characterisation, ASTM-standard mechanical testing, and accelerated wear simulation, while policymakers enforce stricter quality standards and manufacturers invest in double-stir casting with 5–10 wt% agricultural residue reinforcement.

ABSTRACT

This study is a computational mass and energy assessment based on secondary literature data obtained from (Xun et al., 2014). As a sustainable and renewable source of energy, microalgae derived biofuel has a growing potential to solve the problem of global energy crisis as a result of higher demand for energy, as well as environmental impact such as global warming associated with fossil fuel. Mass and energy assessment of the pyrolysis of low lipid microalgae Dunaliella salina was carried out to produce 1kg of bio-oil. A fixed bed tubular reactor was used to carry out direct pyrolysis on the microalgae biomass at $300 - 700℃$. *Mass and energy assessment was done to estimate the products yield, mass ratio, energy ratio, energy efficiency, higher heating value (HHV) and energy consumption ratio (ECR) of the biofuel. The maximum yield of bio-oil, bio-char and biogas at* $500℃$ *were 64.9%, 28.0% and 3.9% respectively. The maximum mass ratio and energy ratio of the bio-oil were 0.649 and 77.98%. The higher heating value (HHV) and energy efficiency of the bio-oil at* $500℃$ *were obtained as 25.47MJ/kg and 74.50%. The maximum energy consumption ratio (ECR) of the pyrolysis process at* $500℃$ *was 0.043. The ECR is less than 1, which shows that the pyrolysis process was favourable since it exhibits net energy products with higher energy content than that required for the reaction to occur. The results obtained from mass and energy balances show that pyrolysis temperature has a great influence on the distribution yield and energy efficiency of the products. The production of 1kg of bio-oil from the algae biomass feedstock was obtained via pyrolysis of low lipid microalgae.*

1 INTRODUCTION

The use of sustainable energy sources and renewable energy sources is highly pertinent in Nigeria due to the fact that the country's energy sector still focuses largely on conventional fossil fuel sources of energy despite its great potential to generate renewable energy. By diversifying energy sources by the use of biofuel and other forms of renewable sources of energy, the issue of energy sustainability could be addressed along with minimizing the reliance on traditional sources of energy generated from petroleum sources. The biomass resource that can be used is that of microalgae since it can be processed to form energy products using processes like pyrolysis. Thus, conversion of microalgae biomass to bio-oil would help the country use resources in an innovative way.

The current study is thus in line with the International Conference on Engineering Innovation for Sustainable Development (ICESID) 2026 theme "Innovating Tomorrow: Leveraging Engineering for the Sustainable Development of Nigeria," especially through the themes of Innovative Resource Utilization and Sustainable Engineering Processes. Evaluation of the microalgae pyrolysis and bio-oil generation processes offers a basis for demonstrating the use of engineering analysis to assess the other possible routes for renewable biomass transformation into energy products. The study results can offer an insight into the evaluation of the technical and energy aspects of microalgae utilization and may form part of future research studies on renewable biomass utilization in Nigeria.

Energy is an essential component of human existence. Every sector, including industry, agriculture, healthcare, transportation, and domestic activities, relies on the use of energy (Mckendry, 2002). The increasing global demand for energy, along with the environmental consequences such as global warming linked to fossil fuels and their diminishing availability, has prompted the exploration of alternative energy sources from various biomass feedstock (Christi, 2012). The combustion of fossil fuels emits vast quantities of carbon dioxide, which is considered a primary contributor to global warming (International Energy Agency, 2015). Unlike the greenhouse gas emissions resulting from fossil fuel combustion, biomass represents a valuable feedstock for generating biofuels and other important chemicals. Renewable biomass feedstock comprises aquatic biomass, terrestrial biomass, municipal waste, agricultural solid waste, forest residue, and industrial waste (Jay, 2010).

Recent advancements in biotechnology have prompted researchers to investigate microalgae as a promising feedstock for sustainable biofuel production. Microalgae comprise a diverse group of aquatic, photosynthetic microorganisms, typically unicellular or multicellular, and are classified as third-generation biofuels (Veillette, 2012). Through the process of photosynthesis, algae and seaweed use sunlight to absorb carbon dioxide from the atmosphere and release oxygen (Kumar et al., 2016). Despite making up only 0.5% of all plant biomass, algae create roughly 60–75% of the oxygen required by people and animals, and every pound of algae biomass reduces carbon dioxide by 1.8 pounds (Wolkers et al., 2011). High photosynthetic efficiency, increased oil production productivity, and a high capacity to store significant amounts of lipids are characteristics of microalgae. The aforementioned qualities make microalgae one of the most exceptional sources of biofuel (Mohammad et al., 2015).

The evaluation of mass and energy regarding microalgae biofuel indicates that the cultivation, harvesting, drying, and processing of microalgae biomass can yield an environmentally sustainable feedstock for biofuel generation (Yanfen et al., 2012). Using a low lipid microalgae (Dunaliella salina) as feedstock for pyrolysis is a reasonable alternative because of the low cost and high oil yield. Dunaliella salina is a type of green microalgae mostly found in sea salt fields (Chen et al., 2012). The low lipid content strains of microalgae result in its cost lower with faster growth rates (Aresta et al., 2005). In this study, direct pyrolysis pathway is used to evaluate the mass and energy assessment of pyrolysis of low lipid microalgae (Dunaliella salina) at different temperatures from 300-700^{o}C (Xun et al., 2014).

