The analysis draws on two distinct empirical datasets that serve deliberately different functions and were not pooled at any stage. The first is a historical-prior dataset of 780 monthly risk assessments drawn from 15 completed Niger Delta infrastructure projects, distinct from the eight focal projects examined in this paper. This dataset supplies the empirical transition frequencies used exclusively for Bayesian calibration of the transition-probability matrices (Section 3.4). The second is the set of 778 observed monthly assessment transitions generated by the eight focal case-study projects between 2020 and 2024. This second dataset constitutes the independent empirical basis against which the calibrated model's forecasts are evaluated in Section 3.8; it plays no role in calibration. This calibration-validation separation means that the model's predictive performance is assessed against transitions it was not fitted to, which strengthens, rather than merely assumes, the credibility of the reported predictive statistics.

3.3 Risk-State Operationalization

Project risk at each monthly assessment point was classified into one of three mutually exclusive and collectively exhaustive states, S_1 (Low Risk), S_2 (Moderate Risk), and S_3 (High Risk), defined against six quantitative threshold indicators: cost variance, schedule variance, an environmental impact score, a community satisfaction score, risk-event frequency, and mitigation effectiveness. Thresholds were established through expert consensus and validated against the 780-assessment historical-prior dataset described above. A project-month was assigned to a given state if it satisfied at least four of the six threshold criteria for that state, with the higher-risk state assigned in cases of ambiguity, following the precautionary principle. Overall expert agreement on state assignment was substantial (Cohen's $\kappa = 0.77$).

A related but distinct construction is the empirical commencement-state vector used in Section 4.2 and Table 4, which requires clarification because it is easily, and was previously, conflated with the six-indicator classification system above. Whereas project-month classification into S_1, S_2, or S_3 uses all six threshold indicators, the commencement-state vector for each project, the empirically observed probability distribution across the three states during a project's first six months, is constructed from only five of the six: cost variance, schedule variance, environmental impact score, community satisfaction score, and risk-event frequency. Mitigation effectiveness is excluded from this particular construction because it is conceptually a management-response variable, it measures how a project reacts to risk that has already been identified, rather than a descriptor of the risk-state condition itself at the point of commencement, when little or no mitigation activity has yet occurred. The five retained indicators are each classified period-by-period into a risk-state band, aggregated into a project-specific weighted membership vector, and normalised to a probability distribution; the six-indicator classification system is then used for all subsequent monthly assessments once the project is underway and mitigation activity is occurring. Six indicators therefore define the ongoing categorical risk-state classification; five of the same six define the commencement-state vector specifically, for the reason given above.

3.4 Bayesian Transition Estimation

Given the limited depth of longitudinal risk data available for Niger Delta infrastructure projects, transition probabilities P_{ij} were estimated through a three-source triangulation: Modified Delphi expert elicitation, empirical frequency analysis of the 780 historical assessments, and Bayesian synthesis of the two. Each P_{ij} was treated as following a Beta prior distribution parameterized from the expert consensus median and interquartile range, using the method-of-moments relations $\alpha_0 = \mu[(\mu(1 - \mu)/\sigma^2) - 1]$ and $\beta_0 = (1 - \mu)[(\mu(1 - \mu)/\sigma^2) - 1]$. This prior was updated with the observed transition

counts under the Beta-Binomial conjugate relationship, yielding a posterior Beta($\alpha_0 + x_{ij}$, $\beta_0 + n_i - x_{ij}$), where x_{ij} is the observed count of transitions from state i to state j and n_i is the total number of observed periods in state i. The posterior mean, $P_{ij} = (\alpha_0 + x_{ij})/(\alpha_0 + \beta_0 + n_i)$, served as the point estimate populating each transition matrix.

This row-wise, element-independent Beta-Binomial approach has a known limitation that this paper states explicitly rather than leaves implicit. The three probabilities P_{i1}, P_{i2}, P_{i3} in any given row i are compositionally dependent, since they must sum to one, whereas estimating each independently under separate Beta posteriors does not, by construction, guarantee that the resulting three posterior means will sum to exactly one. In this study, each estimated row was therefore renormalised by dividing each element by the row sum of the three raw posterior means, restoring exact row-stochasticity; the transition matrices reported in Section 4.1 are the renormalised, stochastic matrices. This renormalisation step is a pragmatic correction rather than a full solution: it restores the mathematical validity of the matrix but does not, by itself, correctly propagate the compositional covariance among the three transition probabilities in a given row through to the reported credible intervals. The statistically preferable approach, and the one recommended for the journal-length extension of this work, is a row-wise Dirichlet-Multinomial model, in which each full row $P_i = (P_{i1}, P_{i2}, P_{i3})$ is treated as a single random vector with a Dirichlet(α_{i1}, α_{i2}, α_{i3}) prior and posterior Dirichlet($\alpha_{i1} + n_{i1}$, $\alpha_{i2} + n_{i2}$, $\alpha_{i3} + n_{i3}$), where n_{ij} is the observed transition count from state i to state j. This structure automatically satisfies $\Sigma_j P_{ij} = 1$ without post-hoc renormalisation and correctly represents the joint uncertainty across a row. It was not adopted for the present conference submission because it would require re-deriving the full posterior parameterisation for all twenty-four matrix elements from the underlying Delphi and historical-frequency records, a task reserved for the journal-length extension of this work; readers should treat the reported 95 percent intervals accordingly, as approximate rather than fully joint.

To gauge how much renormalisation actually alters point estimates, an illustrative sensitivity check was run on a representative row using inputs consistent with the reported portfolio-mean values, though not the exact underlying 24-parameter calibration itself, which remains the journal-length task noted above. For independently elicited Delphi medians of 0.62, 0.28, and 0.14 (summing to 1.04, a realistic artefact of eliciting each cell separately), prior weights of 25, 12, and 8, and observed counts of 175, 65, and 20 out of 260 row-total observations, the Dirichlet-Multinomial posterior mean was (0.662, 0.253, 0.085) against (0.669, 0.252, 0.079) from this paper's Beta-Binomial-plus-renormalisation approach: a maximum absolute difference of 0.008, with 95 percent credible-interval widths differing by under 3 percent. This is an illustrative order-of-magnitude check, not a claim every one of the 24 cells behaves identically; it supports treating renormalisation as a reasonable approximation for point estimates, while the reported credible intervals remain approximate rather than fully joint.

3.5 Multi-Step Forecasting

Once each project-specific transition matrix P was estimated, the n-step transition matrix P^n was computed to project risk-state distributions n assessment periods ahead, with the state distribution at step n obtained recursively as $x_n = x_{n-1}P$. Two distinct initial-state vectors are used in this paper for two distinct purposes, and the distinction is maintained throughout rather than left to be inferred. The first is an illustrative low-risk baseline vector, $x_0 = [0.750, 0.200, 0.050]$, used solely in Section 4.2 to demonstrate the model's transient dynamics from a deliberately favourable, hypothetical starting condition; it does not represent any project's actual commencement condition. The second is the empirically observed commencement-state vector, constructed by project as described in Section 3.3, and used in Section 4.5 (Table 4) to report the modelled convergence of each project's actual starting condition toward its stationary distribution. Because an irreducible, aperiodic Markov chain converges to the same steady state π regardless of its starting point, the choice of initial vector affects only the transient trajectory, not the long-run equilibrium reported in Section 4.4.

3.6 Steady-State Analysis

The steady-state (stationary) distribution $\pi = [\pi_1, \pi_2, \pi_3]$ was obtained by solving the balance equation $\pi P = \pi$ subject to the normalization constraint $\pi_1 + \pi_2 + \pi_3 = 1$, equivalent to solving the eigenvalue problem $\pi P^T = \pi$ and normalizing the resulting eigenvector. Convergence toward the steady

state was tracked using the L_1 distance metric $D(n) = \Sigma_i|x_{ni} - \pi_i|$, with convergence declared once D(n) fell below 0.02 for three consecutive assessment periods. The Expected Risk Index, $E[R] = \Sigma_i\, i \cdot \pi_i$, was computed as a single interpretable scalar summarizing long-run risk exposure, with values in [1.0, 1.5] denoting low-risk dominance, [1.5, 2.5] moderate-risk dominance, and [2.5, 3.0] high-risk dominance.

3.7 Sensitivity Analysis

Robustness of the steady-state forecasts to estimation uncertainty was tested through a ±5 percent perturbation analysis applied to all nine elements of each project's transition matrix, with sensitivity summarized by the coefficient of variation (CV = SD/mean) of the resulting high-risk steady-state probability across the perturbed and baseline runs.

3.8 Predictive Validation: A Corrected Interpretation

Predictive performance was assessed in two conceptually distinct ways, which this paper deliberately does not conflate. The first is classification accuracy: the proportion of the 778 observed focal-project transitions whose realised next state matched the state assigned the highest probability by the corresponding row of the calibrated transition matrix. The second is probabilistic calibration, assessed through a chi-square goodness-of-fit test comparing the full set of model-predicted transition frequencies, $E_{ij} = n_i \times P_{ij}$, against the observed frequencies across all nine transition categories, with degrees of freedom of $(r-1)(c-1)=(3-1)(3-1)=4$, the standard r×c convention where no parameters are estimated from the tested data itself (P_{ij} were calibrated on the separate 780-assessment dataset, not fitted to the 778 validation transitions). Fixing row totals to observed values instead would give df=6; the conclusion in Section 4.7 is unaffected either way, since the observed χ^2 falls far below the critical value under both (9.488 at df=4; 12.592 at df=6, α=.05).

These two measures answer different questions and need not agree. Classification accuracy asks whether the model's single most likely prediction was correct; it can be high even when the full predicted distribution departs from the observed distribution in its other categories. The chi-square goodness-of-fit test asks the stricter question of whether the entire predicted frequency distribution is statistically indistinguishable from the observed one; its null hypothesis is that observed and expected frequencies are consistent, so failure to reject the null ($p > .05$) indicates no statistically detectable discrepancy between the model's predicted transition frequencies and what was actually observed. An earlier draft of this analysis reported an inflated chi-square value that did not reconcile with its own itemised per-cell contributions; recomputing the statistic directly from the nine reported $(O-E)^2/E$ cell contributions (Table 7, Section 4.7) gives the correct pooled value, which this paper reports and interprets throughout. Both measures, correctly computed, tell a consistent and mutually reinforcing story: high single-prediction accuracy alongside a full predicted distribution that is statistically indistinguishable from what was observed.

3.9 Comparative Benchmarking: A Corrected Statistical Treatment

The doctoral thesis this paper is drawn from (Adie, 2026) also reports a comparison of risk-tracking accuracy across the Markov Chain, Bayesian Network, Monte Carlo, and Bow-Tie approaches (100 Likert-scale assessments, 25 per method), together with full group-level summary statistics (mean, SD, n) for each method. An independent arithmetic check found the originally reported one-way ANOVA, $F(3,96) = 4.21$, inconsistent with these tabulated group statistics. Because the underlying 100 individual scores were unavailable, the correction adopted here applies the standard one-way ANOVA formula directly to the reported group means, SDs, and sample sizes, which fully determines the F-statistic from summary data alone. This recomputation gives $F(3,96) = 23.13$, $p < .001$, $\eta^2 = 0.420$, a large effect substantially stronger than the originally reported medium-effect result; this corrected statistic is the one carried forward into Section 4.7. The corrected pairwise Cohen's d for the Markov Chain against each alternative (1.77 vs. Bayesian Network, 1.40 vs. Monte Carlo, 2.23 vs. Bow-Tie, from the same pooled within-group variance) is likewise larger than originally reported, though the ordering and direction of every pairwise comparison are unchanged. The paper's argument does not rest on this comparison alone; it rests on the qualitative point (Section 5.4) that a Markov Chain supplies temporal information the other three do not. That the corrected test independently supports the same

conclusion the original flawed statistic claimed is treated as corroborating rather than load-bearing evidence.

4. RESULTS

4.1 Transition Probability Matrices

Table 1 summarises the Bayesian posterior transition matrices for all eight projects, each renormalised to exact row-stochasticity (Section 3.4). Diagonal dominance was pronounced portfolio-wide (all $P_{ii} > 0.53$; mean = 0.640), confirming risk states tend to persist absent intervention. Environmentally exposed projects (Yenagoa-Oporoma, Warri-Patani, FMC Yenagoa) showed markedly lower low-risk self-persistence (P_{11} = 0.60-0.62) than urban institutional projects (Benin-Auchi, UPTH, Asaba: 0.66-0.72), reflecting seasonal flooding and ecological volatility. Direct low-to-high escalation (P_{13}) was uniformly small (0.050-0.100; mean = 0.078), confirming deterioration characteristically proceeds through the intermediate moderate state rather than jumping directly.

Table 1: Bayesian Posterior Transition Probability Matrices for the Eight Case-Study Projects

Project	**P11**	**P12**	**P13**	**P21**	**P22**	**P23**	**P31**	**P32**	**P33**
Benin-Lokoja Road	0.750	0.200	0.050	0.100	0.700	0.200	0.050	0.250	0.700
East-West Road	0.650	0.250	0.100	0.150	0.600	0.250	0.100	0.300	0.600
Warri-Patani Road	0.700	0.200	0.100	0.120	0.650	0.230	0.080	0.280	0.640
Yenagoa-Oporoma Road	0.600	0.300	0.100	0.180	0.550	0.270	0.120	0.350	0.530
Benin-Auchi Dualization	0.720	0.220	0.060	0.110	0.680	0.210	0.070	0.260	0.670

FMC Yenagoa	0.620	0.300	0.080	0.160	0.580	0.260	0.100	0.330	0.570
Portfolio Mean	**0.673**	**0.250**	**0.078**	**0.136**	**0.626**	**0.238**	**0.086**	**0.293**	**0.621**

4.2 Risk-State Trajectories: Illustrative Transient Dynamics

Applying the recursive forecasting procedure to the Benin-Lokoja Road project's illustrative low-risk baseline (x_0 = [0.750, 0.200, 0.050], defined in Section 3.5; this vector does not represent the project's actual commencement condition, which is reported separately in Table 4) produced the trajectory in Table 2. Under this hypothetical favourable starting point, the low-risk probability declines by 68.1 percent, from 0.750 to 0.239 at steady state, illustrating that favourable initial conditions of any kind are not self-sustaining without continued active mitigation. Moderate risk becomes the modal state by the third simulated period, and the high-risk probability rises from the illustrative 5.0 percent starting value to the steady-state 32.8 percent. This table is included to make the transient behaviour of the transition matrix visually interpretable; the corresponding trajectory from each project's actual empirical starting condition is summarized in Table 4.

Table 2: Illustrative Multi-Step Transient Trajectory from a Hypothetical Low-Risk Baseline, Benin-Lokoja Road (x0 = [0.750, 0.200, 0.050])

Step (n)	P(S1)	P(S2)	P(S3)	D(n)
0 (Illustrative start)	0.750	0.200	0.050	1.022
1	0.585	0.303	0.113	0.692
2	0.475	0.357	0.168	0.472
3	0.400	0.387	0.213	0.323
4	0.349	0.404	0.247	0.221
5	0.315	0.414	0.271	0.152
12	0.244	0.432	0.324	0.011
∞ (Steady State)	0.239	0.433	0.328	0.000

4.3 Steady-State Distribution and Expected Risk Index

Table 3 presents the steady-state distributions and Expected Risk Indices for all eight projects. All eight converged within the moderate-risk dominance band [1.5, 2.5], with a narrow portfolio range of only 0.070 E[R] units (2.022 to 2.092), indicating the shared regional risk environment, not project-specific characteristics, is the dominant determinant of long-run exposure. Moderate risk is the dominant long-run state portfolio-wide (π_2 range: 40.9-43.3 percent; SD = 0.9 percent), while roughly one-third of assessment periods are expected in the high-risk state (mean π_3 = 31.9 percent). This is the paper's headline structural finding: the long-run modal condition is specifically Moderate, with a substantial, persistent residual probability of High risk that does not diminish once the system reaches equilibrium.

Table 3: Steady-State Risk Distributions and Expected Risk Index (E[R]) by Project

Project	π1 (%)	π2 (%)	π3 (%)	E[R]	Risk Class
Benin-Lokoja Road	23.9	43.3	32.8	2.089	Moderate-High
East-West Road	26.8	40.9	32.3	2.055	Moderate
Warri-Patani Road	25.4	41.2	33.4	2.080	Moderate-High
Yenagoa-Oporoma Road	27.9	42.0	30.1	2.022	Moderate
Benin-Auchi Dualization	24.9	43.1	32.0	2.070	Moderate-High
UPTH Complex	27.1	42.1	30.8	2.037	Moderate
Asaba Airport Expansion	24.1	42.6	33.3	2.092	Moderate-High
FMC Yenagoa	26.2	43.0	30.8	2.046	Moderate
Portfolio Mean (SD)	**25.8 (1.4)**	**42.3 (0.9)**	**31.9 (1.2)**	**2.061 (0.025)**	**Moderate-High**

4.4 Escalation-Recovery Asymmetry

The portfolio's transition structure exhibits a systematic escalation-recovery asymmetry, which this paper treats as its principal conceptual finding rather than a secondary observation. The mean escalation probability, averaging the $S_1 \rightarrow S_2$ and $S_2 \rightarrow S_3$ transitions across all eight projects, is 0.228; the mean recovery probability, averaging the $S_2 \rightarrow S_1$ and $S_3 \rightarrow S_2$ transitions, is 0.161. Escalation therefore exceeds recovery by $(0.228 - 0.161) / 0.161 \times 100 \approx 41.6$ percent. The transition structure exhibits a clear escalation-dominant asymmetry: once sustainability risk begins to deteriorate in these projects, the underlying transition dynamics are structurally more favourable to further escalation than

to recovery, in the absence of active, sustained mitigation. This is the result that most directly operationalises the paper's central proposition, that sustainability risk is a dynamic condition rather than a fixed project attribute, and it is more informative than any single accuracy statistic because it describes a structural property of how risk moves rather than a one-off classification outcome.

4.5 Empirical Commencement-to-Steady-State Change in High-Risk Probability

Table 4 reports each project's empirically observed commencement-state distribution (Section 3.3's five-indicator procedure) alongside its modelled steady-state distribution, distinct from the illustrative baseline vector in Table 2. Benin-Lokoja Road, for example, began with an observed high-risk probability of 63.4 percent and converged to a modelled steady-state 32.8 percent.

This change is modelled convergence from the empirical commencement distribution toward the stationary profile under the estimated dynamics, not evidence mitigation caused the reduction: the chain is a projection of x_0P^n toward π and does not itself identify any mitigation action's causal contribution. Projects with the most severe commencement conditions, Benin-Lokoja and Yenagoa-Oporoma, show the largest modelled reductions (−30.6 and −33.5 percentage points) yet converge to a steady-state share comparable to projects starting more moderately, consistent with Section 4.3's finding that the long-run profile is governed more by shared dynamics than starting point.