2 MATERIALS AND METHODS

2.1 Description of Pathways for Biofuel from Microalgae Pyrolysis

This study is a computational mass and energy assessment based on secondary literature data obtained from (Xun et al., 2014). This research examines the direct pyrolytic processes for producing bio-oil from microalgae (Dunaliella salina) at temperatures ranging from 300 to 700°C. Direct pyrolysis

deals with the method of pyrolysing the entire microalgae, resulting in bio-oil that predominantly consists of long-chain hydrocarbons including various terminal groups. This study examined the direct pyrolysis pathway by closely examining the mass ratio, energy ratio, energy efficiency, and energy consumption ratio (ECR). GC-MS (Agilent 7890A-5975C workstation software) was used to examine and identify bio-crude composition and the chemical constituents through the direct pyrolysis process. The area percentage approach was used to quantitatively analyse the composition of pyrolysis oil (Tang et al., 2015). The higher heating value of the bio-oil was calculated by equation (2.1) below: (Ferdinand et al., 2012).

$$HHV(kJ/kg) = 35098C + 116050H + 6267N - 11073O \quad \text{Equation 2.1}$$

Where: C, H, N, O are the fractions of the elements of carbon, hydrogen, nitrogen and oxygen in the compound respectively which can be obtained from the ultimate analysis for bio-char and bio-oil as shown in table (2.1) and (2.2) below.

Table 2.1: Ultimate Analysis (wt %) and HHV of Dunaliella salina (Bio-char) (Xun et al., 2014).

Temperature (℃)	C	H	N	S	O	HHV (MJ/kg)
300	57.9	4.7	10.7	0.6	11.3	25.4
400	57.2	3.8	9.8	0.5	6.3	24.1
500	55.2	2.9	9.0	0.3	3.7	21.8
600	54.7	2.2	8.2	0.2	2.2	20.6
700	54.0	2.0	7.4	0.2	1.7	19.6

Table 2.2: Ultimate Analysis (wt %) and HHV of Dunaliella salina (Bio-oil) (Xun et al., 2014).

Temperature (℃)	C	H	N	S	O	HHV (MJ/kg)
300	32.0	9.0	8.1	0.4	50.6	16.6
400	45.8	8.7	8.3	0.2	37.0	22.6
500	53.0	8.3	8.6	0.3	29.8	25.5
600	55.6	8.2	9.4	0.2	26.5	26.6
700	56.3	7.8	10.8	0.2	24.8	26.7

2.2 Mass and Energy Assessment

A fixed bed tubular reactor operating at 300–700°C was used to carry out the pyrolysis experiment as seen in (Xun et al., 2014). The mass balance efficiency was evaluated using the maximum bio-oil yield. The yields of the pyrolysis products were used to calculate the mass balance. The equations utilized in the mass and energy assessment are displayed in equations (2.2) to (2.5) (Yang et al., 2014).

Equation (2.2) defines mass ratio as seen below:

$$\eta_m = \frac{m_{fuel}}{m_{biomass}} \quad \text{Equation 2.2}$$

Where: η_m = Mass ratio m_{fuel} = Mass of liquid fuel (kg) $m_{biomass}$ = Mass of biomass (kg)

The energy ratio is defined as:

$$\eta_{ef} = \frac{m_{fuel} \times HHV_{fuel}}{m_{biomass} \times HHV_{biomass}}$$ Equation 2.3

Where: η_{ef} = Energy ratio HHV_{fuel} = Higher heating value of fuel (MJ/kg)
$HHV_{biomass}$ = Higher heating value of biomass (MJ/kg)

Energy efficiency is determined using equation (2.4) below. It evaluates all of the energy inputs needed for the conversion process as well as the energy contained in the original feedstock and the desired fuel.

$$\eta_{ef}^{1} = \frac{m_{fuel} \times HHV_{fuel}}{m_{biomass} \times HHV_{biomass} + Q_{input}}$$ Equation 2.3

Where: η_{ef}^{1} = Energy efficiency Q_{input} = Net process energy

Each process's energy balance can be evaluated using the energy consumption ratio (ECR). The energy needed to heat the microalgae cells to reaction temperature is divided by the energy of the oil, gas, and char that are produced to determine the ECR (Chaiwong et al., 2013). Since the product has more energy than what is needed for the reaction, the reaction is energy favorable if ECR < 1. However, if ECR > 1, the total energy used to make the bio-oil exceeds the energy in the fuel. The energy consumption ratio (ECR), of the pyrolysis process is expressed as seen in equation (2.5) below:

$$ECR = \frac{Q}{H_{oil}Y_{oil} + H_{char}Y_{char} + H_{gas}Y_{gas}}$$ Equation 2.4

Where: H_{oil} , H_{gas} and H_{char} = HHVs of the bio-oil, bio-gas and bio-char
Y_{oil} , Y_{gas} and Y_{char} = Yield of the bio-oil, bio-gas and bio-char

2.3 Pyrolysis Process

It was estimated that 1 kg of bio-oil (wet basis) would be produced by direct pyrolysis at 300, 400, 500, 600, and 700°C. The pyrolysis distribution yield of products for Dunaliella salina is displayed in Table 2.3.

Table 2.3: Pyrolysis Distribution Yield of Products (Biofuel) (Xun et al., 2014)

Temperature	**Bio-gas**	**Bio-oil**	**Bio-char**	**Undetected**
(℃)	**(% mass)**	**(% mass)**	**(% mass)**	**(% mass)**
300	0.4	32.3	57.7	9.5
400	2.7	53.5	34.0	9.7
500	3.9	64.9	28.0	3.2
600	8.0	59.9	24.2	7.9
700	15.5	52.6	22.1	9.8

According to (Xun et al., 2014), a fixed-bed tubular reactor was used for the pyrolysis experiment. For this investigation, 1g (0.001kg) of each microalgae sample was utilized. 20 minutes (1200 seconds) was determined to be the residence time needed to finish the pyrolysis process. At 500°C, the maximum output of bio-oil (wet basis) for Dunaliella salina was 64.9%. The elemental compositions of table (2.2) were used to estimate the HHVs of the bio-oil using (Ferdinand et al., 2012) method of equation (2.1). The direct pyrolysis route flow chart, which includes bio-oil, bio-char, and biogas, is depicted in Figure (2.1).

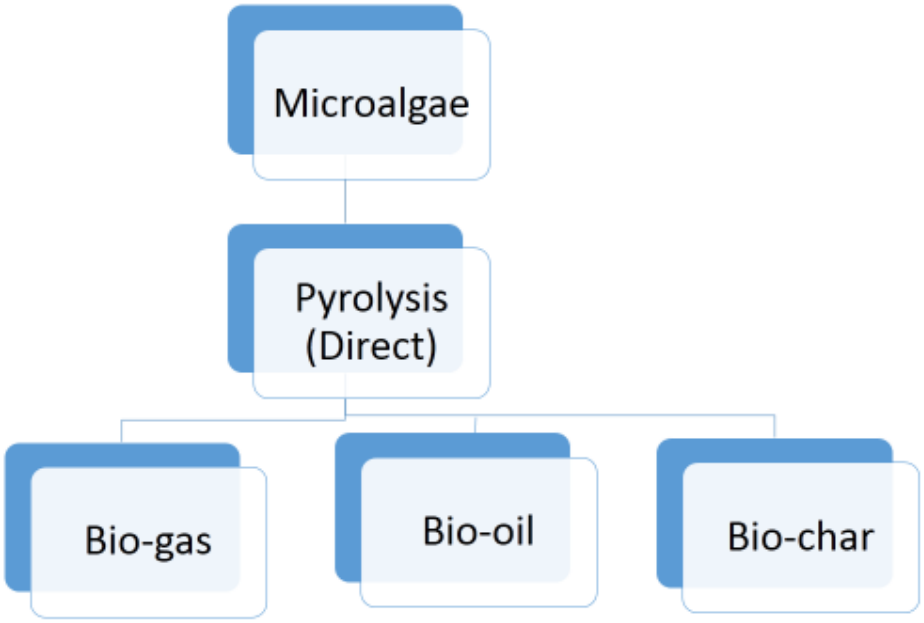

Figure 2.1: Flow chart of direct pyrolysis pathway for biofuel production

3 RESULT AND DISCUSSION

In this evaluation study, low-lipid microalgae (Dunaliella salina) were directly pyrolysed to produce 1 kg of bio-oil from algae biomass feedstock.

3.1 Pyrolysis Distribution Yield of Products (Biofuel)

The product yield distribution of D. salina via the direct pyrolysis pathway at 300–700°C is displayed in Figure 3.1. The data for the pyrolysis distribution yield of products (biofuel) in table 2.3 are used to produce Figure 3.1.