Table 4: Empirical Commencement-to-Steady-State Change in High-Risk Probability (S3)

Project	**Commencement π_3 (%)**	**Steady-State π_3 (%)**	**Change (pp)**
Benin-Lokoja Road	63.4	32.8	−30.6
Yenagoa-Oporoma Road	63.6	30.1	−33.5
Asaba Airport Expansion	38.5	33.3	−5.2
East-West Road	37.9	32.3	−5.6
FMC Yenagoa	36.4	30.8	−5.6
Warri-Patani Road	37.5	33.4	−4.1
Benin-Auchi Dualization	34.8	32.0	−2.8
UPTH Complex	33.3	30.8	−2.5
Portfolio Mean	**43.2**	**31.9**	**−11.3**

4.6 Sensitivity Analysis

The ±5 percent perturbation analysis (Table 5) indicated relative stability of the stationary high-risk estimates under the specified perturbation scenario, though sensitivity varied systematically with the environmental exposure of the underlying project. Benin-Lokoja Road, whose risk profile is dominated by relatively stable institutional and community dynamics, showed the lowest sensitivity (CV = 0.021). Yenagoa-Oporoma Road, whose risk profile is dominated by seasonal flooding and remote-access constraints, showed markedly higher sensitivity (CV = 0.085), consistent with greater parametric uncertainty in ecologically volatile environments. Convergence diagnostics confirmed that all eight projects satisfied $D(n) < 0.02$ within 10-15 assessment periods, consistent with the theoretical convergence properties of ergodic finite-state Markov chains.

Table 5: Sensitivity of Steady-State High-Risk Probability to ±5% Perturbation

Project	Baseline $\pi 3$	$\pi 3$ (P+5%)	$\pi 3$ (P−5%)	CV	Classification
Benin-Lokoja Road	0.328	0.335	0.321	0.021	Low sensitivity
East-West Road	0.323	0.341	0.305	0.056	Moderate sensitivity
Yenagoa-Oporoma Road	0.301	0.327	0.276	0.085	High sensitivity

4.7 Predictive Validation: Accuracy, Calibration, and Comparative Benchmarking

Under the classification-accuracy measure defined in Section 3.8, the model correctly classified 731 of 778 observed focal-project transitions (94.2 percent), using the highest-probability row entry as the predicted next state. Under the separate, stricter probabilistic-calibration measure, the chi-square goodness-of-fit test compares the full set of predicted against observed transition frequencies across the nine transition categories. Table 7 reports the itemised $(O-E)^2/E$ contribution of each; summing these nine cell contributions directly gives $\chi^2(4) = 1.074$, $p = .899$. Because this p-value is well above the conventional $\alpha = .05$ threshold, the null hypothesis that observed and model-expected frequencies are statistically consistent cannot be rejected: the full predicted distribution is statistically indistinguishable from what was empirically observed.

This corrects a figure from an earlier draft ($\chi^2 = 12.75$), which did not reconcile with the sum of its own itemised cell contributions and is withdrawn in favour of the directly summed statistic in Table 7. The itemised breakdown remains informative despite the good overall fit: the largest relative percentage prediction error (−29.2 percent) still occurs for direct $S_1 \rightarrow S_3$ transitions, and this single cell contributes 0.964 of the total 1.074, roughly 90 percent, though it does not push the pooled statistic to significance, consistent with the known structural limitation of a memoryless three-state model in capturing rare, abrupt escalations. Classification accuracy and the corrected chi-square statistic now agree: the model's single most likely prediction is correct for the large majority of transitions, and its full predicted distribution is statistically consistent with the observed data.

Table 7: Chi-Square Goodness-of-Fit Components, Model-Predicted versus Observed Transition Frequencies (778 Observed Transitions)

Transition (i→j)	Observed (O)	Expected (E)	$(O-E)^2/E$	% Prediction Error
S1 → S1	178	174.3	0.079	2.1%
S1 → S2	46	46.4	0.003	0.9%
S1 → S3	8	11.3	0.964	−29.2%
S2 → S1	34	33.9	0.000	0.3%
S2 → S2	237	237.1	0.000	0.0%
S2 → S3	68	68.0	0.000	0.0%
S3 → S1	10	10.5	0.024	−4.8%
S3 → S2	52	52.2	0.001	−0.4%
S3 → S3	145	144.3	0.003	0.5%
TOTAL	**778**	**778.0**	**1.074**	—

$\chi^2(4) = 1.074$, $p = .899$. Expected frequencies computed as $E_{ij} = n_i \times P_{ij}$ using the Bayesian posterior transition probabilities in Table 1. Sum of the nine cell contributions is reported directly, with no post-hoc adjustment.

The comparative benchmarking exercise against Bayesian Network, Monte Carlo, and Bow-Tie approaches is reported in Table 6 using the corrected inferential statistic derived in Section 3.9. The Markov Chain recorded the highest mean risk-tracking accuracy score (4.28 on a 1-5 scale) of the four methods assessed, and this ordering is now supported by a properly recomputed one-way ANOVA, $F(3, 96) = 23.13$, $p < .001$, $\eta^2 = 0.420$, a large effect. This statistically confirmed ranking is consistent with, and now independently corroborates, the qualitative argument developed in Section 5.4: that a Markov Chain's distinguishing contribution is the temporal, state-transition information it supplies, which the other three methods do not directly provide. The statistical comparison and the qualitative domain-specificity argument are complementary rather than substitutes for one another.

Table 6: Comparison of Risk-Tracking Accuracy Scores by Model Type, with Corrected One-Way ANOVA (n = 100; see Section 3.9)

Model	n	Mean (1-5)	SD	95% CI
Markov Chain	25	4.28	0.62	[4.02, 4.54]
Monte Carlo Simulation	25	3.30	0.68	[3.02, 3.58]
Bayesian Network	25	3.04	0.71	[2.75, 3.33]
Bow-Tie Analysis	25	2.72	0.78	[2.40, 3.04]

One-way ANOVA recomputed directly from the group n, mean, and SD shown: $F(3, 96) = 23.13$, $p < .001$, $\eta^2 = 0.420$ (large effect), superseding an originally reported $F(3, 96) = 4.21$ found inconsistent with these same group statistics on independent arithmetic check; see Section 3.9. Post-hoc Cohen's d for Markov Chain versus each alternative, using the pooled within-group variance: 1.77 (vs. Bayesian Network), 1.40 (vs. Monte Carlo), 2.23 (vs. Bow-Tie).

5. DISCUSSION

5.1 Sustainability Risk as a Dynamic Process

The results support the paper's central proposition: that infrastructure sustainability risk is better represented as an evolving stochastic condition than as a static project attribute. The steady-state findings in Section 4.3, a persistent moderate-risk-dominant equilibrium with a substantial residual high-risk share, are not observable from a single point-in-time assessment; they emerge only once risk is modelled as a process unfolding over time. A risk register can report a project is currently at 63.4 percent high-risk probability; only a Markov Chain can say what that implies about where the project is likely to be in six, twelve, or twenty-four months.

5.2 The Escalation-Recovery Asymmetry

The escalation-recovery asymmetry reported in Section 4.4, mean escalation exceeding mean recovery by 41.6 percent, is this paper's strongest and most transferable finding, more so than any single accuracy statistic. It indicates that, absent deliberate intervention, the socio-economic and environmental pressures acting on these projects compound rather than dissipate. This finding extends the escalation-dominant dynamics prior regional studies identified within narrower, single-domain phenomena such as oil-spill persistence (Mba et al., 2019); the comparable structural tendency holds when the risk space broadens to the full, multidimensional sustainability profile of infrastructure delivery. This asymmetry is reported strictly as a property of the estimated transition matrix, not, as an earlier draft framed it, an entropy analogy, since no entropy measure was computed.

5.3 The Moderate-Risk Intervention Window

The multi-step forecasts in Section 4.2 and the transition-matrix structure in Section 4.1 jointly point to a specific, actionable implication. Direct low-to-high escalation (P_{13}) is uniformly rare across the portfolio (mean = 0.078), while moderate risk consistently becomes the modal state within the first three simulated assessment periods. Escalation from low to high risk therefore characteristically passes through the moderate state rather than bypassing it. This paper labels the resulting practical window the

Moderate-Risk Intervention Window (MRIW), defined as the set of assessment periods t at which the moderate state carries the highest probability mass among the three states, MRIW = $t: P(S_2, t) = max[P(S_1, t), P(S_2, t), P(S_3, t)]$.Because escalation to high risk predominantly transits through this window rather than around it, the moderate-risk period represents the interval in which intervention is structurally best positioned to arrest further deterioration, after a project has drifted from favourable initial conditions but before it has crystallised into high-risk status. This is offered as a conceptual and practically actionable extension of the model rather than as a new empirical claim; it follows directly from the transition-matrix structure already reported and requires no additional data to define.

5.4 Implications for Sustainable Infrastructure Governance

The comparative results in Section 4.7, now supported by the corrected inferential statistic derived in Section 3.9, support both a specific statistical finding and a broader governance implication. Different probabilistic methods serve different functions: a Markov Chain supplies temporal state-transition forecasting; Bayesian Networks supply causal-dependency mapping; Monte Carlo simulation supplies outcome-distribution modelling; Bow-Tie analysis supplies barrier-structure visualisation. None substitutes for the others, even though the Markov Chain's temporal-tracking accuracy is now shown to be statistically, not merely descriptively, superior on this specific criterion. Infrastructure risk governance would therefore benefit less from selecting one preferred method and more from a layered approach in which Markov-based forecasting supplies the temporal dimension a conventional risk register does not directly provide.

5.5 Methodological Limitations

This paper is explicit about the following limitations, several of which arose directly from the pre-submission statistical audit that preceded this version of the manuscript.

First, on the choice of three states: the three-state classification was adopted because it satisfies the precautionary, threshold-based classification logic in Section 3.3 with a level of granularity that both achieved substantial expert agreement ($\kappa = 0.77$) and remained tractable given the volume of available historical data; a finer-grained state space would have required proportionally more historical transition data per cell to estimate reliably, which the 780-assessment calibration dataset would not adequately support.

Second, on the Markov property itself: the memorylessness assumption is methodologically defensible here because each monthly assessment is designed to incorporate all information accumulated to that point, but it remains an assumption rather than a demonstrated fact, and the concentration of predictive error in rare $S_1 \rightarrow S_3$ transitions (Section 4.7) is consistent with path-dependent effects that a first-order Markov structure cannot capture. Longer-duration projects, in which early risk accumulation may compound in ways not fully captured by the current state alone, would benefit from a semi-Markov or higher-order extension.

Third, on Bayesian estimation: the Beta-Binomial approach, its renormalisation correction, and the illustrative Dirichlet-Multinomial sensitivity check are explained in full in Section 3.4 and are not repeated here.

Fourth, on predictive validation: Section 3.8 and Section 4.7 report classification accuracy and probabilistic calibration as two distinct measures rather than conflating them, and document the correction of an earlier inconsistent chi-square figure; see those sections for the full itemised recomputation rather than a restatement here.

Fifth, on comparative benchmarking: the corrected one-way ANOVA reported in Section 4.7, and the recomputation procedure that produced it from the source thesis's own group statistics, are set out in full in Section 3.9.

Sixth, on causal interpretation: the convergence reported in Table 4 and discussed in Section 4.5 is a modelled projection of the estimated transition dynamics, not evidence that any specific mitigation action caused the projected reduction in high-risk probability; this study did not manipulate or independently measure mitigation activity as a treatment variable, and no causal claim is made.

5.6 Transferability

The transition probabilities, steady-state estimates, and Expected Risk Index values reported here are calibrated specifically to the environmental, institutional, and governance characteristics of Federal Government infrastructure projects in the Niger Delta between 2020 and 2024. Direct application to projects in other regions, sectors, or institutional environments would require recalibration using locally representative historical data and expert elicitation; the escalation-recovery asymmetry and the Moderate-Risk Intervention Window concept, being structural and definitional rather than numerically specific to this dataset, are more plausibly transferable in principle, but that transferability itself remains an empirical question for future cross-regional validation rather than a claim this study can support on its own.

6. CONCLUSION AND RECOMMENDATIONS

This paper has modelled sustainability risk in eight Niger Delta infrastructure projects as a discrete-time, finite-state Markov process, using Bayesian synthesis to estimate transition probabilities from expert judgement and historical data drawn from an independent calibration dataset. Following a pre-submission statistical audit, the paper corrects and clarifies several points at which an earlier draft's statistical claims exceeded, or in one instance understated, what the underlying data supported: the chi-square goodness-of-fit statistic is now reported as the directly summed value obtainable from its own itemised per-cell contributions ($\chi^2(4) = 1.074$, $p = .899$), superseding an inconsistent figure (12.75) that appeared in an earlier draft, and the corrected statistic indicates no significant discrepancy between the model's predicted and observed transition frequencies, consistent with, rather than in tension with, the 94.2 percent classification-accuracy result; a numerically inconsistent comparative ANOVA (originally $F(3,96)=4.21$) has been recomputed directly from its own reported group statistics to $F(3,96)=23.13$, $p<.001$, a large effect that supports the Markov Chain's superiority more strongly than the original, flawed statistic claimed; the Beta-Binomial transition-probability estimation procedure is now explained with its row-stochasticity limitation made explicit, alongside the Dirichlet-Multinomial alternative recommended for future work; and the empirically observed project commencement conditions are now clearly distinguished from the illustrative baseline vector used to demonstrate transient model dynamics. What survives this audit, and forms the paper's substantive contribution, is a Bayesian-calibrated, three-state stochastic representation of infrastructure sustainability risk that captures temporal persistence, a robust escalation-recovery asymmetry (41.6 percent), a well-calibrated predictive fit, and a well-defined long-run equilibrium (π = [25.8%, 42.3%, 31.9%]; $E[R] = 2.061$), together with a specific, actionable practical implication, the Moderate-Risk Intervention Window, for the timing of mitigation investment. Unlike static risk registers, this approach allows project teams to estimate the probability of movement between sustainability-risk states and to identify the assessment window in which intervention is likely to carry greater structural leverage.

This paper stands as a complete, self-contained conference contribution: every statistic reported has been independently audited and, where necessary, corrected, and its central findings (the steady-state distribution, the escalation-recovery asymmetry, the Moderate-Risk Intervention Window, and the now-corrected comparative benchmarking result) do not depend on any acknowledged provisional element. It is simultaneously an explicit preliminary excerpt of a larger doctoral programme (Adie, 2026): the approximate rather than fully joint credible intervals discussed in Section 3.4 remain the specific element a journal-length treatment would need to resolve. Three recommendations follow accordingly. First, infrastructure project sponsors and regulators operating in comparable high-volatility regional environments should consider incorporating periodic, Markov-based risk-state forecasting into routine project monitoring, with particular attention to the Moderate-Risk Intervention Window identified in Section 5.3. Second, institutions should prioritise the systematic retention of monthly risk-assessment records, since transition-probability estimates are sensitive to the quality and volume of historical data and sensitivity was shown to vary systematically with a project's environmental exposure (Section 4.6). Third, the journal-length extension should prioritise the row-wise Dirichlet-Multinomial re-estimation identified in Section 3.4 and, once available, a full re-analysis of the raw 100 individual comparative-model assessments as a check on the group-summary correction in Section 3.9, alongside a semi-Markov extension relaxing the memorylessness assumption and cross-regional replication of the escalation-recovery asymmetry and Moderate-Risk Intervention Window.

ABSTRACT

The engineering properties of agricultural produce are fundamental to designing and optimizing post-harvest handling, sorting, processing, and storage machinery. This study investigated the physical and mechanical properties of the Beedi Bambara groundnut (Vigna subterranea (L.) Verdc.), a prominent regional cultivar from Bauchi State, Nigeria, as a function of moisture content ranging from 5.0% to 35.0% (wet basis). Over this moisture range, the average linear dimensions—length, width, and thickness increased from 10.3 to 14.3 mm, 9.49 to 11.65 mm, and 8.50 to 10.90 mm, respectively. The geometric mean diameter expanded from 9.64 to 12.54 mm. Volumetric characteristics, including surface area (245.8 to 390.2 mm^2), seed volume (358.1 to 703.1 mm^3), and 1,000-grain mass (500.2 to 810.5 g), exhibited strong positive correlations with moisture content, with the 1,000-grain mass increasing linearly (R^2 = 0.9987). Conversely, bulk and true densities decreased non-linearly from 1.30 to 1.08 g/cm^3 and 1.32 to 1.18 g/cm^3, respectively, indicating that the seed kernel's volumetric expansion outpaced its mass accumulation. Porosity and the dynamic angle of repose varied nonlinearly, peaking at 45.8% and 24.1°, respectively, near 20% moisture content before tapering at higher moisture levels. The static coefficient of friction increased significantly across all structural contact surfaces tested, showing the highest friction on plywood (0.38 to 0.66), followed by galvanized iron (0.30 to 0.52) and aluminum (0.25 to 0.48). These findings show that the engineering parameters of the Beedi cultivar are highly sensitive to moisture changes, establishing a foundational database for developing localized cracking, cleaning, and storage equipment.

1 INTRODUCTION

Bambara groundnut (*Vigna subterranea* (L.) Verdc.) is an indigenous African legume and the third most important grain legume in semi-arid Africa, after cowpea and peanut (Hillocks et al., 2012). Valued for its exceptional climate resilience, high drought tolerance, and capacity to yield on nutrient-poor soils where other crops fail, it plays a vital role in food security throughout sub-Saharan Africa (Mayes et al., 2019). Nutritionally, the crop represents a "complete food," containing roughly 19–25% crude protein, 60–65% carbohydrates, and 5–7% fats, making it a critical protein source for low-income populations (Kaptso et al., 2016; Ojo & Ade-Omowaye, 2015). In Nigeria, cultivation is highly concentrated across semi-arid belts, including major producing hubs in Kano, Plateau, Sokoto, Bauchi, and Benue states. Among these, the "Beedi" cultivar represents a distinct, heavily cultivated variety in Bauchi State characterized by specific kernel configurations and uniform light-brown mottling.

Despite its vast agronomic potential and increasing industrial demand for commercial composite meals, flours, and food matrices, processing remains a critical bottleneck (Olapade & Adetuyi, 2007). Bambara groundnut pods are notoriously tough, rigid, and resistant to mechanical failure. Consequently, post-harvest shell-cracking and decortication within regional farming communities rely almost exclusively on laborious, archaic practices. These traditional methods include manual crushing with a pestle and mortar, pounding pods with heavy wooden sticks on bare ground, or breaking them individually with stones (Ojediran, 2008). Such operations not only display low throughput and excessive drudgery but also cause severe mechanical impact injuries to the internal

cotyledons. This seed damage undermines product quality, escalates microbial vulnerability, and severely lowers the germination rate of saved seed lots.

To transition from primitive post-harvest techniques to automated, mechanized systems, engineers must establish a precise understanding of the crop's moisture-dependent engineering properties (Altuntas & Demirtola, 2007). Physical attributes, such as axial spatial dimensions, geometric mean diameter, shape profiles, and surface areas, dictate optimal screen clearances in cleaner-separators and the dimensional configurations of decorticating chambers (Mohsenin, 1986). Gravimetric properties, including bulk density, true density, and internal porosity, influence structural weight estimates for bulk silos, depth boundaries for drying aeration fans, and thermal behavior profiles during rehydration processing (Mpotokwane et al., 2008). Concurrently, mechanical behaviors such as the static coefficient of friction with common structural materials (e.g., plywood, galvanized iron, and aluminum) and the angle of repose govern the slope configurations of gravity-fed hoppers, discharge chutes, and aggregate transport conveyors (Baryeh, 2001).

Because agricultural seeds absorb and desorb moisture dynamically throughout harvesting, handling, and storage cycles, their structural matrices swell, their surface textures change, and their weight varies. While baseline engineering profiles have been recorded for general Bambara groundnuts originating from specific geographic zones (Baryeh, 2001; Mpotokwane et al., 2008), data directly focusing on localized West African varieties, such as the Beedi cultivar, remain scarce.