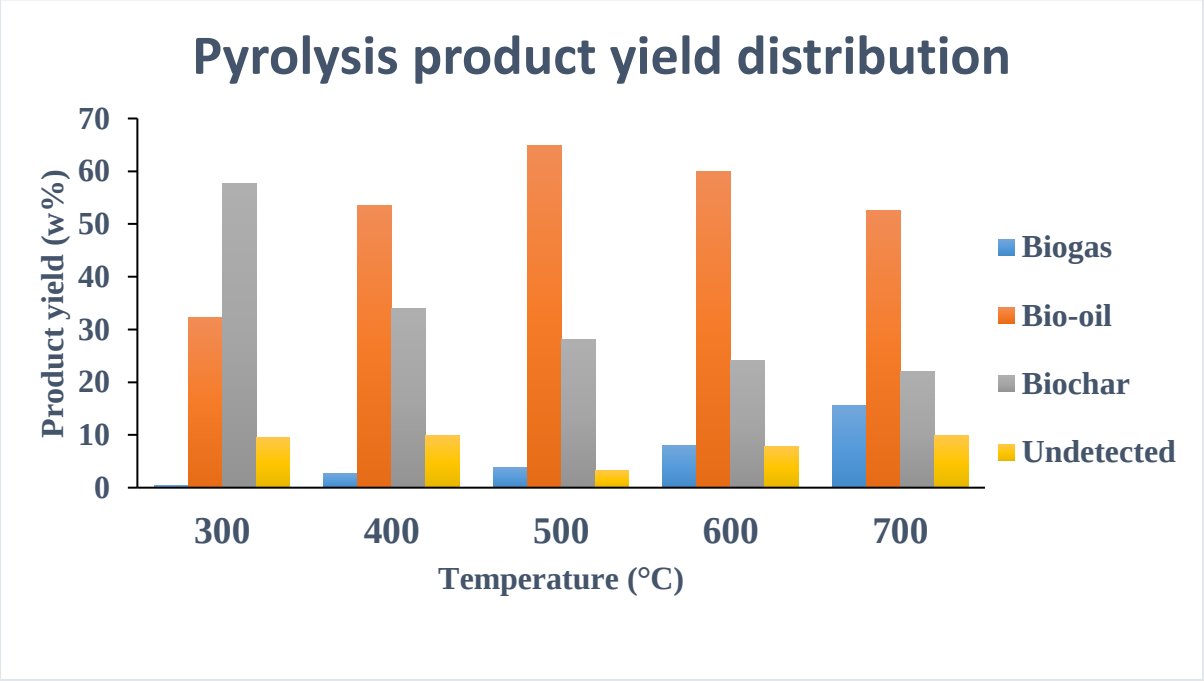

Figure 3.1: Pyrolysis product yield distribution

Figure 3.1 shows a graphical representation of the product yield distribution of Dunaliella salina, with a significant percentage of undetected biogas, bio-oil, and bio-char. Over the course of the

analysis, the percentage of undetected cases was less than 10%. Figure 3.1 shows that at 500°C, the maximum yield of bio-oil estimated in the assessment was 64.9%. The biogas yield rose from 0.4 to 15.5% while the bio-char yield fell from 57.7 to 22.1% as the temperature ranged from 300−700°C. The yield of bio-oil increased between $300 - 500℃$, reaching over 60% at the microalgae's reactor temperature of 500°C. The yields of bio-oil, bio-char, and biogas from the pyrolysis of Chlorella vulgaris and Dunaliella salina at different temperatures between $300 - 500℃$, were assessed by (Xun et al., 2014), who reported bio-oil yields of 49.2%wt for Chlorella vulgaris and 55.4%wt for Dunaliella salina at both 500°C. The bio-oil yield estimated in the present computational assessment was 64.9 wt%, compared with 55.4 wt.% reported by (Xun et al., 2014) for D. salina at 500 °C. The difference of 9.5% is associated with differences in the calculation procedure, process assumptions, product definition, or operating conditions." Additionally, at 600°C, Nannochloropsis microalgae produced a 60%wt bio-oil yield (Tang et al., 2015). The results shows that pyrolysis temperature has a significant effect on the distribution yield of products.

3.2 Mass and Energy Assessment

Table 3.1 and 3.2 shows the mass and energy assessment parameters for direct pyrolysis route in the production of 1kg of bio-oil from Dunaliella salina. The mass and energy assessment parameters include mass balance, mass ratio (η_m), energy ratio (η_{ef}), higher heating value (HHV), energy efficiency (η_{ef}^1) and energy consumption ratio (ECR) of the pyrolysis at $300 - 700℃$. At 500°C, the bio-oil's maximum mass ratio and energy ratio were 0.649 and 77.98% respectively. As the temperature rises from 300°C to 500°C, the bio-oil's mass ratio and energy ratio vary from 0.323 to 0.649 and 25.26 to 77.98% respectively. As the temperature rises from 300 to 500°C, the mass and energy ratios of biogas and bio-char are inversely correlated. At 300–500°C, the bio-oil's higher heating value (HHV) and energy efficiency rise from 16.58 to 25.47 MJ/kg and 24.10 to 74.50% respectively. The higher heating value of the bio-oil exceeds the higher heating value of the algal biomass at 500°C. A high heating value is achieved by increasing the temperature for thermal decomposition of the microalgae. The maximum energy consumption ratio (ECR) of the pyrolysis process at $500℃$ was 0.043 (4.3%). The ECR is less than 1, which shows that the pyrolysis process is favourable since it exhibits net energy products with high energy content than that required for the reaction.

3.3 Elemental Mass Balance for the Production of 1kg of bio-oil

Table 3.3 shows the elemental balance for the production of 1kg of bio-oil via direct pyrolysis from the microalgae biomass. The HHV of bio-oil increases with decrease in H/C and O/C ratio. The atomic hydrogen/carbon and oxygen/carbon of the bio-oil were determined as shown in table 3.3 The H/C and O/C ratios decreases from 0.28 to 0.12 and from 1.59 to 0.44 as temperature increases from $300 - 700℃$ respectively.

3.4 Ternary Plot Diagram

The ternary diagram was used to signify the microalgae pyrolysis process at $300 - 700℃$, relative percentage of oxygen, hydrogen and carbon whose summation is 100% or a ratio of 1. It also compares the relative ratio of carbohydrate, protein and lipid composition. The Ternary plots in figure 3.2 below were created at www.Ternaryplot.com. The carbohydrate, protein and lipid composition of Dunaliella salina and Chlorella vulgaris in figure 3.2b were adapted from (Xun et al., 2014). Table 3.1 for ultimate analysis of bio-char and table 3.3 for elemental balance of bio-oil and biomass were used to create the ternary plot in figure 3.2.

Figure 3.2a shows the ternary distribution of hydrogen, carbon, and oxygen for the products obtained at different operating temperatures. The positions of the points show the relative elemental composition of the resulting products; those located near the upper vertex have a higher relative carbon content, and shifts towards the lower-left and lower-right areas indicate increasing relative amounts of hydrogen and oxygen respectively. Hence, the way the points move across the ternary diagram provides useful evidence of the changes in elemental composition resulting from thermal conversion.

The DC points (DC1 to DC5) are mostly situated in the area dominated by carbon on the ternary diagram. This suggests that the DC products contain a higher proportion of carbon together with relatively smaller amounts of hydrogen and oxygen. As the DC points shift gradually towards the carbon-rich region, this shows that the degree of carbon richness increases with more intensive conversion conditions. This trend is consistent with the formation of carbon-rich bio-char through the stepwise thermal decomposition of the original biomass and the removal of the volatile compounds which contain hydrogen and oxygen. On the ternary diagram, the DO points show a clear trend. DO1 is located further away from the apex which is rich in carbon, whereas DO2 through DO5 are found at successively greater distances from this carbon-rich region. This indicates that the composition of the product alters as the temperature rises. The shift towards the carbon-rich area means that the carbon concentration increases together with a reduction in the amounts of hydrogen and oxygen relative to the other components. These kinds of changes are typical of the continuous deoxygenation and dehydrogenation processes that take place during thermal conversion.

The DB points are abundant in the ternary diagram's intermediate region, especially in the vicinity of the compositions that the higher-temperature DO products represent. The elemental composition between the very carbon-rich DC products and the less carbon-rich DO products is indicated by their placements. The DB points' comparatively tight distribution indicates that, under the conditions under investigation, the elemental composition of these products changes less than that of the DC products. The effect of temperature on the elemental composition of the products is demonstrated by the overall migration of the points toward the carbon-rich region with increasing temperature. As the temperature rises, more carbon-rich products are formed and molecules containing hydrogen and oxygen are broken down. As a result, the ternary distribution presents a graphic portrayal of how the starting biomass gradually converts into products with a bigger relative carbon content.

Figure 3.2b was used to show the comparison in biochemical composition between D. salina and C. vulgaris. In order to explain more about the biochemical composition of the two microalgal bio-feedstocks, the use of the ternary diagram came in handy, when comparisons were made between D. salina and C. vulgaris. Both strains lie within the lipid-rich part of the ternary diagram, although not at the exact same point. While D. salina lies relatively closer to the lipid-rich part, this indicates that D.

salina has higher amounts of lipids. The variation in the placement of the two raw materials is an indication that there is some variation in the biochemical composition of both and this may affect their behaviours during thermal conversion processes. This variation is crucial in analysing the pyrolysis products since there are different thermal decomposition pathways for lipids, proteins, and carbohydrates which may lead to the formation of different levels of bio-oil, bio-char, and gas. Therefore, the initial biochemical composition of the microalgae is useful in explaining the variations in the elemental composition of the resulting products.

4 CONCLUSIONS

Based on the mass and energy assessment carried out from the pyrolysis of low lipid microalgae Dunaliella salina at varying temperatures of 300-700℃, the maximum yield obtained for bio-oil at 500℃ was 64.9%. The yield obtained for biogas and bio-char at 500℃ was 3.9% and 28.0%. The results obtained for mass and energy balances show that pyrolysis temperature has a great influence on the distribution yield and energy efficiency of the products. Therefore, the production of 1kg of bio-oil from the algae biomass feedstock was obtained via direct pyrolysis of low lipid microalgae. The maximum mass ratio and energy ratio at 500℃ for the bio-oil was 0.649 and 77.98%. The higher heating value (HHV), energy efficiency and energy consumption ratio (ECR) of the pyrolysis process at 500℃ was 25.47 MJ/kg, 74.50% and 0.043 (4.3%). The ECR is below 1, indicating that the pyrolysis process is beneficial, as it generates products with higher energy content than what is needed for the reaction process.