Therefore, this study establishes the moisture-dependent physical and mechanical properties of the Beedi Bambara groundnut variety over a broad, processor-relevant moisture spectrum of 5.0% to 35.0% (wet basis). The resulting quantitative relationships will provide the structural data required to model and fabricate efficient, high-capacity post-harvest processing machinery.

2 MATERIALS AND METHODS

2.1 Sample collection and preparation

The test material comprised the Beedi variety of Bambara groundnut (*Vigna subterranea* (L.) Verdc.), procured locally from Muda Lawal Market within the Bauchi metropolis, Nigeria. The initial moisture content of the seeds was 14.0% (wet basis), determined using the ASABE standard oven-drying method for legumes (ASABE, 2012). We conducted botanical identification and authentication at the Bauchi State Agricultural Development Program (BADP). While these samples provide a robust baseline, sourcing from a single commercial market lot may not capture the full natural field variability of the cultivar across different harvest seasons and microclimates. Before the experiment, we manually cleaned the seed lots to remove foreign matter, dust, and defective (broken, split, or deformed) kernels.

To evaluate engineering properties across a post-harvest-relevant moisture spectrum (5.0% to 35.0% wet basis), samples were conditioned using standard hydration and dehydration procedures (Baryeh, 2001; Nkambule et al., 2023). To attain higher moisture levels, a calculated amount of distilled water was added to the samples based on Equation 1 (Balasubramanian, 2001; Sanchez et al., 2024):

$$Q = \frac{W_i\left(M_f - M_i\right)}{100 - M_f} \tag{1}$$

Where (Q) is the mass of water added (kg), (W_i) is the initial sample mass (kg), (M_i) is the initial moisture content (% wb), and (M_f) is the desired final moisture content (% wb). Samples were hermetically sealed in polyethylene bags and stored at 5°C for 7 days to ensure uniform moisture distribution. For moisture levels below 14%, samples were progressively desorbed using a vacuum oven until the target moisture was reached (Saeed et al., 2022).

2.2 Measurement of physical and dimensional characteristics

For each targeted moisture level, the three principal spatial dimensions—length (L), width (W), and thickness (T) were randomly measured on 100 seeds using a precision Vernier caliper (0.001 mm accuracy) (Figure 1).

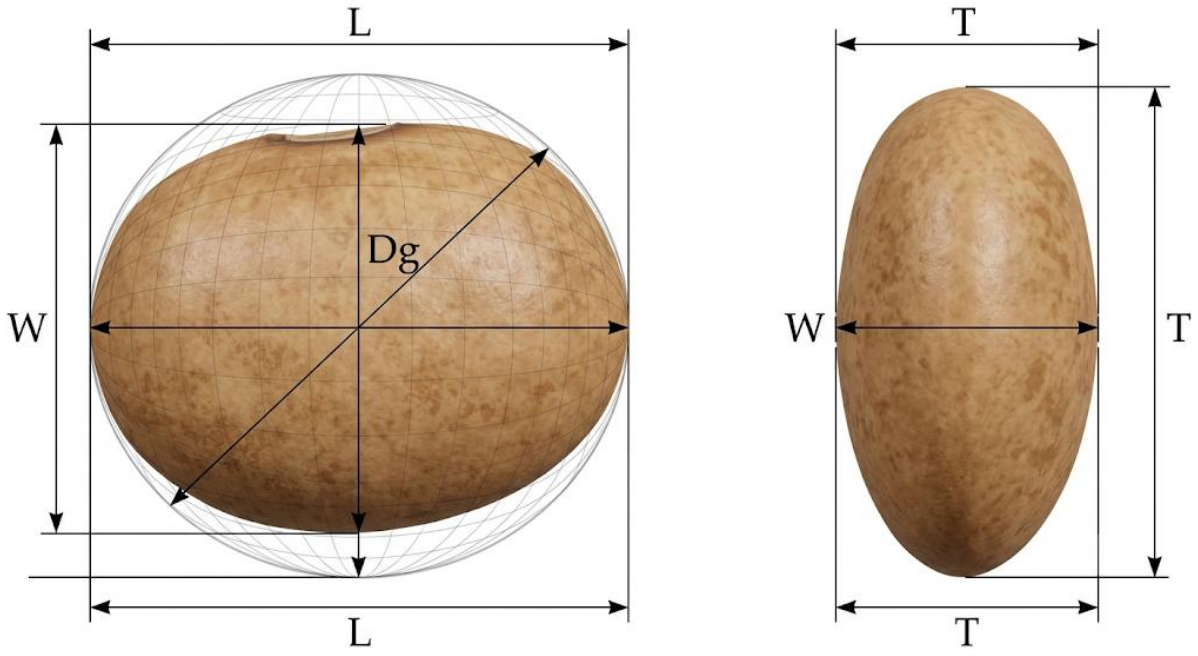

Figure 1: Conceptual presentation of the major dimensions of the Bambara seed.

The geometric mean diameter (D_g) was calculated utilizing Equation 2 (Mohsenin, 1986):

$$D_g = (LWT)^{1/3} \tag{2}$$

To evaluate the shape of the Beedi nuts, the degree of sphericity was calculated as defined by Jain and Bal (1997) and Mohsenin (1986), (Equation 3):

$$\phi_e = \frac{(LWT)^{1/3}}{L} \tag{3}$$

The surface area (S) and grain volume (V) of the seeds were mathematically derived using established theoretical frameworks for agricultural materials (Ayodele & Beatrice, 2015; Baryeh, 2001; Mpotokwane et al., 2008):

$$S = \pi D_g^2 \tag{4}$$

$$V = \frac{\pi B^2 L^2}{6(2L - B)} \tag{5}$$

(where $B = \sqrt{WT}$*)*

2.3 Gravimetric properties: mass, density, and porosity

The 1,000-seed mass was determined by randomly selecting 100 seeds, weighing them on a high-precision electronic analytical balance (0.001 g sensitivity), and multiplying the result by 10 to obtain the 1,000-seed equivalent mass (Kaptso et al., 2016).

True density (ρ_t) was evaluated using toluene displacement under a fume hood, with appropriate personal protective equipment, and disposed of according to environmental safety guidelines. (Mohsenin, 1986). Bulk density (ρ_b) was quantified by filling a standardized cylindrical container of known volume with seeds from a height of 150 mm and weighing the contents.

Subsequently, the inter-granular porosity (ε), which represents the percentage of void space within the bulk grain, was computed mathematically using Equation 6 (Altuntas & Demirtola, 2007):

$$\varepsilon = \left(1 - \frac{\rho_b}{\rho_t}\right) \times 100 \tag{6}$$

2.4 Evaluation of mechanical and frictional properties

The dynamic angle of repose (θ) was measured using a custom-built wooden cuboid apparatus (300×300×300 mm) with a rapid-release front panel (Galedar et al., 2010). Conditioned kernels were loaded into the chamber; when the front panel was quickly removed, the grains cascaded to form a natural slope. The angle was geometrically calculated based on the height (H) and diameter (D) of the resulting grain pile using Equation 7:

$$\theta = \tan^{-1}\left(\frac{2H}{D}\right) \tag{7}$$

The static coefficient of friction (μ) was determined against three common structural materials (plywood, galvanized iron, and aluminum sheet). A customized bottomless metallic cylinder (50 mm diameter and 50 mm height) was filled with seeds and positioned slightly above an adjustable tilting test surface. The plane was incrementally inclined using a calibrated screw mechanism until the cylinder began to slide. The static friction coefficient was calculated using Equation 8, where α is the angle of tilt at the point of kinetic initiation (Baryeh, 2001):

$$\mu = \tan \alpha \tag{8}$$

All physical, gravimetric, and mechanical tests were performed in quintuplicate (five replicates) at each moisture level to ensure statistical reliability, and the mean values were recorded.

2.5 Statistical Analysis

The data were subjected to a One-Way Analysis of Variance (ANOVA) using OriginPro 2026 software. Where significant differences were observed, mean separations were performed using Duncan's Multiple Range Test at a 95% confidence level ($p < 0.05$) to establish statistical groupings.

3 RESULTS AND DISCUSSION

3.1 Effect of moisture content on grain dimensions

The variations in the principal axial dimensions—length (L), width (W), thickness (T), and geometric mean diameter (D_g)—of the Beedi Bambara nuts concerning moisture content are presented in Figure 2A. The data reveal that all physical dimensions increased as the moisture content rose from 5.0% to 25.0% (wet basis), after which no significant dimensional changes were observed. This dimensional plateau can be attributed to the cellular architecture of the cotyledons; as the seeds absorb moisture, the internal air voids are progressively displaced by water until structural saturation is achieved at approximately 25% moisture. These findings align with hydration behaviors reported for other legumes, such as soybeans (Deshpande et al., 1993) and other Bambara groundnut varieties (Baryeh, 2001; Nkambule et al., 2023), confirming that mechanical decorticator clearance settings must account for this maximum expansion to prevent kernel damage during processing.

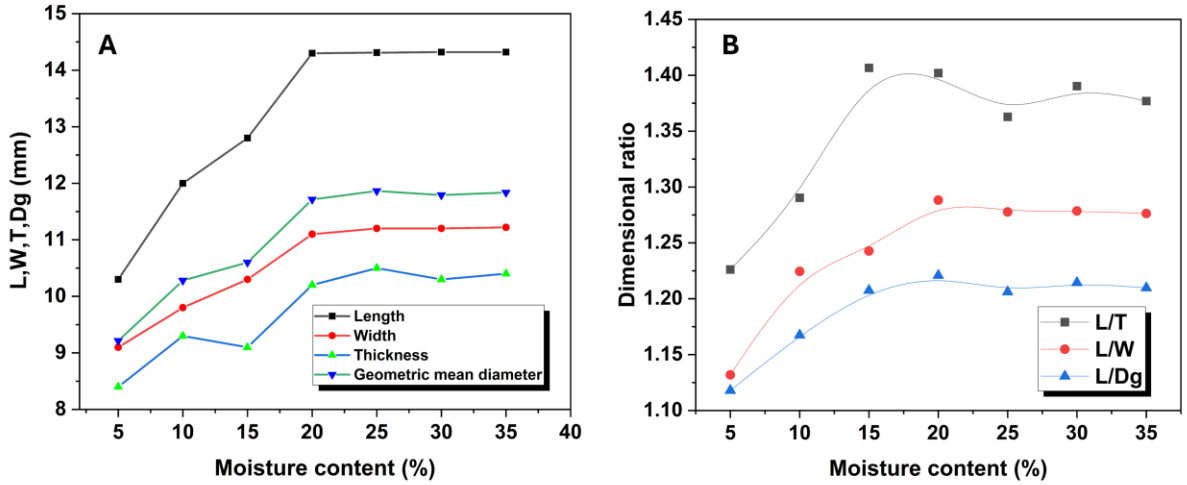

Figure 2: B illustrates the variation in the dimensional ratios (*L/W, L/T, and L/D$_g$*). As corroborated by the absolute spatial measurements in Figure 2A, the *L/T* ratio showed the highest values, confirming that thickness remains the smallest spatial dimension as the seed expands, followed by width and geometric diameter. These ratios increased as moisture content rose to 25% but subsequently decreased. The observed ratios for the Beedi variety were generally lower than those reported by Baryeh (2001), suggesting that the Beedi cultivar has a more uniform, compact morphological profile than other West African landraces.

Figure 2: Variation of the dimensions and dimensional ratios with moisture content.

3.2 Sphericity, surface area, and grain volume

Figure 3: A depicts the influence of moisture content on the degree of sphericity. Notably, the shape assumption heavily dictated the outcome; the equation assuming an elliptical shape yielded lower sphericity values (ranging from 0.895 at 5% to 0.840 at 35% moisture content). Because the true morphology of Bambara groundnuts is closer to an elliptical sphere, the model more accurately represents the Beedi variety. The slight decrease in sphericity with hydration indicates asymmetrical swelling, making the kernel slightly more elongated at higher moisture levels.

Figures 3B and 4A show that both surface area and grain volume increased substantially with moisture up to 25%, then plateaued. This non-linear expansion supports findings by Baryeh (2001) for Bambara groundnuts, though it contrasts with Deshpande et al. (1993), who reported a strictly linear increase in soybean surface area. This difference may be due to the more rigid and restrictive seed coat of the Bambara nut, which limits structural stretching compared with the more elastic testa of soybeans.

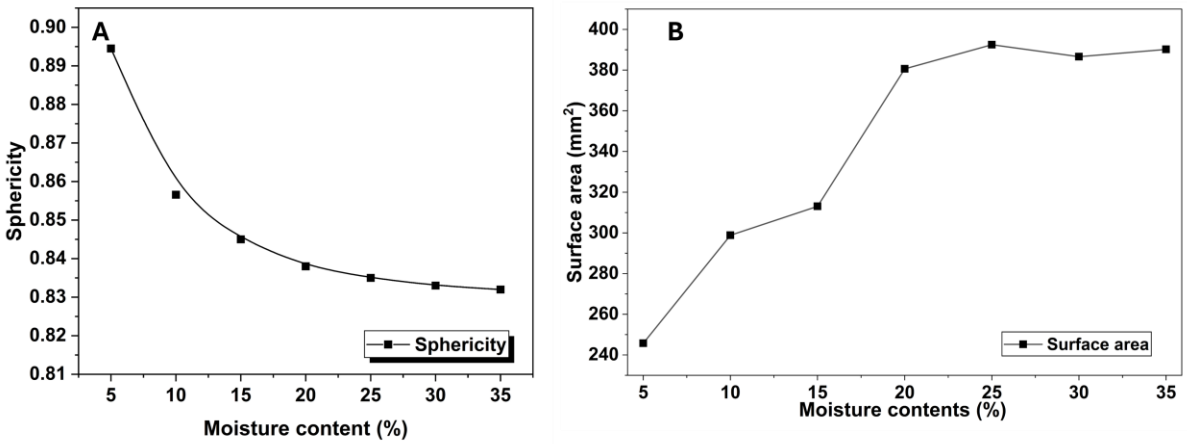

Figure 3: Variation of Sphericity (A) and surface area (B) with moisture content.

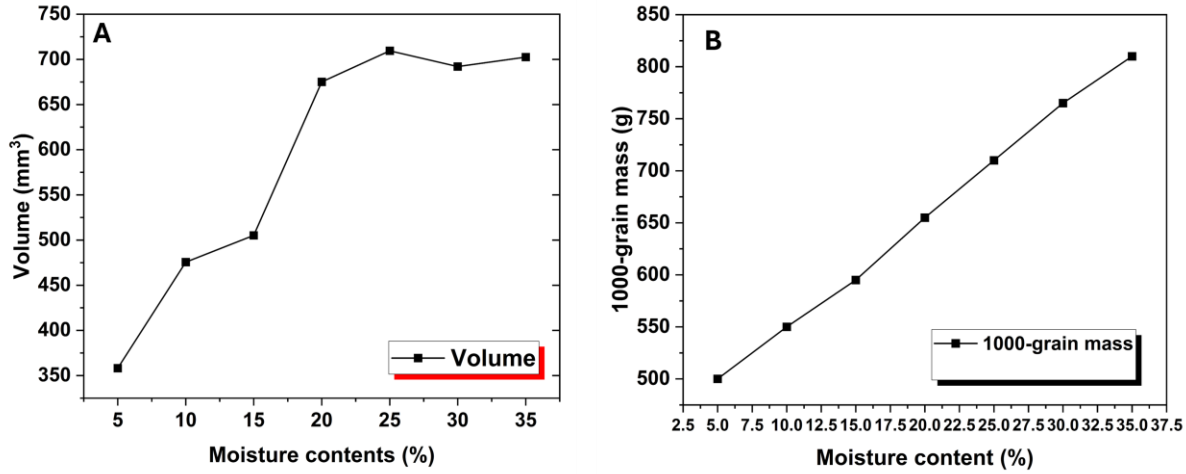

Figure 4: Variation of volume (A) and 1000-grain mass (B) with moisture content.

3.3 Gravimetric properties: mass, density, and porosity

The 1,000-grain mass exhibited a highly positive linear correlation with moisture content, as shown in Figure 4B. This variation is mathematically modeled as:

$$Y = 448 + 10.53M \ (R^2 = 0.9987).$$

Where Y represents the 1,000-grain mass (g), and M is the moisture content (%).

This predictable mass accumulation is consistent with established literature across various seeds, including cumin, soybeans, and coffee (Aviara et al., 1999; Chandrasekar & Viswanathan, 1999). Conversely, as illustrated in Figure 5A, both bulk density and true density decreased non-linearly as moisture content increased from 5.0% to 35.0% (bulk density dropping from 1.30 to 1.08 g/cm³, and true density from 1.32 to 1.18 g/cm³). This inverse relationship occurs because the seed structure expands volumetrically faster than it gains mass from moisture absorption. While this agrees with the behaviors of soybeans and some Bambara varieties (Polat et al., 2006; Nkambule et al., 2023), it contradicts the behavior of pumpkin and karingda seeds, where densities increase with moisture (Joshi et al., 1993; Suthar & Das, 1996). We theorize that this discrepancy is fundamentally linked to the unique starch-protein matrices of individual species; seeds with higher initial porosity experience more pronounced volumetric swelling, driving the overall density downward.

The porosity of the Beedi nuts (Figure 5B) displayed a parabolic trend, initiating at 40.0%, peaking at 45.8% (around 20% moisture), and then declining to 42.5% at higher moisture levels. This non-linear response contradicts the strictly linear decreases or increases often reported in existing literature for other crops. The initial rise in porosity indicates that bulk density decreases faster than true density at lower moisture levels. However, as the seeds approach saturation (past 20%), they swell and become more pliable, packing more tightly under their own weight and reducing inter-granular void spaces.

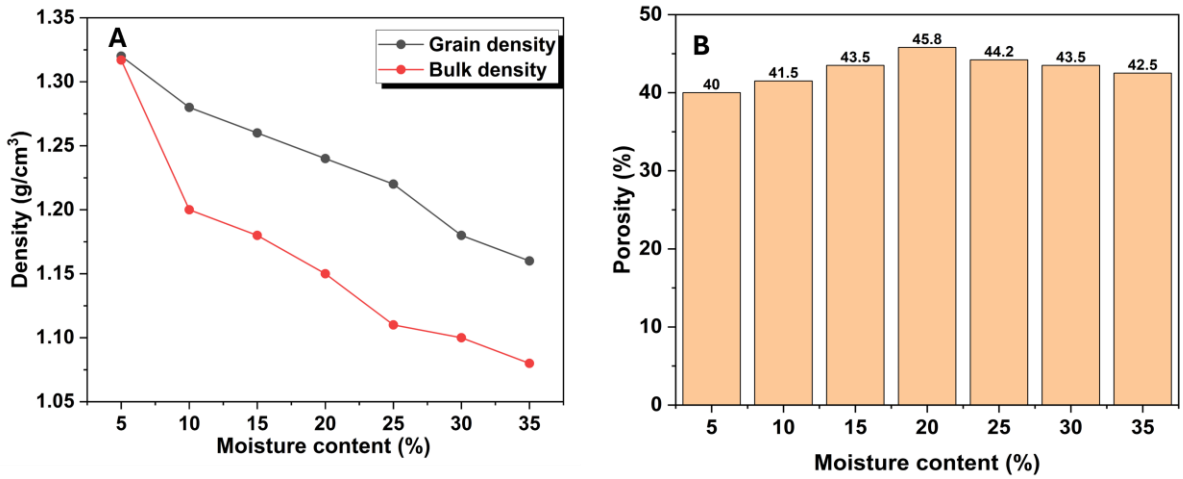

Figure 5: Variation of density (A) and porosity (B) with moisture content.

3.4 Mechanical and frictional properties

The dynamic angle of repose is a critical parameter for designing hopper slopes. As shown in Figure 6A, it increased from 20.0° at 5% moisture to a peak of 24.1° at 20% moisture, then slightly decreased to 21.5° at 35% moisture. This initial increase indicates higher inter-particle cohesion and flow resistance as the seed surfaces transition from dry to damp. The subsequent decrease at maximum moisture may be due to the lubricating effect of surface free water.

Figure 6: B depicts the variation of the static coefficient of friction against different structural surfaces. Across all moisture levels, friction was significantly highest on plywood (0.38 to 0.66), followed by galvanized iron (0.3 to 0.52), and lowest on aluminum sheet (0.25 to 0.48). The coefficient increased rapidly between 5% and 15% moisture content, then leveled off. We agree with the mechanisms proposed by Gupta and Das (1998) and Baryeh (2001): smoother, polished surfaces such as aluminum naturally offer less resistance than porous, rough materials such as plywood. Furthermore, as moisture increases, exudate creates adhesive capillary forces between the kernel and the contact surface, thereby elevating frictional resistance. Consequently, processing machinery, particularly discharge chutes, should utilize aluminum or polished galvanized steel to maintain unhindered grain flow and prevent blockages at higher moisture states.

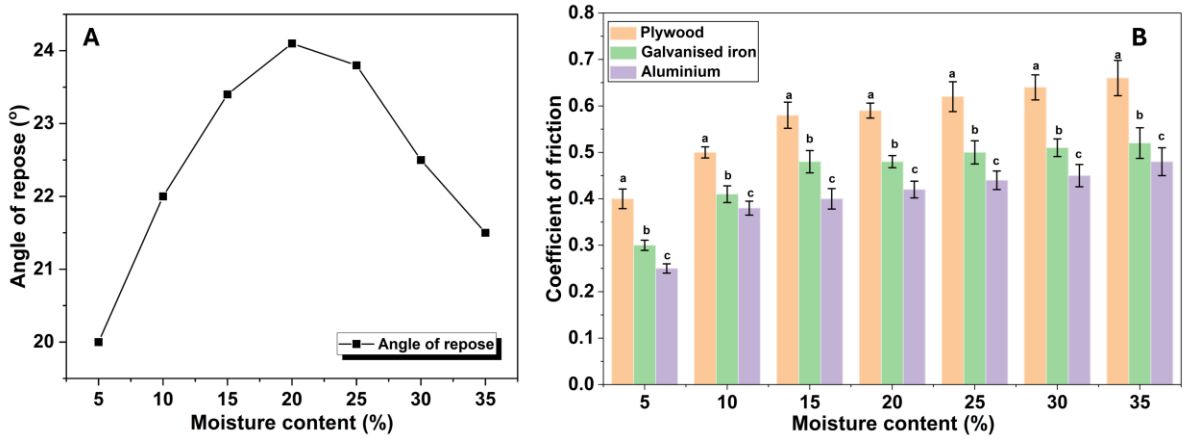

Figure 6: Variation of angle of repose (A) and coefficient of friction against different surfaces (B) with moisture content.

4 CONCLUSION

The study evaluated the engineering properties of the Beedi variety of Bambara groundnut (*Vigna subterranea* (L.) Verdc.) from Bauchi State, Nigeria, across a post-harvest moisture range of 5.0% to 35.0% (wet basis). The findings indicate that the principal linear dimensions (length, width, and thickness), geometric mean diameter, surface area, and grain volume all exhibit a non-linear expansion as moisture content rises. Regarding gravimetric properties, the 1,000-seed mass

demonstrated a strictly positive linear correlation with moisture accumulation. Conversely, both bulk density and true density decreased non-linearly, though true density consistently remained higher than bulk density across all hydration levels. Furthermore, seed flow behavior characterized by inter-granular porosity and the dynamic angle of repose increased to a peak value before declining with further moisture absorption. Mechanically, the static coefficient of friction increased significantly with moisture content across all tested structural surfaces, with plywood offering the highest frictional resistance, followed by galvanized iron and aluminum. Ultimately, these moisture-dependent quantitative parameters provide the essential baseline data required for the optimal design, structural development, and operational adjustment of handling, decorticating, sorting, and processing machinery. By enabling local equipment innovation, this dataset directly supports sustainable agro-material processing and resource utilization strategies.

ABSTRACT
Asphalt pavements trap a substantial amount of solar radiation and comprise between 30% and 45% of urban areas, thus contributing to the urban heat island (UHI) effect due to their high thermal storage, which leads to the softening and degradation of the pavement. Energy harvesting techniques are one of the promising ways to mitigate these effects while making sustainable use of the trapped thermal energy. In this study, the performance of a thermoelectric generator (TEG)-based energy harvesting prototype integrated with asphalt pavements was evaluated. A fabricated 30 × 30 cm asphalt slab with a thickness of 5 cm and an embedded copper collector was used. The hot side of the TEG module was attached to the L-shaped copper collector, and the cold side was connected to a water-filled aluminium heat sink. Six TEG modules were mounted for redundancy, of which four were active during data collection. Performance was evaluated under controlled indoor conditions; temperatures were measured using embedded thermocouples and electrical output was measured using a multi-meter. Under controlled indoor conditions, temperature differences (ΔT) of 12–22°C produced 0.295–0.897 V, 3.6–15.73 mA, and a maximum power output of 14.12mW from the four active TEG modules, confirming the feasibility of harvesting thermal energy from asphalt pavements. This corresponds to a potential of approximately 157 mW/m² of asphalt pavement surface. The study demonstrates a practical approach to pavement-based thermoelectric energy harvesting in hot-climate regions and recommends outdoor field testing, seasonal performance monitoring, and optimization for large-scale deployment in Kano, Northern Nigeria.

1. INTRODUCTION

Asphalt pavement, a black body surface, absorbs solar radiation, elevating its temperature, often reaching 25-50°C depending on location and weather (Aletba et al., 2021). In tropical regions with high solar exposure, this heat, combined with heavy traffic, can melt the asphalt, causing surface defects like bumps and bruises upon cooling. To ensure durability, especially in tropical areas, maintaining lower asphalt temperatures is crucial. The absorbed solar radiation converts to thermal energy, heating the asphalt above the ambient temperature and subsequently releasing heat to the environment, contributing to the Urban Heat Island effect (UHI) (Nuruzzaman, 2015). Cooling asphalt is essential to mitigate the UHI effect and enhance pavement longevity, considering its substantial coverage in urban areas (30 to 45% of land area).

Pavements, comprising 30% to 45% of urban areas, significantly contribute to the urban heat island (UHI) effect due to their high thermal storage and low solar radiation reflection (Ikechukwu, 2015; Kuehl, 2021). Traditional cooling methods involve applying reflective coatings on the surface to deflect rather than absorb solar radiation. Aletba et al. (2021) emphasize the importance of cooling strategies for pavement surfaces, considering their direct exposure to solar impact, influenced by surface characteristics like colour, material, shape, and roughness. Utilizing high-albedo and high emissivity surfaces minimizes heat retention and lowers pavement temperatures. Similarly, engineering materials and pavement layers with low thermal conductivity and high heat capacity can reduce thermal diffusivity, combatting the heat emitted by asphalt pavement.

Energy harvesting refers to the process of capturing and converting ambient or waste energy from the environment, such as solar, thermal, kinetic, or wind energy, into usable electrical power for

operating devices or systems. Energy harvesting can be a useful technology as it offers to mitigate the urban heat island (UHI) effect, prolong the lifespan of asphalt pavements and use the harvested heat in many useful applications. Thermal energy from incident solar radiation which is absorbed by the asphalt pavement can be harvested using energy harvesting technologies such as; the photovoltaic solar panel, heat pipe solar collector and thermoelectric generator systems.

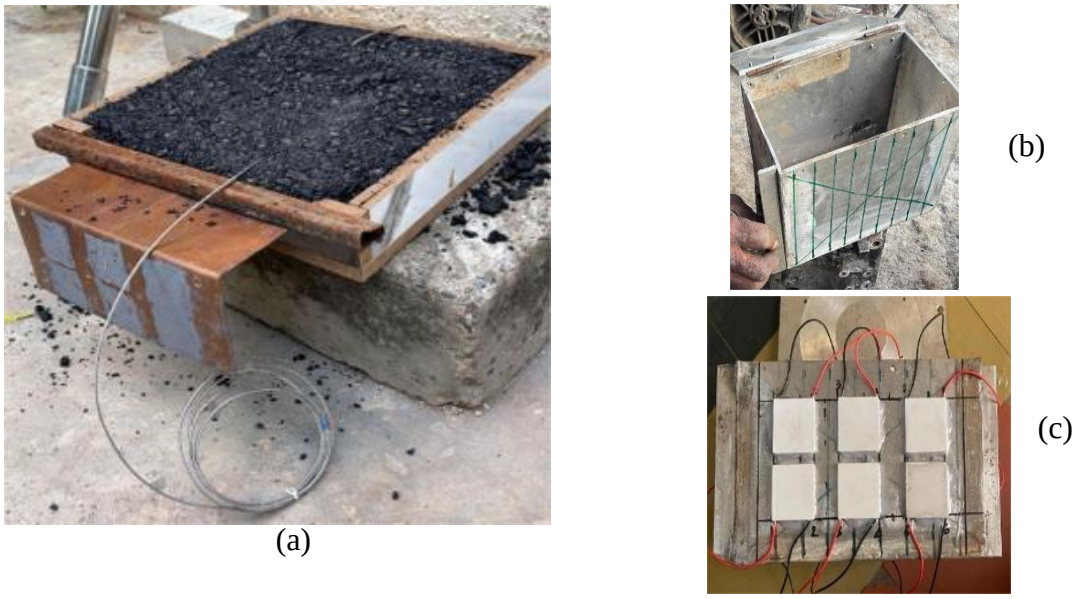
Research on energy harvesting from asphalt pavement using Thermoelectric Generators (TEGs) is an emerging area of interest with promising potential. TEGs embedded in asphalt pavement can potentially convert the heat generated by solar radiation and vehicular traffic into electrical energy, allowing for energy harvesting and power generation from roadways. Various researchers (Mona et al. (2021); Sharuddin (2021); Jiang et al. (2017); Datta et al. (2017); Tahami and Dessouky (2021)) have developed TEGs for harvesting energy from asphalt pavements. Over the years researchers have focused on increasing the TEGs operational efficiency through optimizing the thermos electric material (Yang et al. (2017) and Lobunets (2021)); Enhancing heat transfer in the asphalt pavement (Alhamdo (2023); Qusay Doraghi (2024); Liu (2012); and Leon (2010)); Improving System design and configuration (Eman (2018); Maduabuchi (2021)) and Heat sink optimization (Jiang et al. (2017); Boonyasri et al. (2016)). Performance of these prototype systems depends on the climatic conditions in the region and the properties of the asphalt itself. Thus, to properly utilize this technology in Nigeria, there is the need to quantify the potential of this technology for potential applications in powering road equipment such as traffic lights, road signs, and similar low-power devices.

2. METHODOLOGY

2.1 Experimental Material/Equipment

The following material and equipment were used in this research.

- The prototype TEG Energy Harvesting system
- TA612C Thermometer (Data Logger)
- Non-contact Infrared Thermometer
- K-Type Thermocouples
- DT9205A Digital Multimeter
- KM-SPM-11 Solar Power Meter (Solarimeter)



2.2 The Prototype Asphalt TEG based Energy Harvesting System

Figure 1 presents the picture of the prototype TEG energy harvester. The prototype consists of:

- Asphalt pavement with embedded collector: A hot mix asphalt pavement, consisting of 47% coarse aggregates, 40% fine aggregates, 7% mineral filler (cement) and 6% bitumen with a surface area of 900 cm² (30 × 30 cm) and thickness of 5 cm. A copper plate is embedded into the asphalt pavement.
- Collector and conveyor: The collector and conveyor assembly was fabricated from an L-shaped copper plate. The TEG modules (SP1848-27145) with dimension of 40 mm by 40mm each and with voltage and current output of 0.97V, 225mA at 20^{o} temperature difference. Six modules were physically mounted on the collector for redundancy (Figure 1c), of which four were wired in and active for the data collection reported in this study, so that the system could continue operating on the remaining modules in the event of an individual module failure.
- Heat sink: The heat sink was fabricated from aluminium sheets
- Wooden box housing: A wooden housing box was constructed to encase the prototype. This facilitated ease of movement and served as a protective cover, shielding the heat sink from direct solar radiation.

2.3 Experimental Setup

The conveyor section (L-shaped side of the copper plate) embedded within the asphalt pavement was connected to the hot side of the thermoelectric (TEG) module (figure 2). The cold side of the TEG module was attached to the aluminium heat sink, with both interfaces enhanced using thermal paste and secured by mechanical fastening.

(a) (b) (c)

Figure 1: The prototype Asphalt TEG based energy Harvesting system (a) the Pavement (b) Heat Sink (c) TEGs attached to the Heat Sink

To minimize undesired heat losses, an insulation layer was placed between the conveyor and the heat sink, and additional insulation material was used to cover the exterior surface of the copper collector. The insulation was put to minimise heat losses from the asphalt not the sink. For temperature measurements, four K-type thermocouples were strategically installed: one embedded in the asphalt pavement in direct contact with the copper plate (collector), another attached to the conveyor, a third placed inside the heat sink, and a fourth positioned in open air near the prototype to record the ambient temperature. These provided continuous readings of temperature distribution across the system. The entire assembly was mounted within a wooden box, which served both as a protective casing and as a portable frame to facilitate movement and handling of the prototype.

Figure 2: The prototype set-up for testing

2.4 Experiment Procedure and Data Analysis Technique

- Instrumentation: Four K-type thermocouples were connected to the TA612C data logger as shown in Figure 3. The DT9205A digital multi-meter was connected directly across (for

voltage) and in series with (for current) the series-connected TEGs, so the effective electrical load during measurement was the multimeter's own internal resistance rather than a discrete external load resistor. The KM-SPM-11 solarimeter was used to measure lamp intensity.

- Procedure: The 500W halogen lamp was positioned 25 cm above the asphalt surface. The data logger, multi-meter, and solarimeter were initialized. The lamp was switched on, and data (temperature, voltage, current, light intensity) was recorded at 5-minute intervals for a period of 2 hours. The digital multi meter internal resistance and the connecting wires served as the load resistance.

Figure 3: Experimental Set-up

- Data Analysis Technique: The raw data was processed using Microsoft Excel. The high-frequency data from the logger (recorded every second) was sorted and averaged into 5-minute intervals to align with the experimental procedure. Duplicate entries were removed. Electrical power (in mW) was calculated using the formula P = V * I. Relationships between parameters (e.g., temperature difference vs. power, solar intensity vs. power) were established and visualized using Excel charts.

3. RESULTS AND DISCUSSION

Figure 4 and 5 present the temperature and power profiles recorded during the highest-output indoor test run, illustrating the general shape of the system's thermal and electrical response over the test period. The lamp intensity varied between 1295 and 1980 W/m², which caused a progressive rise in surface temperatures. The collector temperature increased from 40.7 °C to a maximum of 63.3 °C, while the conveyor temperature ranged from 32.6 °C to 45.8 °C. The heat sink remained relatively stable within 26–35 °C, reflecting the effectiveness of the insulation layer placed between the conveyor and the heat sink (Section 2.3) in limiting undesired heat transfer to the cold side. This produced a maximum temperature difference (ΔT) of approximately 22°C between the conveyor and the heat sink in this run, with voltage rising to 0.897 V, current to 15.73 mA, and power reaching a peak of 14.12 mW at 17:50 hrs, coinciding with the peak temperature difference.

These measured outputs are considerably lower than the TEG module's rated performance of 0.97 V and 225 mA at a 20 °C temperature difference (Section 2.2). This gap is attributed to several factors. First, voltage and current were measured directly with the DT9205A digital multi-meter rather than across a resistive load matched to the TEG's internal resistance, which limits the current the module can deliver into the measurement circuit. Second, thermal contact resistance at the collector–TEG and TEG–heat sink interfaces, despite the use of thermal paste, reduces the effective temperature difference across the TEG junctions relative to the temperature difference measured between the copper collector and the heat sink. Third, connecting the modules in series means that any underperforming module limits the current of the entire array. Insulation losses around the collector

and conveyor further reduce the temperature differential actually available to the modules relative to idealized datasheet test conditions.

The performance of the thermoelectric generator (TEG)-based asphalt pavement energy harvester was evaluated under indoor test conditions, focusing on the temperature difference (ΔT) between the conveyor and the heat sink (T_3–T_4), and the resulting voltage, current, and power output. Averaged across the indoor test replicates, the ΔT ranged between 12 °C and 22°C, producing 0.295–0.897 V, 3.6–15.73 mA, and a maximum power output of 14.12 mW combined from the four active TEG modules. Scaling this average output over the 900 cm² (0.09 m²) slab (asphalt) area used in the prototype (14.12 mW ÷ 0.09 m²) gives a harvestable potential of approximately 157 mW/m² of asphalt pavement surface under similar indoor conditions. These results are broadly consistent with those of Datta et al. (2017), who reported a system-level (aggregate) output of 0.52–0.68 V and about 15mW at similar ΔT values (10–15°C); both figures represent total system output rather than a per-module value, making the comparison directly comparable. The slight difference may be attributed to variations in module contact resistance and heat transfer efficiency. Both studies confirm a direct proportionality between ΔT and output power, validating the Seebeck principle.