From a Nigerian context, these findings highlight the prospect of using microalgae pyrolysis as another process through which renewable biomass and biofuels could be used. The production of bio-oil from microalgae biomass can help in the diversification of energy resources in Nigeria. This will facilitate the production of more sustainable engineering processes. Further studies are needed on the techno-economic, environmental and scale-up aspects of this process before it is implemented on a larger scale. These findings lay the foundation for future research on microalgae fuels as a supplement in the sustainable-energy system being developed in Nigeria.

ABSTRACT

Infrastructure projects in socio-ecologically volatile regions are commonly assessed using static risk registers describing risk at a point in time rather than its evolution across the project life cycle. This study models the temporal evolution of socio-economic and environmental sustainability risk in eight Federal Government infrastructure projects in Nigeria's Niger Delta as a discrete-time, finite-state Markov process, directly addressing ICESID 2026's Sustainable Engineering Processes and Systems sub-theme. Three mutually exclusive states, Low, Moderate and High, were operationalized using six risk indicators. Transition probabilities were estimated through Bayesian synthesis combining Modified Delphi elicitation from 23 experts with empirical transition frequencies from 780 monthly assessments across 15 completed projects, then applied to eight focal projects to generate multi-step forecasts, stationary distributions and Expected Risk Indices. The portfolio converged to 25.8% Low, 42.3% Moderate and 31.9% High risk, an Expected Risk Index of 2.061. Mean escalation exceeded mean recovery probability by 41.6%, a persistent tendency toward risk accumulation. The model correctly classified 94.2% of 778 observed transitions, and a chi-square test found no significant discrepancy between observed and model-expected frequencies ($\chi^2(4)=1.074$, $p=.899$), indicating strong calibration. A corrected comparative benchmark against three alternatives, recomputed from the source thesis's group statistics, confirms superior temporal risk-tracking ($F(3,96)=23.13$, $p<.001$). These findings indicate sustainability risk is better interpreted as an evolving stochastic condition than a static attribute, and the Moderate-risk state constitutes a critical intervention window for anticipatory management. The study contributes a mathematically explicit, transparently limited approach for temporal risk dynamics in sustainable infrastructure governance.

Keywords: *Markov chain model; sustainability risk; Bayesian calibration; stochastic modelling; infrastructure projects*

1. INTRODUCTION

Infrastructure delivery in developing regions is increasingly expected to satisfy not only technical and financial performance criteria but also the socio-economic and environmental obligations associated with sustainable development. Yet the analytical instruments most widely used to manage risk on such projects, risk registers, qualitative probability-impact matrices, and periodic risk workshops, were designed principally to catalogue risk at a point in time. They are comparatively poorly suited to representing how risk moves: how a socio-economic pressure that is manageable in month one can compound into a governance crisis by month twelve, or how an environmental hazard that appears contained can re-emerge as a dominant driver of project failure once seasonal or institutional conditions shift. This distinction between describing risk and modelling its evolution is not a semantic one. It determines whether a project team can anticipate where a project is heading, or can only report where it currently stands.

Stochastic state-transition modelling, and the Markov Chain Model (MCM) in particular, offers a mathematically disciplined way of closing this gap. Under the Markov property, the probability that a system occupies a given state at the next time step depends only on its current state, not on the full history of states that preceded it (Norris, 1997). This memoryless structure is well suited to risk assessment regimes, such as monthly project reviews, in which each evaluation is intended to incorporate all information accumulated to that point rather than requiring an unwieldy accounting of

the entire risk history. Markov Chains have consequently found application across finance, ecology, epidemiology, and engineering reliability (Ching, Huang, Ng, & Siu, 2013; Kemeny & Snell, 1976; Yang, 2020), and within infrastructure systems specifically they underpin pavement- and asset-degradation forecasting and, increasingly, climate-adjusted infrastructure resilience modelling (Papoulis & Pillai, 2018; Shehadeh, Alshboul, & Tamimi, 2024). Their application to the socio-economic and environmental dimensions of infrastructure sustainability, however, remains comparatively underdeveloped, particularly within data-constrained, high-volatility regional contexts such as Nigeria's Niger Delta.

The Niger Delta presents an unusually demanding proving ground for this kind of modelling. Infrastructure projects in the region are exposed to recurring flooding, community opposition rooted in decades of extractive-industry grievance, funding volatility, and institutional fragmentation. Where prior regional studies have applied Markovian methods, they have generally done so to narrowly bounded, single-domain phenomena, oil-spill volumes (Mba, Mba, Arazu, Urama, Machebe, & Eze, 2019) or discrete industrial-safety incident categories (Omoyi & Omotehinse, 2022), rather than to the multidimensional risk profile that construction and infrastructure projects actually present. Internationally, Markov-based studies of construction and infrastructure risk have tended to concentrate on cost, schedule, or asset-condition variance (Zhang, Li, & Yang, 2021), leaving the socio-economic and environmental dimensions that define sustainability performance comparatively unmodelled.

This paper addresses that gap directly, and, following a pre-submission statistical audit, does so with explicit attention to what the underlying statistics can and cannot support. It develops and validates a three-state, Bayesian-calibrated Markov Chain Model of sustainability risk evolution for eight Federal Government infrastructure projects across four Niger Delta states. The contribution addresses ICESID 2026's Sustainable Engineering Processes and Systems sub-theme directly, and is also relevant to Strategies for Infrastructural and Industrial Transformation, since dynamic risk forecasting is a precondition for the phased, evidence-sequenced governance those strategies require. Specifically, the paper aims to: (i) formalise a three-state risk classification for socio-economic and environmental sustainability risk that can be populated from routinely observable project indicators; (ii) estimate project-specific and portfolio-level transition probability matrices through Bayesian synthesis, with explicit treatment of the row-stochasticity constraint that a transition matrix must satisfy; (iii) generate multi-step forecasts and steady-state distributions that characterise the long-run risk trajectory of each project, distinguishing clearly between illustrative and empirically observed initial conditions; and (iv) evaluate the statistical validity of the resulting forecasts in a manner that does not conflate classification accuracy with probabilistic calibration. The contribution is deliberately narrow and mathematically precise: rather than proposing a general sustainability framework, the paper isolates the stochastic mechanics of risk evolution, reports what the data actually show, and is explicit about where the evidence is provisional. This paper is a condensed, conference-length derivative of a broader doctoral research programme (Adie, 2026), presenting the Markov-modelling component as a self-contained contribution; the full thesis additionally develops the AI-classification and technology-adoption strands reported in companion papers.

2. LITERATURE REVIEW

2.1 Sustainability Risk in Infrastructure: The Static-Assessment Problem

Infrastructure resilience scholarship has converged on the observation that measurement frameworks for risk and resilience remain fragmented and predominantly cross-sectional. A systematic review of critical-infrastructure resilience measurement frameworks found wide disparities among existing approaches, identifying the prioritisation of resilience-based investment as a persistent challenge precisely because most frameworks describe a system's condition rather than its trajectory (Sathurshan, Saja, Thamboo, Haraguchi, & Navaratnam, 2022). This is the static-assessment problem motivating the present study: a risk register can report where a project stands today, but not, by construction, where it is heading or how quickly.

Sustainable Risk Management (SRM) extends conventional Enterprise Risk Management by embedding environmental, social, and governance considerations, rather than financial exposure alone, into the assessment of organisational and project risk (Aziz, Manab, & Othman, 2016). Its theoretical anchor is Elkington's (1997) Triple Bottom Line, which treats economic, social, and environmental

performance as jointly determinative of long-term viability rather than as competing objectives to be traded off. Freeman's (1984) Stakeholder Theory supplies a complementary rationale for why socio-economic risk factors, community opposition, labour relations, and regulatory friction, belong inside the same analytical frame as environmental hazards: both categories of risk arise from the same underlying network of interests that a project must manage simultaneously.

2.2 Dynamic and Stochastic Risk Modelling

A Markov Chain is a stochastic process in which the probability of transitioning to a future state depends exclusively on the present state and not on the sequence of states that preceded it, a property formally described as memorylessness (Norris, 1997). For a discrete-time process $\{X_t\}$, this is written as $P(X_{t+1} = s_j \mid X_t = s_i, X_{t-1} = s_k, \ldots, X_0 = s_0) = P(X_{t+1} = s_j \mid X_t = s_i)$. The process is fully characterised by a transition matrix P, whose element P_{ij} gives the one-step probability of moving from state i to state j. Because each row of P must sum to unity, the matrix satisfies the basic axioms of probability while remaining computationally tractable even for systems with many discrete states (Kemeny & Snell, 1976).

The long-run behaviour of such a system is governed by properties including irreducibility, periodicity, and ergodicity. For an ergodic chain, repeated application of the transition matrix, $x_n = x_0P^n$, converges to a unique steady-state distribution π that satisfies the balance equation $\pi P = \pi$, independent of the initial state vector. Recent multi-state reliability scholarship formalises this convergence property for resilience assessment, showing Markov-process representations allow degradation, disruption and recovery to be modelled as one coherent stochastic structure rather than separate deterministic stages (Tan, Wu, & Che, 2023). This convergence property is what allows a Markov Chain to be used not merely descriptively but predictively: a system observed only briefly can, given a credible transition matrix, be projected toward its long-run equilibrium.

2.3 Markov Chains in Infrastructure Systems

Within infrastructure engineering specifically, Markov-based transition modelling has a substantial and growing track record, though the majority of applications concern physical asset condition rather than socio-economic or environmental risk. Pavement- and highway-asset management has used Markov transition matrices for condition-state forecasting for decades, and recent work extends this to incorporate climate-change effects directly into transition probabilities. Shehadeh, Alshboul, and Tamimi (2024), for example, developed an advanced Markovian framework that integrates a multi-tiered exponential erosion-risk model with climate projections to forecast highway-infrastructure degradation, finding acceleration of 15 to 20 percent in degradation rates under projected climate scenarios. This work is instructive for the present study in two respects: it confirms that Markov transition structures can be meaningfully extended to incorporate environmental and climate-related drivers rather than purely mechanical deterioration, and it illustrates the now-standard practice of pairing a Markovian core with an explicit, separately validated risk driver rather than treating the chain as a self-contained black box.