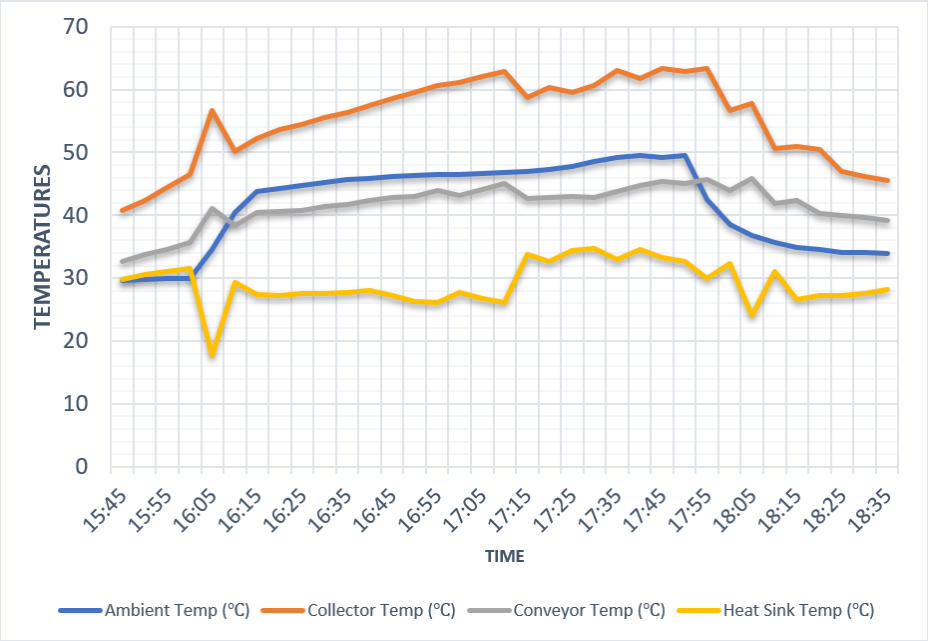


Figure 4: Temperature profile recorded during the highest-output indoor test run

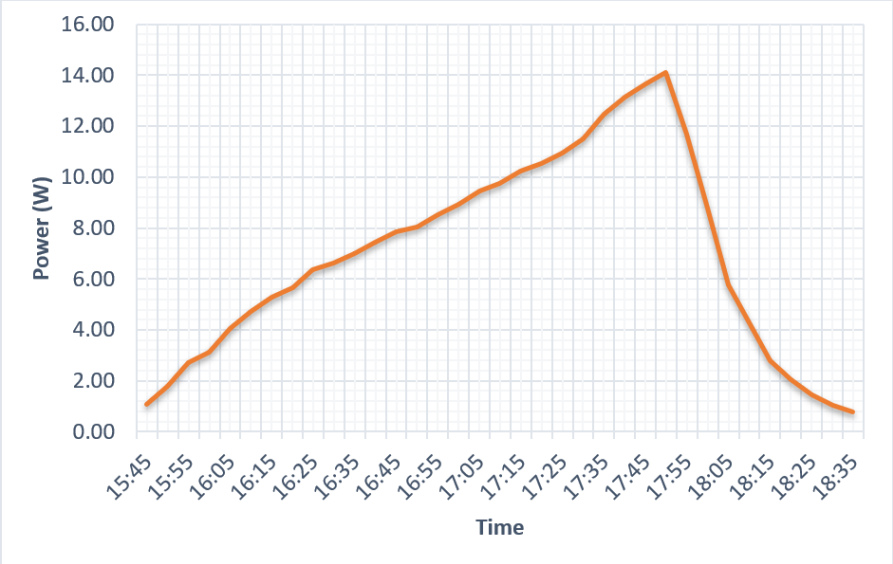

Figure 5: Power output recorded during the highest-output indoor test run

4. CONCLUSION

The design demonstrated technical feasibility for harvesting low-grade thermal energy from asphalt pavements. The completed prototype was tested under laboratory conditions, where simulated solar radiation produced stable electrical outputs, with a maximum indoor power output of 14.12 mW combined from the four active TEG modules, recorded during the highest-output trial, consistent with related studies such as Datta et al. (2017). For context, these output levels are comparable to the power budgets of several classes of low-power roadside electronics: commercial low-power wireless sensor nodes typically draw on the order of 3–12 mW during active operation (for example, the Crossbow MICAz draws approximately 2.8 mW and the Intel IMote2 approximately 12 mW (Raj & Steingart, 2018), and a single low-power LED indicator draws on the order of several milliwatts. This suggests that, while the harvested power is insufficient to continuously supply conventional road electrical systems such as full traffic signal heads, it is within range of intermittently duty-cycled sensor nodes or indicator LEDs when paired with an energy storage buffer such as a supercapacitor or small battery. Comparative analysis showed that system performance is strongly influenced by temperature gradient, ambient conditions, and material thermal properties. Although the harvested power is insufficient to independently supply conventional road electrical systems, the results demonstrate the system's viability as a supplementary energy source when integrated with hybrid renewable systems and energy storage. The next step is to test the prototype under real outdoor conditions in Kano, Northern Nigeria and to explore load-matched circuitry to help close the gap between the modules' rated and measured performance.

ABSTRACT

This study investigated the preliminary screening and characterization of α-cellulose from cotton stalk (CS), sugarcane bagasse (SCB), and sawdust (SD) to establish practical process parameters for subsequent optimization. A uniform particle size of 125 µm and solid-to-liquid ratio (1:10 w/v) were applied. CS was treated with 7.5–27.5 g NaOH/100 mL at 90°C for 1.5 h, while SCB and SD Method 1 were treated with 10–30 g NaOH/100 mL at 95°C for 1.5 h. SD Method 2 incorporated an initial 7 mL HNO_3 pretreatment at 95°C for 1.41 h prior to alkali treatment. Recovered fractions were evaluated by α-cellulose yield, purity, Van Soest fiber analysis, FTIR, XRD, and SEM–EDX. CS2 produced 30% yield and 84.06% purity; SCB2 produced 20% yield and 83.82% purity; SD3 produced 80% yield and 85.71% purity; and SDA3 produced 20% yield and 90.14% purity. FTIR confirmed substantial solubilization of non-cellulosic components. XRD analysis demonstrated shifts in Crystallinity Index (CrI) from raw to treated states: CS RAW (61.5%) to CS2 (61.4%), SCB RAW (55.7%) to SCB2 (59.6%), SD RAW (51.3%) to SD3 (66.1%), and reaching 75.2% for dual-pretreated SDA3. SEM–EDX revealed microfiber exposure, matrix disruption, and mineral leaching. Direct-alkali SD3 was selected as the optimal practical condition for sawdust due to high mass recovery (80%), process simplicity, avoiding acid consumption and multi-stage washing, where the +4.43% purity increase in SDA3 did not justify the 75% loss in recovered yield and added reagent cost. The selected conditions provide experimental starting points for subsequent DOE–CCD multi-pulping optimization; DOE–CCD and ANN/FFNN modelling are not claimed as completed in this preliminary study.

1. INTRODUCTION

Lignocellulosic agricultural and wood residues are renewable resources containing cellulose, hemicellulose and lignin and offer important feedstocks for value-added cellulose-based materials (Riseh *et al.*, 2023). However, the close association of cellulose with hemicellulose and lignin makes direct recovery difficult. Chemical pretreatment, particularly alkaline treatment, can disrupt lignin–carbohydrate associations, promote fiber swelling and facilitate removal of non-cellulosic components, thereby increasing cellulose accessibility (Abolore *et al*., 2023; Hassana *et al*., 2021).

Cotton stalk, sugarcane bagasse and sawdust have different lignocellulosic structures and therefore require biomass-specific pretreatment conditions (Darmenbayeva *et al*., 2026). Preliminary screening is consequently important for identifying suitable treatment conditions before subsequent process optimization. In this study, FTIR spectroscopy was used to evaluate changes in characteristic lignin, hemicellulose and cellulose functional groups through peak positions and transmittance responses. In this study, sodium hydroxide concentration was varied to screen suitable extraction conditions for the three biomasses, while an additional HNO_3–NaOH pretreatment was examined for sawdust.

The aim of this work is to produce α-cellulose from cotton stalk, sugarcane bagasse and sawdust by varying the concentration of sodium hydroxide applied to the three biomasses, with an additional HNO_3–NaOH route examined for sawdust only, in order to compare the two methods and identify the optimum preliminary conditions. The specific objectives were to evaluate the effect of NaOH

concentration on α-cellulose extraction; determine cellulose, hemicellulose and lignin fractions using the Van Soest method; characterize the extracted α-cellulose using FTIR, XRD and SEM–EDX; compare the alkaline and HNO_3–NaOH routes for sawdust; and identify the preliminary optimum treatment conditions as a basis for subsequent RSM–CCD optimization.

2 METHODOLOGY

2.1 Biomass Preparation and Pretreatment

Cotton stalks were collected from a farm in Funtua - Katsina State, sugarcane bagasse from Samaru- Zaria and mixed sawdust from a local timber market Sabon Gari market Zaria. Cotton stalk and sugarcane bagasse were air dried for 2 months, while mixed sawdust was dried for a week to reduce the moisture content to 5%. The dried materials were pulverized using a Retsch mechanical grinder and ball mill to further reduce the particle sizes. An Endecotts test sieve (120 mesh; 125 µm apertures) was used to sieve the pulverized biomass to a uniform particle size of 125 µm. Ten grams (w/w) of biomass was used for each preliminary treatment. A constant solid-to-liquid ratio of 1:10 (w/v) was maintained throughout the pretreatment experiments, using 10 g of biomass and 100 mL of distilled water for each treatment, while varying the NaOH loading. For cotton stalk, CS1–CS5 were treated with 7.5, 12.5, 17.5, 22.5, and 27.5 g NaOH, respectively, at 90°C for 1.5 h in a water bath. Following pretreatment, the samples were washed repeatedly with distilled water until pH 5–7, filtered, oven-dried at 105°C for 3 h, and weighed. Similarly, sugarcane bagasse (SCB1–SCB5) and sawdust Method 1 (SD1–SD5) were treated with 10, 15, 20, 25, and 30 g NaOH, respectively, at 95°C for 1.5 h in a water bath, followed by washing to pH 5–7, filtration, oven drying and weighing. For sawdust Method 2 (SDA1–SDA5), the samples were initially treated with 7 mL HNO_3 diluted in 100 mL distilled water at 95°C for 1.41 h in a water bath. The samples were then washed to pH 5–7 and subsequently treated with 10, 15, 20, 25, and 30 g NaOH, respectively, at 95°C for 1.5 h in a water bath. The treated samples were then washed, filtered, oven-dried and weighed. The pretreatment conditions are summarized in Table 1.

Table 1: Preliminary pretreatment conditions used for biomass screening.

Biomass/method	Samples	NaOH (g/100 mL)	Temp. (°C)	Time (h)	Additional step
Cotton stalk	CS1–CS5	7.5–27.5	90	1.5	None
Sugarcane bagasse	SCB1–SCB5	10–30	95	1.5	None
Sawdust Method 1	SD1–SD5	10–30	95	1.5	None
Sawdust Method 2	SDA1–SDA5	10–30	95	1.5	7 mL HNO_3 + 100 mL H_2O; 95°C; 1.41 h

2.2 Yield, Purity and Van Soest Fibre Analysis

Percentage α-cellulose yield was determined from recovered dry mass relative to the initial biomass mass. Purity was assessed using Van Soest detergent-fibre measurements through neutral detergent fibre (NDF), acid detergent fibre (ADF), acid detergent lignin (ADL) and ash add (Bartos et al., 2020). Hemicellulose was calculated from NDF (%) minus ADF (%), while cellulose and lignin were obtained from the corresponding fibre fractions. For NDF, 1.0 g of sample was placed in a round-bottom flask, followed by 100 mL neutral detergent solution and 0.5 g sodium sulphite, and refluxed at 100°C for 1 h. The residue was filtered, washed with hot distilled water to pH 5–7, rinsed with 20 mL acetone twice, oven-dried at 105°C for 1 h, and weighed in grams and recorded as NDF residue. For ADF, the dried NDF residue was transferred to the reflux flask, mixed with 100 mL acid detergent solution, and refluxed at 100°C for 1 h. The residue was filtered, washed with hot distilled water to pH 5–7, rinsed with 20 mL acetone twice, dried at 105°C for 1 h, and weighed (g) as ADF residue. For ADL and ash determination, the dried ADF residue was treated with 72% (v/v) H_2SO_4 for 3 h at room temperature with occasional stirring to solubilize cellulose. The remaining acid-insoluble residue was filtered, washed with hot distilled water until acid-free, dried to constant weight, and recorded in

grams as ADL residue. This residue was subsequently ashed in a muffle furnace at 550°C for 3 h and cooled in a desiccator, and the residual inorganic ash weight was recorded ash in grams. The equations for the Van Soest method is reported by Hassana *et al.*, 2021.

$$\text{Percentage Yield (\%)} = \frac{mass\ of\ dried\ \alpha-cellulose}{mass\ of\ raw\ biomass} \text{ X } 100 \quad \ldots\ldots\ldots\

conditions. SDA3 gave 64% cellulose and 4% lignin, showing the stronger compositional effect of the acid–alkali route as presented in Table 2.

Table 2: Van Soest Fiber Composition of Raw and Calculated Fraction Purity of the Pretreated Biomass

Sample	NDF %	ADF %	ADL %	Ash %	Hemicellulose %	Cellulose %	Lignin %

3.2 Percentage Yield and Purity of Alpha Cellulose of CS, SCB, SD, and SDA

Alpha cellulose was extracted from cotton stalk (CS), sugarcane bagasse (SCB), and sawdust under two distinct processing regimes—Method 1 (SD) and Method 2 (SD-A)—to evaluate trade-offs between mass yield and chemical purity.

CS yields ranged from 29% to 30% (2.9–3.0 g) with purities between 76.67% and 84.06%, where CS2 achieved peak purity (84.06% purity, 30% yield) and CS4 (81.25% purity, 29% yield). SCB exhibited lower yields of 15–20% (1.5–2.0 g) while maintaining strong purity levels, led by SCB2 at 83.82% purity (20% yield). Method 1 treated sawdust (SD) provided the highest mass recoveries overall at 50–80% (SD4: 80% yield, 83.82% purity; SD3: 60% yield, 85.71% purity). Method 2 treated sawdust (SD-A) experienced reduced yields (20–30%) due to intensified delignification, but delivered the highest polymer purity, peaking at 90.14% for SD3A (20% yield).

Overall, while Method 2 (SD3A) achieved the absolute highest purity (>90%) across all feedstocks, peak-purity representatives—CS2 (84.06%), SCB2 (83.82%), and Method 1 SD3 (85.71%)—highlight key refinement thresholds, with Method 1 SD3 providing the optimal balance between throughput mass recovery (60%) and high chemical purity. The summary of the results is presented in Table 3.

Table 3: Van Soest Fibre Composition and Calculated Cellulose Fraction Purity

SAMPLE ID	Initial wgt (g) Raw sample	Final wgt dried α-cellulose (g)	% yield α-cellulose	% purity α-cellulose
CS1	10	3	30	76.66666667
CS2	10	3	30	84.05797101
CS3	10	3	30	78.78787879
CS4	10	2.9	29	81.25
CS5	10	3	30	81.96721311
SCB1	10	2	20	75
SCB2	10	2	20	83.82352941
SCB3	10	1.5	15	79.36507937
SCB4	10	2	20	81.53846154
SCB5	10	2	20	81.96721311
SD1	10	5	50	75
SD2	10	6	60	80.3030303
SD3	10	8	80	85.71428571
SD4	10	6	60	83.82352941
SD5	10	5	50	84.61538462
SD1A	10	2	20	80
SD2A	10	2	20	85.07462687
SD3A	10	3	20	90.14084507
SD4A	10	2	30	88.4057971
SD5A	10	2	20	86.36363636

3.3 FTIR Characterization

FTIR confirmed substantial chemical modification. CS2 showed disappearance of the carbonyl feature near $1720\ \text{cm}^{-1}$ and reduction of the lignin-associated $1510\ \text{cm}^{-1}$ region, with a clearer cellulose fingerprint. SCB2 similarly showed disappearance of the $1720\ \text{cm}^{-1}$ feature and reduction of lignin-associated signals. In sawdust, Method 1 retained lignin aromatic skeletal vibrations, whereas SDA3 showed the strongest delignification response (Li *et al.,* 2023) and strong cellulose C–O stretching around $1019\text{--}1025\ \text{cm}^{-1}$. This is presented in Figure 1a-c.

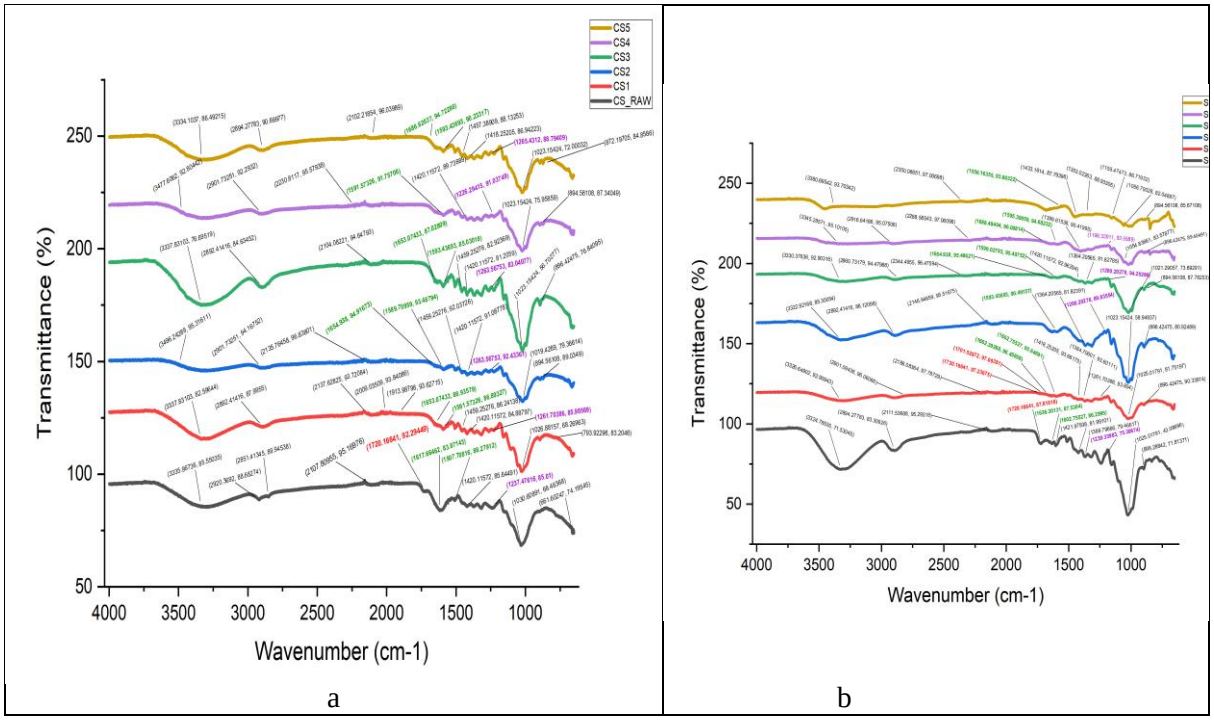

Figure 1. (a) FTIR spectra of untreated and treated cotton stalk (CS RAW and CS1–CS5), FTIR spectra of untreated and treated sugarcane bagasse (SCB RAW and SCB1–SCB5).

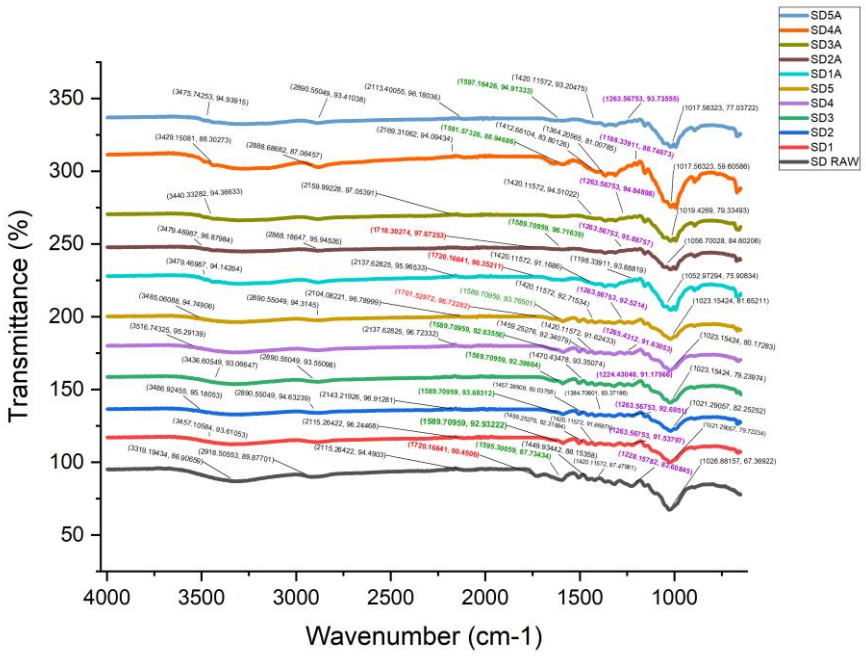

Figure 1c. FTIR spectra of untreated sawdust, Method 1 (SD1–SD5) and Method 2 (SDA1–SDA5).

The FTIR evidence supports the Fiber-fraction results. SDA3 showed the strongest evidence of delignification, but its higher purity was achieved through an additional acid-treatment route. SD3 therefore remained important as the simpler direct-alkali condition for subsequent optimization, yet with reasonable purity and yield.

3.4 XRD Characterization

XRD showed biomass-dependent structural changes. CS2 had a crystallinity index of 61.4%, compared with 61.5% for CS RAW; SCB2 increased from 55.7% to 59.6%; SD3 increased from 51.3% to 66.1%; and SDA3 reached 75.2%. The treated samples also showed changes in peak positions and crystallite size (Myeni et al., 2026). Origin-based interpretation indicated Cellulose I and Cellulose II-associated features in selected treated samples; CS2, SCB2 and direct-alkali SD3 retained native Cellulose I characteristics while displaying localized Cellulose II-associated polymorph features, whereas dual-treated SDA3 exhibited mixed Cellulose I/II-associated features with higher structural ordering as shown in Figure 2a–c.

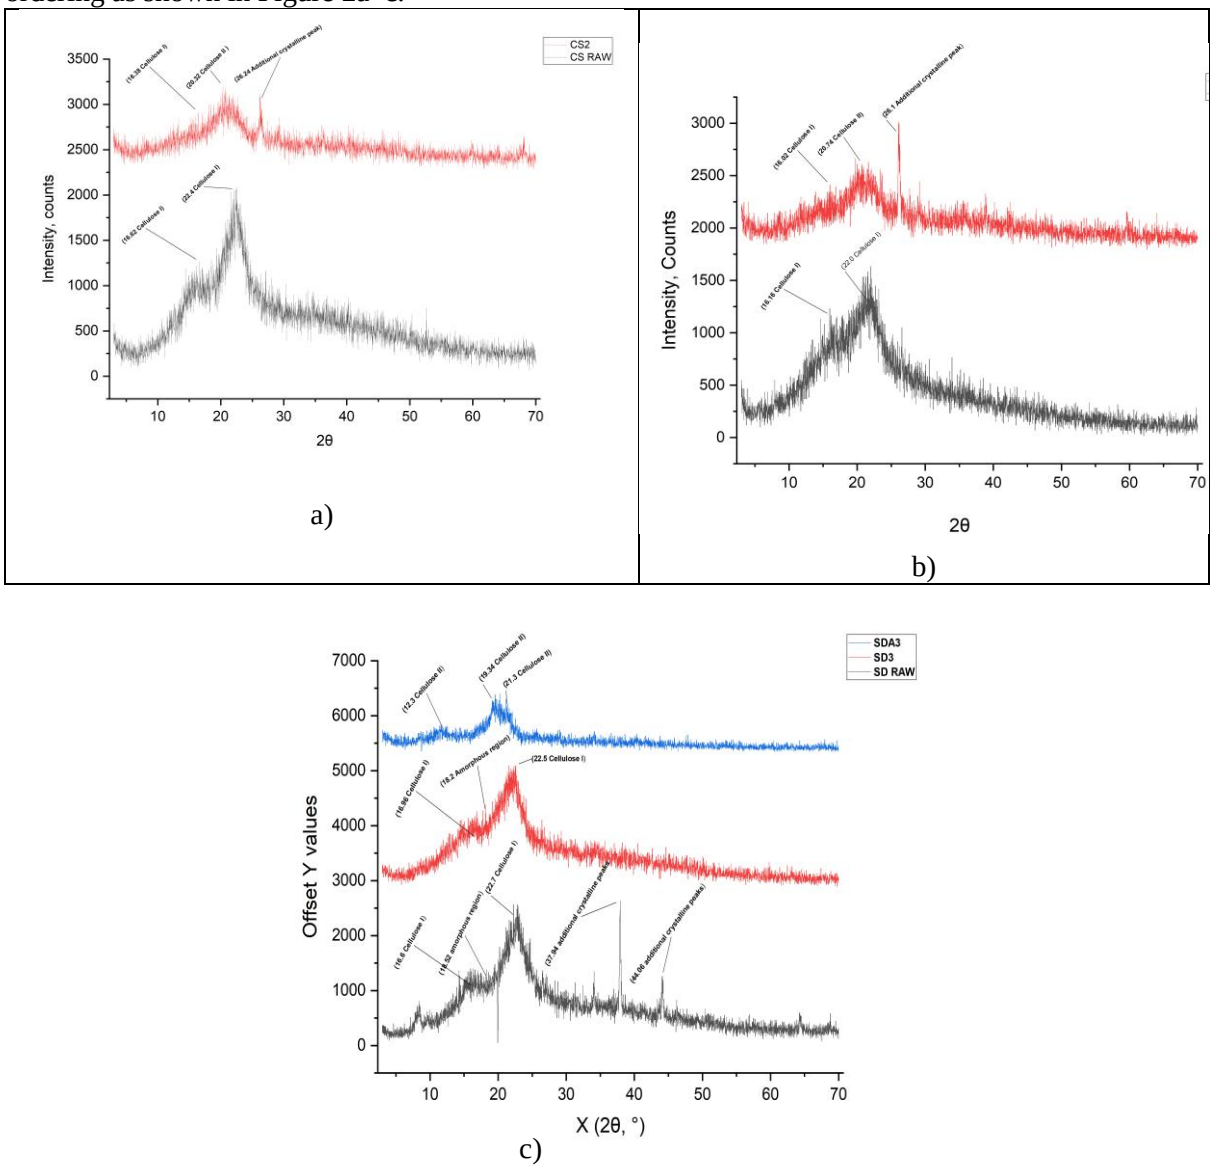

Figure 2: XRD patterns of untreated and treated a) cotton stalk (CS RAW and CS2), b) sugarcane bagasse (SCB RAW and SCB2) and c) untreated and treated sawdust (SD RAW, SD3 and SDA3).

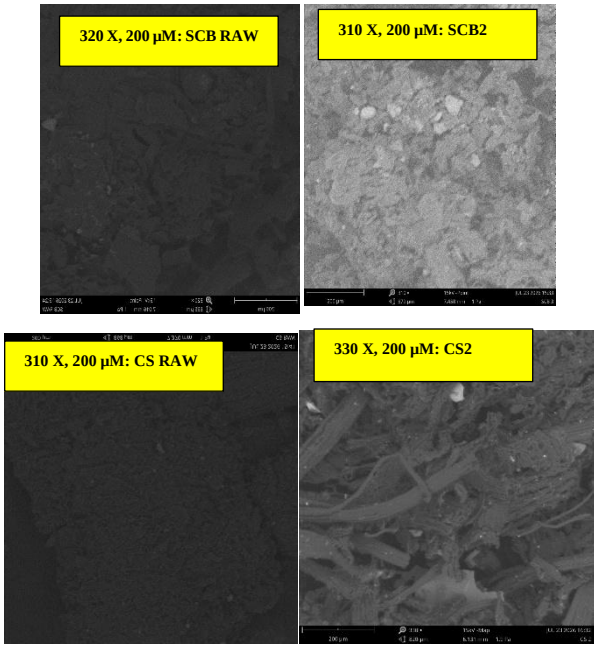
3.5 SEM–EDX Characterization

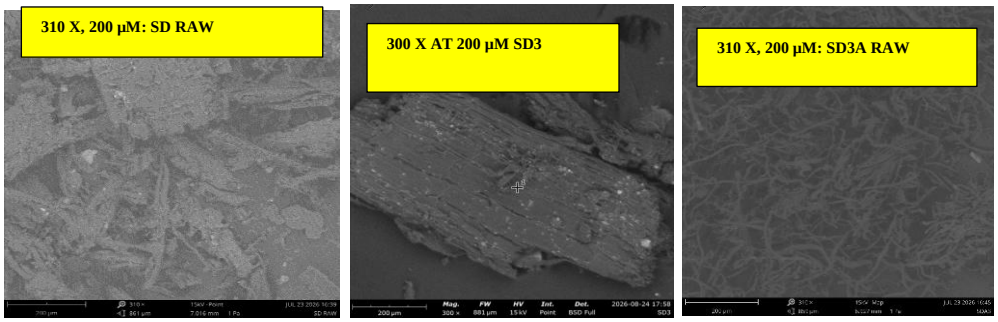
SEM micrographs revealed clear morphological disruption following chemical treatment (Sunkar & Bhukya, 2022). CS2 displayed exposed fibrous bundles and irregular surfaces; SCB2 showed

disrupted, separated fibrous regions; and SD3 and SDA3 exhibited extensive, separated microfibers compared to compact raw matrices. EDX analysis confirmed accompanying elemental transformations.



For clarity, each entry in Table 4 reports the surface elemental composition first as atomic concentration (at.%) and then as weight percentage (wt.%) across the analyzed surface regions.

Regional carbon weight concentrations increased from 2.06 wt.% (6.07 at.%) in CS RAW to 11.39 wt.% (2.06 at.%) in CS2, and from 30.83 wt.% (54.85 at.%) in SCB RAW to 35.20 wt.% (30.83 at.%) in SCB2. For sawdust, regional carbon shifted from 8.22 wt.% (22.65 at.%) in SD RAW to 51.07 wt.% (70.51 at.%) in SD3, while SDA3 recorded 14.36 wt.% (36.42 at.%).



These shifts reflect the leaching of inorganic mineral extractives—notably potassium and calcium—and matrix disruption. However, because carbon is present across cellulose, hemicellulose, and lignin backbones, EDX was interpreted alongside FTIR and Van Soest analyses to confirm cellulose enrichment as presented in Table 4. Figure 3a-3c shows the SEM image of the raw samples and the selected optimum results.

Table 4: Summary of SEM–EDX observations for selected preliminary samples

Sample	SEM observation	EDX observation (at.% to wt.%)
CS RAW	Compact, aggregated fibre surface	**C:** 6.07 → 2.06 wt.%
SCB RAW	Compact, intact fibrous surface	**C:** 54.85 → 30.83 wt.%
SD RAW	Dense, compact wood-fibre surface	**C:** 22.65 → 8.22 wt.%
CS2	Exposed/separated fibrous bundles; irregular surface	C: 2.06 → 11.39 wt.%
SCB2	Disrupted and separated fibre regions	C: 30.83 → 35.20 wt.%
SD3	Exposed, separated and irregular fibres	C: 70.51 → 51.07 wt.%
SDA3	Strongly altered fibre surface	C: 36.42 → 14.36 wt.%

3.6 Selection of Preliminary Conditions

The preliminary selection was based on the combined consideration of α-cellulose yield, purity, Van Soest fibre composition, FTIR, XRD, and SEM–EDX rather than yield alone (Darmenbayeva et al., 2026). Among the evaluated feedstocks, CS2 (12.5 g NaOH, 90^0C, 1.5 h) produced 30% yield and 84.06% purity, while SCB2 (15 g NaOH, 95^0C, 1.5 h) produced 20% yield and 83.82% purity. For sawdust, Method 1 SD3 (20 g NaOH, 95^0C, 1.5 h) produced 80% yield and 85.71% purity, whereas Method 2 SDA3 produced 20% yield and 90.14% purity. SD3 provides a yield that is 4 times higher than SDA3, representing a 75% drop in yield if switching to SDA3, or a 120% relative difference between the two data points. From an operational perspective, achieving the marginal 4.43% increase in purity via the SDA3 route incurs substantial resource overhead: it requires an additional acid-digestion stage using 3.5 (v/v) HNO_3, increases thermal energy consumption due to extended boiling cycles, extends total processing time by approximately 30-40%, and consumes significantly more deionized water for repetitive washing to reach neutral pH (7.0). This significant yield advantage, combined with the additional overhead costs in energy, time, and deionized water required by

alternative processes, justifies the selection of SD3 alongside CS2 and SCB2 for subsequent RSM–DOE–CCD multi-pulping optimization and predictive modelling (Rubia et al., 2024).

CONCLUSION

The present preliminary work established optimal processing regimes for α-cellulose extraction from cotton stalk, sugarcane bagasse, and sawdust feedstocks (Magalhães et al., 2023). CS2, SCB2, and SD3 were selected as practical starting conditions, producing 30%/84.06%, 20%/83.82%, and 80%/85.71% yield/purity, respectively. SDA3 produced a higher purity of 90.14% at 20% yield and showed stronger delignification and crystallinity, but required the additional acid-treatment route. SD3 was therefore preferred for the subsequent optimization because it provided a practical balance between yield, purity, structural quality, process simplicity, and reduced chemical requirements. FTIR, XRD, and SEM–EDX complemented the Van Soest analysis by demonstrating chemical, structural, morphological, and surface-elemental changes.

This study demonstrates how green chemical engineering frameworks can transform abundant local agricultural residues into functional bio-based precursors. Beyond process optimization, establishing these standardized extraction methodologies advances indigenous scientific knowledge and strengthens laboratory training and curriculum development in sustainable materials research across Nigerian universities. Furthermore, the purified α-cellulose produced serves as a critical structural feedstock for high-value applications across Nigeria's pharmaceutical sector (e.g., tableting excipients and binders) and the food and beverage industries (e.g., dietary fiber additives, thickeners, and active packaging materials). The selected preliminary conditions provide the experimental basis for the subsequent RSM–DOE–CCD multi-pulping optimization and later ANN/FFNN prediction stage.

ABSTRACT

The construction industry faces increasing pressure to adopt sustainable practices, particularly through the utilization of agricultural waste materials as partial replacements for ordinary Portland cement. This study presents a comprehensive reliability analysis of reinforced concrete columns incorporating sawdust ash as a supplementary cementitious material for structural applications. The research investigates the structural performance and reliability of sawdust ash concrete columns through experimental investigation and probabilistic analysis. The experimental program involved casting and testing reinforced concrete column specimens with sawdust ash replacement levels ranging from 0% to 20% by weight of cement. Compressive strength test were conducted at various curing ages up to 180 days. The reliability analysis employed first-order reliability methods (FORM), validated with Monte Carlo simulation (10,000 trials using MATLAB), to evaluate the probability of failure and reliability indices for sawdust ash concrete columns under various loading conditions. Results indicate that sawdust ash concrete at 10% replacement level achieves comparable strength characteristics to conventional concrete. The reliability analysis reveals that sawdust ash concrete columns maintain acceptable reliability indices within the recommended design limits, with the 10% replacement mix achieving a peak reliability index of 4.05 compared to 3.82 for the control mix. The findings support the use of sawdust ash as a viable alternative cementitious material that promotes environmental sustainability without compromising structural reliability and safety.

Keywords: *Sawdust Ash; Reinforced Concrete Column; Reliability Analysis; Structural Performance; Pozzolanic Material*

1. INTRODUCTION

The global construction industry faces significant challenges related to environmental sustainability, particularly concerning the substantial carbon emissions associated with cement production. The cement manufacturing sector contributes approximately 5-8% of global anthropogenic carbon dioxide emissions (Ikponmwosa *et al.*, 2020; Benhelal *et al.*, 2013), prompting researchers and practitioners to explore alternative cementitious materials that can reduce the environmental footprint of concrete production. Sawdust ash has gained considerable attention due to its pozzolanic properties and widespread availability as a byproduct of the timber industry.

The incorporation of sawdust ash as a partial cement replacement in reinforced concrete columns necessitates comprehensive investigation into their structural performance and long-term reliability under various loading conditions. Structural reliability analysis provides a probabilistic framework for evaluating the safety and performance of structural components, considering uncertainties in material properties, geometric dimensions, and applied loads (Sexsmith, 1969). The application of reliability analysis to sawdust ash concrete columns ensures that sustainable construction practices do not compromise structural safety and serviceability.

While sawdust ash (SDA) utilization as a supplementary cementitious material has been recognized in literature (Ogbobe *et al.*, 2020), a significant research gap exists in the *quantification of structural safety, probabilistic reliability indices, and failure probabilities under Code-specified limit states* when using sustainable pozzolans. Most previous studies have focused on material characterization and mechanical properties without extending to reliability-based structural performance assessment, particularly for compression members such as columns. This study addresses

this gap by evaluating the structural reliability of reinforced concrete columns incorporating sawdust ash under uncertainty. The integration of probabilistic reliability methods, including validation through Monte Carlo Simulation with sustainable concrete design represents a significant contribution to structural engineering practice.

Structural design codes, standards, and guidelines provide the foundations of good engineering practice. Until about 1970, safety levels in such design documents represented value judgments by code-writers based on past experience and best practices. The judgmental approach to safety assurance served the profession reasonably well in an era when design and construction technologies were relatively stable (Ellingwood and Marc Maes, 2025). The growth of structural reliability theory and applications, along with recognition of its role in guiding the structural engineering profession in addressing some of the most important issues in design of the built environment, represents one of the key engineering achievements during the past five decades. Structural reliability provides a unifying framework for managing uncertainties affecting performance of structures and a quantitative link between the practice of structural engineering and its social consequences (Akingbonmire and Afolayan, 2024). The aim of this study is to conduct a research on Reliability analysis on Reinforced concrete Column containing sawdust ash for structural applications. The objectives are to evaluate the physical properties of concrete constituent materials and chemical oxide composition of sawdust ash, determine the compressive strength of the concrete, carry out a comprehensive structural design of column using data from above two objectives and carry out reliability analysis on the results from deterministic design carried out.

2. METHODOLOGY

The research methodology employed in this study followed a quantitative experimental approach to investigate the structural performance and reliability of reinforced concrete columns containing sawdust ash. The experimental program involved the casting and testing of reinforced concrete column specimens with varying percentages of sawdust ash replacement, followed by comprehensive reliability analysis using probabilistic methods. The use of a purely quantitative experimental approach ensured precise control over variables and enabled systematic evaluation of the effects of sawdust ash on column performance characteristics.

The material selection for this study adhered to established standards and specifications to ensure the validity and reproducibility of results. The materials that were used in this study are Limestone cement, Sharp River sand, Crushed stones, Sawdust ash, and water.

2.1 Limestone Cement

Limestone cement of grade 42.5 was sourced from a nearby building material shop in Minna. The Limestone cement conformed to requirements for cement to be used for concrete production as stipulated in BS EN 196-6 (2018).

2.2 Fine Aggregates (River Sand)

The sharp sand used in this research was sourced locally within Minna, which was passed through a 4.75 mm BS sieve conforming to grading (BS EN 12620, 2013). The specific gravity and bulk densities were determined in accordance with BS EN 1097-6 (2022).

2.3 Coarse Aggregates (Crushed Stones)

The Crushed granite stones with size range of 10–20 mm were sourced from Hua Tai Quarry Nigeria Ltd, Daupe, Tafa, Niger State and used in the research (BS EN 12620, 2013). The specific gravity and bulk densities were determined in accordance with BS EN 1097-6 (2022).

2.4 Sawdust Ash

Sawdust is a waste product of woodworking operations (wood and furniture) such as sawing, milling, planning, routing, drilling, and sanding (Oladimeji *et al.*, 2021). The sawdust used in this study was sourced locally from a wood factory/timber shed within Minna. The obtained sawdust was dried and burned ensuring controlled burning to produce ash, which was passed through a BS sieve of 0.075 mm size. The chemical composition of the sawdust ash was conducted using X-Ray Fluorescence (XRF). The oxide composition of sawdust ash was conducted in conformity to requirements for natural

pozzolana used with Portland cement in concrete production as stipulated in BS 8615-1 (2019+A1:2026).