What this branch of the literature does not yet do is extend the same transition-matrix architecture to the socio-economic and environmental sustainability dimensions of infrastructure delivery, jointly, at the project level rather than the physical-asset level; that extension is what the present study attempts.

2.4 Bayesian Calibration of Transition Probabilities

A recurring practical difficulty in applying Markov Chains to infrastructure settings is that reliable historical transition data are rarely abundant, particularly in developing-region contexts. Bayesian calibration addresses this by combining expert-elicited priors with whatever empirical transition frequencies are available, updating the prior through a conjugate likelihood to produce a posterior estimate more precise than either source alone (Koller & Friedman, 2009). The conventional implementation treats each transition probability P_{ij} independently under a Beta-Binomial conjugate model; Section 3.4 discusses this choice, its row-stochasticity limitation, and the preferred joint alternative in full.

2.5 Empirical Applications: Global, Regional, and Local Evidence

Empirical applications of Markov Chains to project and infrastructure risk have tended to remain single-dimensional. Studies in the highway-project literature have modelled risk states across planning, engineering, and construction phases primarily to support cost and schedule management, while safety-focused applications have coupled transition structure with accident-causation theory to model construction safety-risk trajectories (Zhang, Li, & Yang, 2021). In each case, the analytical boundary remains a single risk dimension, cost, schedule, or safety, rather than the integrated socio-economic and environmental risk space that sustainability assessment requires.

Within the Niger Delta itself, Markov applications have so far been confined to narrowly bounded ecological or safety phenomena. Mba, Mba, Arazu, Urama, Machebe, and Eze (2019) used a two-state Markov Chain to model oil-spill persistence in the region, finding predicted steady-state probabilities that favoured the high-volume spill state, which implied a structural tendency toward environmental deterioration in the absence of intervention. In the industrial-safety domain, Omoyi and Omotehinse (2022) applied a factorial and statistical analysis to health, safety, and environment records in the region's industrial sector to identify the hazard variables most strongly associated with accident outcomes. Beyond stochastic methods specifically, Nigerian infrastructure-sustainability research has begun developing dedicated predictive frameworks, exemplified by Adeoti, Kandasamy, and Vigneswaran's (2024) Predictive Iterative Sustainability Model for water infrastructure, combining viability and sustainability ratings in an iterative, Nigeria-tailored planning-stage evaluation. These studies establish that stochastic and probabilistic methods are analytically viable in the region and, notably, that the oil-spill study in particular surfaces an escalation-dominant dynamic within its isolated risk domain. What they do not do is extend this logic to the multidimensional, ill-defined risk states that construction-project sustainability performance actually comprises, nor do they benchmark a Markov Chain against competing probabilistic paradigms.

2.6 Synthesis and Research Gap

Three convergent gaps emerge from this review. First, Markov Chain applications and sustainability theory have developed along largely parallel tracks: the stochastic modelling literature is mathematically mature but rarely incorporates socio-economic and environmental sustainability constructs directly into its state definitions, while the SRM literature articulates the dynamic, evolving nature of sustainability risk conceptually without operationalizing it stochastically. Second, regional empirical work in the Niger Delta has so far applied Markovian methods only to single, well-bounded phenomena rather than to the integrated risk profile of an infrastructure project, leaving open the question of whether the escalation-dominant dynamics observed in isolated oil-spill and safety-incident data generalize to the broader construction-risk environment. Third, where Markov Chains have been applied to construction or infrastructure risk, comparative benchmarking against alternative probabilistic techniques is rare, and, as this paper's own statistical audit illustrates in Section 4.7, even where such benchmarking is attempted the underlying inferential statistics require careful, independently reproducible verification before they can support a claim of comparative superiority. The present study is positioned at the intersection of the first two gaps, and treats the third as a methodological caution to be handled transparently rather than as a claim to be asserted.

3. MATERIALS AND METHODS

3.1 Study Context and Case Selection

The study was conducted across four Niger Delta states, Edo, Delta, Rivers, and Bayelsa, and examined eight Federal Government infrastructure projects purposively selected to span road and institutional infrastructure and to reflect the diversity of risk profile and geographical spread characteristic of the region. The road infrastructure cases comprised the Benin-Lokoja Road, the East-West Road (Warri-Oron corridor), the Warri-Patani Road, and the Yenagoa-Oporoma Road; the institutional infrastructure cases comprised the Benin-Auchi dualisation, the University of Port Harcourt Teaching Hospital Complex, the Asaba International Airport Expansion, and the Federal Medical Centre, Yenagoa.

A structured 31-item questionnaire was administered to a stratified sample of project stakeholders, engineers, government and regulatory officers, project managers, and community or environmental representatives, drawn from a Cochran-derived target of 442 respondents (Cochran, 1977). Data collection achieved 350 valid responses (79.2 percent of target), with the shortfall concentrated among community representatives in locations where access and security conditions were most constrained. Survey data were supplemented with archival project records and a Modified Delphi expert elicitation exercise (n = 23 subject-matter experts, three rounds).

3.2 Data Sources and Datasets