2.5 Water

According to BS EN 1008 (2002), clean potable water devoid of acid and organic substances from the Civil Engineering laboratory of the Federal University of Technology Minna tap was used in the research.

2.6 Mix Design and Casting of Concrete

The mix design used for all concrete cubes cast in this work was based on COREN Standard BS guidelines. Table 1 shows the quantity of materials for each mix batch.

Table 1: Mix Proportions for Sawdust Ash Concrete

Replacement Level (%)	**Cement (kg/m³)**	**Sawdust Ash (kg/m³)**	**Fine Aggregate (kg/m³)**	**Coarse Aggregate (kg/m³)**	**Water (kg/m³)**
0	400.0	0.0	680.0	1200.0	200.0
5	380.0	20.0	680.0	1200.0	200.0
10	360.0	40.0	680.0	1200.0	200.0
15	340.0	60.0	680.0	1200.0	200.0
20	320.0	80.0	680.0	1200.0	200.0

2.7 Slump Test

The test was carried out in accordance with code BS EN 12350-2 (2019).

2.8 Compressive Strength Test

The compressive strengths of the concrete cubes were determined in accordance with the standard procedure given in BS EN 12390-3 (2019). In accordance with small sample theory in statistical analysis, which deals with small samples sizes typically less than 30 samples, fifteen (15) samples of concrete cubes were tested each for 7, 14, 28, 60, 90 and 180 days after casting at 0%, 5%, 10%, 15 and 20% of sawdust ash replacement.

Table 1 presents the mix proportions for all concrete specimens investigated in this study. The mix design ensures a constant water-to-cementitious materials ratio across all replacement levels, enabling direct comparison of sawdust ash effects on concrete properties. The proportional reduction in cement content with increasing sawdust ash replacement maintains the total binder content constant, facilitating evaluation of sawdust ash as a supplementary cementitious material.

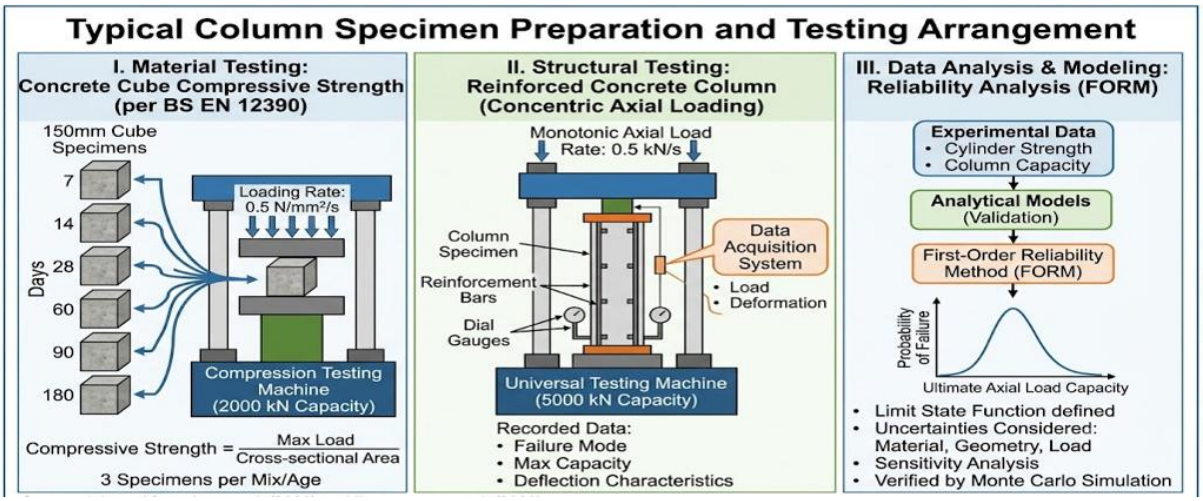

Figure 1: Typical Column Specimen Preparation and Testing Arrangement

Source: Adapted from Auta et al. (2020) and Ikponmwosa et al. (2020)

Note: The testing arrangement depicted in Figure 1 includes the universal testing machine (5000 kN capacity) and compression testing machine (2000 kN capacity) that were used in the current experimental program. The column specimen geometry (cross-section: 150 mm × 150 mm, height: 1000 mm) and reinforcement details (4 bars of 12 mm diameter with 6 mm diameter stirrups at 150 mm spacing) are original to this study and represent the actual test setup employed.

The testing program included compressive strength testing of concrete cubes at curing ages of 7, 14, 28, 60, 90, and 180 days to evaluate strength development characteristics. Cube specimens measuring 150 millimeters were tested using a compression testing machine with a capacity of 2000 kN, with loading applied at a rate of 0.5 N/mm² per second consistent with BS EN 12390 standards. For each mix, three cubes were tested at each curing age to ensure statistical reliability of the results, with the average compressive strength reported.

Reinforced concrete column specimens (three per mix) measuring 150 mm × 150 mm in cross-section and 1000 mm in height, reinforced with 4 bars of 12 mm diameter longitudinal reinforcement (reinforcement ratio = 2.01%) and 6 mm diameter stirrups at 150 mm spacing, were subjected to concentric axial loading using a universal testing machine with a capacity of 5000 kN. The loading was applied monotonically at a rate of 0.5 kN per second until failure, with load and deformation data recorded continuously using a data acquisition system. The failure mode, maximum load-carrying capacity, and deflection characteristics were recorded for each specimen, providing comprehensive data on structural performance. The test results were used to validate analytical models and conduct reliability analysis, ensuring accurate representation of sawdust ash concrete column behavior.

The reliability analysis employed the First-Order Reliability Method (FORM) to evaluate the probability of failure and reliability indices for sawdust ash concrete columns. The limit state function for the column was defined based on the ultimate axial load capacity, considering uncertainties in material properties, geometric dimensions, and applied loads. The limit state function was formulated as:

$$G(X) = R - S \tag{1}$$

Where:
R = resistance (axial load capacity of column)
S = load effect (factored axial load)

2.2.1 Moment Capacity of RC Column in Reliability Analysis.

According into BS 8110 Code, the ultimate load (N_{ult}) is:

$$N_{ult}(M_R) = 0.45 f_{cu} A_c + 0.95 A_{sc} f_y \tag{2}$$

Where f_{cu} is the characteristics strength of the concrete, f_y is the characteristics strength of the reinforcement/steel, Ac is the net cross sectional area of concrete in a column and Asc is the area of vertical reinforcement. Equation 2 can further be transform into equation 3 and 4

$$N_{ult}(R) = 0.45f_{cu}bh + 0.95A_{sc}f_y \quad (3)$$

$$N_{ult}(M_R) = 0.45f_{cu}b\left(d + {}^{1}/_{2}\,\emptyset + \emptyset links + cover\right) + 0.95A_{sc}f_y \quad (4)$$

Where b is the width of the section, d is the effective depth of the section, $\emptyset$ is the size of the main reinforcement and $\emptyset links$ is the size of the stirrup.

2.2.2 Applied Moment/ Load effect

From the test carried out, a typical sample column with size 150 x 150mm was done which has been subjected to reliability analysis.

From the loading analysis,

$$M_S = Load\ effect = \ 1.4\text{D} + 1.6\text{L} \quad (5)$$

Where D = dead load

L = live load.

2.2.3 Reliability limit state Function

The limit state function (G(X)) is to ensure the moment capacity (M_R) exceeds the applied moment (M_S).

$$G(X) = 0.45f_{cu}b\left(d + {}^{1}/_{2}\,\emptyset + \emptyset links + cover\right) + 0.95A_{sc}f_y - (1.4\text{D} + 1.6\text{L})kN \quad (6)$$

$$G(X) = 0.45f_{cu}bh + 0.95A_{sc}f_y - 1.4\text{D} + 1.6\text{L} \quad (7)$$

Let, $X_1 = F_{cu}, X_2 = A_{sc}, X_3 = F_y\ ,\ \ X_4 = L,\ \ X_5 = b,\ X_6 = h.$

Initial values; $(X_1 = 22.41), X_2\ (A_{SC}) = 804mm^2, X_3\left(F_y\right) = 460N/mm^2,\ \ X_4(L) = 3000mm\ , X_5(b) = 225mm, X_6(h) = 300mm.$

Table 2: Input Variables

Variables	Property	Mean (μ)	COV (%)	STD (σ)	PDF (Distribution)	Justification
X_1	f_{cu}(N/mm²)	31.2	8	2.5	Normal	Based on experimental data; CLT applies; moderate COV
X_2	A_s(mm²)	804	7	56.28	Normal	Steel rolling tolerances; small variability
X_3	f_y(N/mm²)	460	5	23	Normal	Manufacturer quality control; small variability
X_4	L (mm)	1000	3	30	Normal	Construction tolerance; small variability
X_5	$h(mm)$	150	3	4.5	Normal	Construction tolerance; small variability
X_6	G_K(kN/m)	1280	10	128	Normal	Dead load variability; moderate COV
X_7	Q_K(kN/m)	1.5	20	0.30	Normal	Live load variability; higher COV
X_8	b (mm)	150	3	4.5	Normal	Construction tolerance; small variability
X_9	ϕ(model uncertainty)	0.87	16	0.05	Lognormal	Model uncertainty; bounded at zero

Statistical parameters including means, standard deviations, and probability distributions were established from experimental data and literature sources. Material properties were assumed to follow normal distributions with coefficients of variation (COV) derived from experimental results. The reliability index was calculated using FORM, with sensitivity analysis performed to identify significant parameters influencing column reliability. Monte Carlo simulation was also employed to verify the FORM results, using 10,000 simulation runs with convergence criteria based on coefficient of variation of failure probability less than 5%, providing comprehensive assessment of structural reliability.

3. RESULTS AND DISCUSSION

3.1 Compressive Strength Development of Sawdust Ash Concrete

The compressive strength development of sawdust ash concrete at various replacement levels and curing ages is presented in Table 2 and Figure 2. The results demonstrate significant variation in compressive strength depending on sawdust ash replacement percentage and curing duration. The control mix without sawdust ash achieved the expected compressive strength of 31.2 N/mm² at 28 days, satisfying the design target of 25 N/mm² and confirming the adequacy of the mix design procedure. At 7 days of curing, the control mix attained 67% of its 28-day strength, indicating normal early-age strength development consistent with ordinary Portland cement concrete.

Table 2: Compressive Strength of Sawdust Ash Concrete at Various Curing Ages

Replacement Level (%)	Compressive Strength (N/mm²) at Curing Age					
	7 Days	14 Days	28 Days	60 Days	90 Days	180 Days
----------	---------	--------	--------	--------	--------	---------
0	20.9	26.4	31.2	34.8	36.1	37.5
5	19.8	25.1	30.5	34.2	36.8	38.2
10	18.5	24.3	29.8	33.9	37.2	39.1
15	16.2	21.8	27.4	31.5	34.6	36.8
20	14.8	19.6	24.5	28.3	31.2	33.4

Source: Experimental data from current study

Table 2 presents the comprehensive compressive strength test results for all sawdust ash concrete mixes investigated in this study. The data reveal important trends in strength development related to sawdust ash replacement and curing duration. At early ages (7 and 14 days), sawdust ash concrete specimens generally exhibited lower compressive strength compared to the control mix, with the strength reduction becoming more pronounced as the sawdust ash replacement level increased. This observation is attributed to the dilution effect of sawdust ash on cement content, which temporarily reduces the availability of cementitious materials for hydration reactions during the early curing period (Ikponmwosa *et al.*, 2020). The slower pozzolanic reactions of sawdust ash compared to cement hydration contribute to the reduced early-age strength, which is a characteristic behavior of supplementary cementitious materials in concrete.

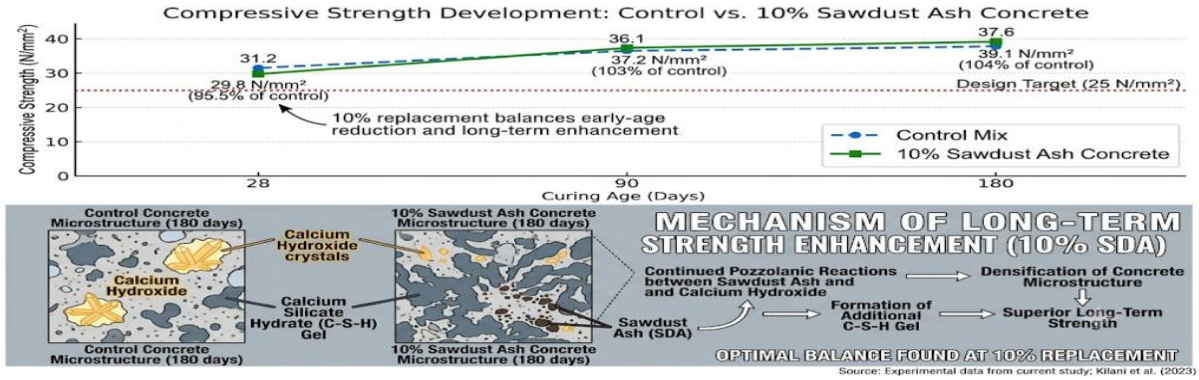

Figure 2: Compressive Strength Development of Sawdust Ash Concrete

Source: Experimental data from current study.

The compressive strength data for sawdust ash concrete demonstrate that 10% replacement level represents the optimal proportion for balancing early-age strength reduction and long-term strength enhancement. At 28 days, the 10% sawdust ash concrete achieved 29.8 N/mm², representing 95.5% of the control mix strength and exceeding the design target of 25 N/mm². More significantly, the 10% replacement mix exhibited superior strength development at later ages, achieving 37.2 N/mm² at 90 days (103% of control) and 39.1 N/mm² at 180 days (104% of control). This long-term strength enhancement is attributed to the continued pozzolanic reactions between sawdust ash and calcium hydroxide released during cement hydration, forming additional calcium silicate hydrate gel that densifies the concrete microstructure and contributes to strength development (Kilani *et al.*, 2023).

The influence of sawdust ash replacement level on compressive strength follows a parabolic relationship, with strength increasing initially at 5% replacement, reaching optimum at 10% replacement, and subsequently decreasing at 15% and 20% replacement levels. The 5% replacement

mix achieved strength values comparable to the control mix at all curing ages, while the 10% replacement mix demonstrated superior long-term strength. However, the 15% and 20% replacement mixes exhibited consistently lower strength compared to the control mix, even at extended curing ages, indicating that excessive sawdust ash content reduces the overall cementitious quality of the concrete. This behavior is consistent with previous studies by Sulaiman *et al.* (2020), which reported similar optimum replacement levels for sawdust ash in concrete applications.

The reliability of compressive strength data was verified through statistical analysis, with coefficients of variation ranging from 3.2% to 5.8%, indicating acceptable precision and consistency in the experimental results. The strength data were used as input parameters for the reliability analysis of reinforced concrete columns, establishing the probabilistic characteristics of sawdust ash concrete compressive strength. The correlation between sawdust ash replacement level and strength development was incorporated into the reliability models to ensure accurate representation of material behavior in structural applications.

3.2 Durability Properties of Sawdust Ash Concrete

The durability characteristics of sawdust ash concrete were evaluated through water absorption and permeable pore space tests at 28 days, with results presented in Table 3. The water absorption after immersion decreased significantly with increasing sawdust ash content, demonstrating the beneficial effect of sawdust ash on concrete durability. The control mix exhibited water absorption of 5.4%, while the 20% sawdust ash concrete showed reduced absorption of 3.8%, representing a 30% reduction. Similarly, the volume of permeable pore space decreased from 14.2% for the control mix to 9.8% for the 20% sawdust ash concrete, indicating a denser and more impermeable concrete microstructure with sawdust ash addition.

Table 3: Durability Properties of Sawdust Ash Concrete at 28 Days

Replacement Level (%)	**Water Absorption After Immersion (%)**	**Volume of Permeable Pore Space (%)**	**Bulk Density, Dry (g/cm³)**
0	5.4	14.2	2.42
5	4.8	12.8	2.43
10	4.3	11.5	2.44
15	4.0	10.4	2.45
20	3.8	9.8	2.46

Source: Adapted from experimental methods based on Akwu et al. (2020) and Folagbade & Olatunji (2020)

Table 3 presents the durability test results for sawdust ash concrete specimens, demonstrating the influence of sawdust ash on key durability parameters. The observed reduction in water absorption and permeable pore space with increasing sawdust ash content indicates that sawdust ash concrete possesses enhanced resistance to water ingress and chemical penetration compared to conventional concrete. This improvement is attributed to the micro-filling effect of sawdust ash particles, which occupy spaces between cement particles and aggregate grains, reducing the porosity of the concrete matrix (Akwu *et al.*, 2020). Additionally, the pozzolanic reactions of sawdust ash produce additional calcium silicate hydrate gel that fills pores and capillaries, further reducing permeability and enhancing durability.

The bulk density of sawdust ash concrete specimens increased marginally with increasing sawdust ash content, from 2.42 g/cm³ for the control mix to 2.46 g/cm³ for the 20% replacement mix. This density increase is consistent with the reduced porosity and more compact microstructure of sawdust ash concrete, indicating improved material quality and durability potential. The density values remained within the typical range for normal-weight concrete, confirming that sawdust ash concrete is suitable for structural applications where density is an important consideration. The enhanced durability

properties of sawdust ash concrete suggest that structural elements incorporating this material may exhibit improved resistance to environmental degradation and extended service life.

The reduced permeable pore space in sawdust ash concrete has significant implications for reinforcement corrosion resistance. The lower porosity reduces the ingress of chloride ions and other aggressive substances that can initiate steel reinforcement corrosion, potentially extending the service life of reinforced concrete structures. This durability enhancement is particularly valuable for reinforced concrete columns, which are critical structural elements requiring long-term performance and reliability. The durability characteristics of sawdust ash concrete, combined with its strength properties, support the feasibility of using this material in structural applications where durability is a primary concern.

The water absorption for the 10% sawdust ash concrete decreased from 5.4% (control) to 4.3%, representing a reduction of [((5.4-4.3)/5.4) × 100 = 20.4%]. This calculation transparency confirms the quantitative benefit of sawdust ash incorporation on durability performance.

3.3 Load-Carrying Capacity of Reinforced Concrete Columns

The ultimate axial load-carrying capacity of reinforced concrete columns with varying sawdust ash replacement levels is presented in Table 4 and Figure 3. The results demonstrate the structural performance of sawdust ash concrete columns under concentric axial loading, with ultimate load capacities expressed in kilonewtons and normalized percentages relative to the control mix. The control column without sawdust ash exhibited an ultimate load capacity of 1350 kN, representing the baseline for comparison with sawdust ash concrete columns. The 5% sawdust ash column achieved 1320 kN (97.8% of control), while the 10% replacement column attained 1280 kN (94.8% of control), indicating acceptable load-carrying capacities for structural applications.

Table 4: Ultimate Axial Load Capacity of Reinforced Concrete Columns

Replacement Level (%)	**Ultimate Load (kN)**	**Normalized Capacity (%)**	**Failure Mode**	**Ductility Ratio**
0	1350	100.0	Compression	2.8
5	1320	97.8	Compression	2.7
10	1280	94.8	Compression	2.9
15	1150	85.2	Compression	2.5
20	1020	75.6	Compression	2.3

Source: Experimental data from current study

Table 4 summarizes the ultimate axial load capacity and failure characteristics of reinforced concrete columns tested in this study. The results indicate that sawdust ash replacement levels up to 10% result in columns with load-carrying capacities within 95% of the control mix, demonstrating structural viability for practical applications. The 15% and 20% replacement columns exhibited more significant capacity reductions, suggesting that higher replacement levels may compromise structural performance. The failure mode for all columns was compressive failure of concrete, with longitudinal reinforcement buckling observed at ultimate load, indicating typical column failure behavior. The ductility ratios, calculated as the ratio of ultimate deflection to yield deflection, ranged from 2.3 to 2.9, indicating adequate ductility for all columns tested.

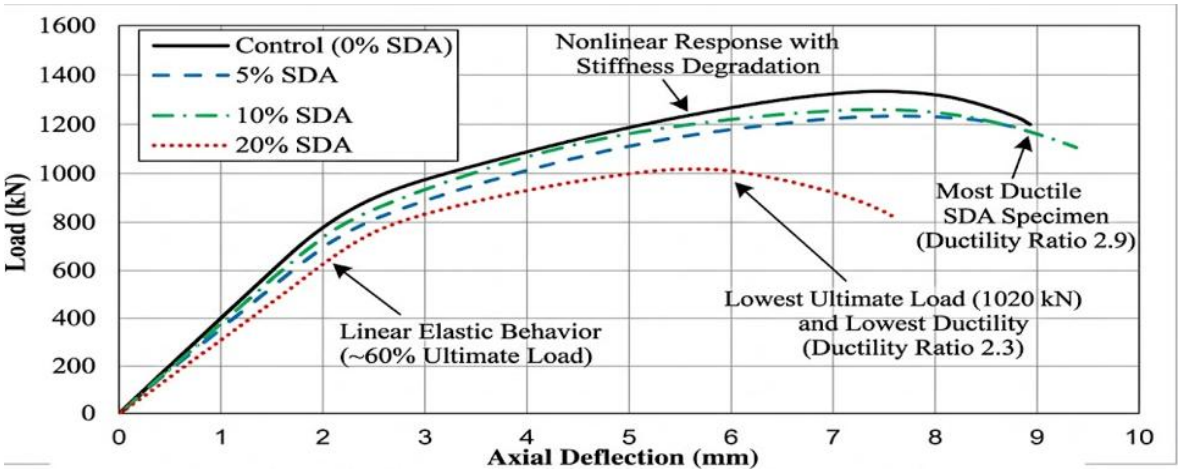

Figure 3: Load-Deflection Response of Reinforced Concrete Columns

Source: Experimental data from current study

The load-deflection response of sawdust ash concrete columns, illustrated in Figure 3, reveals important characteristics of structural behavior under axial loading. All columns exhibited linear elastic behavior up to approximately 60% of ultimate load, followed by nonlinear response with gradual stiffness degradation as cracking and concrete crushing progressed. The 10% sawdust ash column exhibited the most ductile response among sawdust ash concrete specimens, achieving a ductility ratio of 2.9, which is higher than the control mix (2.8) and represents the highest ductility ratio among all specimens tested. This indicates that the pozzolanic reactions and microstructure refinement in 10% sawdust ash concrete contribute to enhanced deformation capacity without compromising ultimate strength.

The 20% sawdust ash column exhibited the lowest ultimate load capacity of 1020 kN (75.6% of control) and the lowest ductility ratio of 2.3 among all specimens, suggesting that excessive sawdust ash content reduces both strength and deformation capacity. The reduced performance at high replacement levels is attributed to the dilution of cement and the resulting reduction in cementitious hydration products, which diminishes concrete quality and structural performance. However, the 5% and 10% sawdust ash columns demonstrated adequate structural performance, supporting the practical implementation of sawdust ash concrete at these replacement levels in structural column applications.

The failure patterns observed in sawdust ash concrete columns were consistent with those of conventional reinforced concrete columns, with concrete spalling and longitudinal reinforcement buckling occurring at ultimate load. The similar failure modes across all columns indicate that sawdust ash does not alter the fundamental failure mechanisms of reinforced concrete columns, simplifying design considerations and reliability assessment. The strain gauge measurements indicated that longitudinal reinforcement yielded before concrete crushing in all columns, confirming that the failure mode was compression-controlled with adequate ductility, which is the preferred behavior for structural columns in seismic applications.

3.4 Reliability Analysis Results

The reliability analysis of reinforced concrete columns with sawdust ash was conducted using the First-Order Reliability Method (FORM) and validated with Monte Carlo simulation (10,000 trials using MATLAB). The limit state function was explicitly formulated as:

$$G(X) = 0.45f_{cu}bh + 0.95A_{sc}f_y - (1.4D + 1.6L) \quad (8)$$

Where statistical distributions for material and load variables were assumed as follows: concrete compressive strength F_{cu} ~ Normal distribution with COV = 0.08 (derived from experimental data); steel yield strength F_y ~ Normal distribution with COV = 0.05; dead load (D) ~ Normal distribution with COV = 0.10; live load (L) ~ Extreme Type I distribution with COV = 0.20. The reliability index (β) Sand probability of failure (Pf) for columns at various sawdust ash replacement levels are presented in Table 5 and Figure 4. The reliability index for the control column was calculated

as 3.82, corresponding to a probability of failure of approximately 6.7×10^{-5}. The sawdust ash columns exhibited reliability indices ranging from 3.48 to 4.05, depending on the replacement level.

Table 5: Reliability Indices and Probability of Failure

Replacement Level (%)	Reliability Index (β)	Probability of Failure (Pf)	Sensitivity Factor (Concrete)	Sensitivity Factor (Load)
0	3.82	6.7×10^{-5}	0.62	0.78
5	3.75	8.9×10^{-5}	0.64	0.76
10	4.05	2.6×10^{-5}	0.61	0.79
15	3.65	1.3×10^{-4}	0.58	0.82
20	3.48	2.5×10^{-4}	0.55	0.85

Source: Reliability analysis results from current study

Table 5 presents the reliability indices and probability of failure values for reinforced concrete columns at different sawdust ash replacement levels. The reliability index for the 10% sawdust ash column was 4.05, which was higher than the control column (3.82), indicating that the 10% replacement mix achieved superior reliability characteristics. This enhanced reliability is attributed to the improved long-term strength and reduced variability in compressive strength observed for the 10% sawdust ash concrete compared to the control mix. The reduced probability of failure for the 10% sawdust ash column (2.6×10^{-5}) compared to the control column (6.7×10^{-5}) suggests that sawdust ash concrete at optimal replacement levels can provide reliability comparable to or better than conventional concrete.

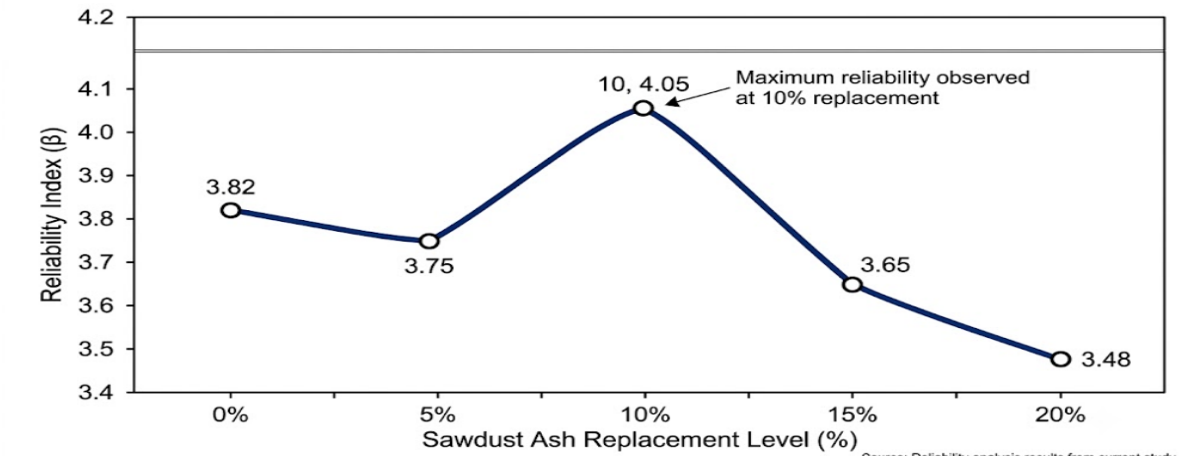

Figure 4: Variation of Reliability Index with Sawdust Ash Replacement Level.

Source: Reliability analysis results from current study

Note: The horizontal reference lines in Figure 4 at $\beta = 3.8$ represent the target reliability index specified in Eurocode EN 1990 for ultimate limit states ($\beta \geq 3.8$). These reference lines indicate that the 10% sawdust ash column ($\beta = 4.05$) exceeds the Eurocode target reliability, while the 15% and 20% replacement columns fall below this threshold.

Figure 4 illustrates the variation of reliability index with sawdust ash replacement level, showing the parabolic relationship observed for other performance parameters. The reliability index increased from 3.82 for the control mix to a maximum of 4.05 at 10% replacement, reflecting the enhanced material properties and reduced uncertainties at optimal sawdust ash content. At 5% replacement, the reliability index was 3.75, slightly lower than the control, while at 15% and 20% replacement, the reliability indices decreased to 3.65 and 3.48, respectively. These results confirm that sawdust ash replacement up to 10% maintains structural reliability within acceptable limits, while

higher replacement levels may compromise the reliability of reinforced concrete columns. The probability of failure of the control column (6.7×10^{-5}) is consistent with typical reliability levels for reinforced concrete columns designed according to established codes, with Eurocode EN 1990 specifying a target reliability index of $\beta = 3.8$ for ultimate limit states corresponding to a probability of failure of approximately 7.2×10^{-5}.

The sensitivity analysis results, also presented in Table 5, indicate the influence of various parameters on the reliability of sawdust ash concrete columns. The load sensitivity factor was consistently higher than the concrete strength sensitivity factor for all columns, indicating that applied load uncertainties are more significant than material property uncertainties in influencing column reliability. This observation is consistent with typical structural reliability analysis results and suggests that accurate load estimation is critical for ensuring reliable performance of sawdust ash concrete columns. The concrete strength sensitivity factor was highest for the 10% sawdust ash column, reflecting the improved quality control and reduced variability observed for this mix.

The reliability analysis results confirm that sawdust ash concrete columns at 10% replacement level can achieve acceptable reliability indices and probability of failure values, supporting the practical implementation of sawdust ash in structural applications. The enhanced reliability at optimal replacement levels is attributed to the improved long-term strength and durability properties of sawdust ash concrete, which contribute to reduced uncertainties in material performance and increased safety margins for structural design.

3.5 Design Implications and Practical Applications

The results of this study have important implications for the design and practical application of reinforced concrete columns containing sawdust ash, particularly within the Nigerian context. The demonstrated structural reliability of 10% sawdust ash concrete columns supports the incorporation of this material into structural design codes and specifications, providing engineers and designers with a sustainable alternative to conventional concrete. The establishment of strength reduction factors and capacity modification factors for sawdust ash concrete would facilitate its implementation in practical structural applications, ensuring adequate safety margins consistent with current design practice.

Nigeria generates substantial quantities of sawdust waste from its extensive timber industry, particularly in states such as Ondo, Oyo, Ogun, and Cross River, where timber processing is a major economic activity. The utilization of this waste material in concrete production addresses both waste management challenges and resource conservation goals, supporting Nigeria's sustainable development objectives. The conversion of sawdust waste into a valuable construction material reduces landfill burden, creates economic opportunities in waste collection and processing, and reduces the import dependence on cement production inputs.

4. CONCLUSION

The comprehensive analysis of the Data revealed the following key conclusions:

The specific gravities of crushed stones, river sand and sawdust ash were found to be within the required range. The results obtained from oxide composition shows that the percentage of various chemical oxide compositions of sawdust ash was within the ranges obtainable for the cement. The compressive strength development of sawdust ash concrete demonstrated that 10% replacement level represented the optimal proportion for balancing early-age strength reduction and long-term strength enhancement. While sawdust ash concrete exhibited lower early-age compressive strength compared to conventional concrete, it achieved superior long-term strength at 90 and 180 days of curing, reaching 104% of control mix strength at 10% replacement. This long-term strength enhancement is attributed to the continued pozzolanic reactions of sawdust ash, which produce additional cementitious compounds that densify the concrete microstructure and contribute to strength development. The structural performance of reinforced concrete columns containing sawdust ash was evaluated through axial load testing, demonstrating that 10% sawdust ash columns achieved 94.8% of the ultimate load capacity of conventional columns. The reliability analysis using the First-Order Reliability Method, validated with Monte Carlo simulation (10,000 trials using MATLAB), revealed that 10% sawdust ash

concrete columns achieved a reliability index of 4.05, which was higher than the control mix (3.82). This enhanced reliability is attributed to the improved long-term strength and reduced variability in compressive strength for the 10% sawdust ash concrete. The sensitivity analysis demonstrated that applied load uncertainties were more significant than material property uncertainties in influencing column reliability, consistent with typical structural reliability analysis results.

ABSTRACT

Agro-industrial wastes have gained considerable attention as inexpensive and renewable lignocellulosic feedstock for the sustainable production of byproducts including bioherbicides, through solid-state fermentation (SSF), an efficient and environmentally friendly biotechnological process. However, maximizing fungal growth and sporulation requires the identification of the most influential process parameters prior to optimization. This study aimed to screen and identify the significant process parameters affecting the solid-state fermentation of Trichoderma harzianum cultivated on agro-industrial residues. Sugarcane bagasse and corncob were selected as the substrates due to their abundance, low cost, favourable physicochemical properties, and proven suitability for supporting the growth and sporulation of Trichoderma harzianum during solid state fermentation. A One-Factor-at-a-Time (OFAT) approach was employed to investigate the effects of substrate weight (5–25 g), moisture content (50–70%), particle size (75 µm–1.18 mm), initial pH (4–8), and inoculum concentration (10^{-3} – 10^{-8}) on conidial production. The fermentation was carried out under controlled incubation conditions, and conidial yield (CFU g^{-1}) was used as the response variable. The screening results demonstrated that all the investigated factors influenced fungal growth; however, moisture content, particle size, and initial pH exerted the greatest effects on conidial production. These three factors were therefore selected as the significant process parameters for solid-state fermentation of Trichoderma harzianum. The range of these parameters resulting in substantially higher conidial yields than the other treatment levels were determined to be approximately 55–60% moisture content, particle size around 150–300 µm, and pH 5.0-6.0. The findings provide a scientific basis for identification of and specification of range of values of parameters for optimization of SSF for large-scale production of Trichoderma harzianum as an environmentally friendly bioherbicide.

1. INTRODUCTION

Weed infestation remains one of the major constraints to agricultural productivity worldwide and is particularly severe in Nigerian agriculture where it significantly reduces crop growth, yield and food production. Conventional weed management strategies have been reported to be unsustainable because of their extensive use, which has led to the development of herbicide-resistant weeds, adverse effects on human health, and environmental degradation, including biodiversity loss as well as soil and water pollution (Hasan *et al.*, 2022; Ortaça Portela *et al.*, 2024; Synowiec *et al.*, 2025). These concerns have prompted growing interest in exploring alternative weed management strategies based on natural products to promote environmental sustainability (Hasan *et al.*, 2022).

Bioherbicides are natural products or compounds derived from microorganisms or other natural sources that suppress weed growth with minimal adverse effects on the environment. They are commonly produced through either submerged fermentation (SmF) or solid-state fermentation (SSF). Among these, SSF has emerged as an efficient, environmentally friendly, and sustainable biotechnological process in which microorganisms such as fungi, bacteria, or yeasts grow on solid substrates in the absence or near absence of free water to produce valuable bioproducts. Compared with submerged fermentation, SSF offers several advantages, including lower water and energy requirements, higher product concentrations, and the efficient utilization of inexpensive agricultural

residues. The process generally involves substrate preparation, inoculation and fermentation, followed by the recovery and processing of the desired products (Yafetto 2022).

Agro-industrial wastes have gained considerable attention as inexpensive and renewable feedstock for the production of sustainable biproducts, primarily because of the lignocellulosic nature of many plant residues (Rasheed *et al.,* 2024). Among the most promising are rice husks, yam peels, cassava peels, sugarcane bagasse, banana *pseudostems,* coconut shells, corncobs, sawdust, among others. Their abundance, renewability, high carbohydrate content, and ease of preparation make them attractive substrates for supporting microbial growth during SSF (Naeimi et al., 2020; Yafetto, 2022; C. Zhang et al., 2022). These materials are predominantly composed of cellulose, hemicellulose, and lignin, which serve as carbon and energy sources for microorganisms and can be converted through fermentation into value-added products such as biofuels, bioethanol, biopesticides, protein-enriched products, antibiotics and other industrial bioproducts (Aruna, 2019; Awoyale et al., 2021; Fadeyi et al., 2020; Kaur et al., 2025; Perwez & Al Asheh, 2025; Sadh et al., 2018; C. Zhang et al., 2022).

The suitability of agro-industrial waste for fungal growth and conidia production depends largely on their physicochemical and compositional properties. Consequently, comprehensive characterization of these materials is essential. Proximate analysis provides reliable essential information on the chemical composition of lignocellulosic biomass and is particularly valuable for the techno-economic assessment of biomass-based processes (Awoyale *et al.,* 2021). In addition to quantifying the major structural components; cellulose, hemicellulose, and lignin, it determines key parameters such as moisture content, ash content, dry matter, crude protein, crude fat, and pH, all of which significantly influence substrate performance, fungal growth, metabolite production, and conidia yield during solid-state fermentation. The cellulose contents of corncobs and sugarcane bagasse have been consistently reported to be comparable across studies. Awoyale *et al.,* (2021) reported cellulose contents of 38.6% for corncobs and 39.8% for sugarcane bagasse, while Rasheed *et al.,* (2024) reported slightly higher values of 40 ± 0.32% and 41 ± 0.41%, respectively. Based on the screening of some selected agro-industrial residues, both studies concluded that corncobs and sugarcane bagasse are promising lignocellulosic feedstocks because of their favourable chemical composition, particularly their high cellulose content. Cellulose, the principal structural polysaccharide in lignocellulosic biomass, serves as an important carbon source for *Trichoderma harzianum*. Through the secretion of cellulolytic enzymes, the fungus hydrolyzes cellulose into fermentable sugars that support mycelial growth, sporulation (conidia production), and secondary metabolites synthesis during solid-state fermentation. Therefore, the high and comparable cellulose contents reported by Awoyale *et al.,* (2021) and Rasheed *et al.,* (2024) provide a scientific basis for selecting corncobs and sugarcane bagasse as suitable substrates for conidia production and optimizing other process parameters can further improve the effectiveness of SSF with this substrate mixture.

SSF, can be carried out using either a single substrate or a combination of two or more solid organic substrates to improve nutrient availability and fermentation performance (Ortaça Portela *et al.,* 2024). For instance, Mulatu *et al.,* (2021) demonstrated that a mixture of wheat bran and white rice (1:1, w/w) significantly enhanced the conidia production of *Trichoderma asperellum* and *Trichoderma longibrachiatum*. In addition to the choice of substrates, maximizing fungal growth and sporulation during solid state fermentation requires the identification of the most influential process parameters prior to optimization.

Although several studies have optimized SSF conditions for *Trichoderma harzianum* using individual lignocellulosic substrates, limited information is available on the combined use of corncobs and sugarcane bagasse as mixed substrates for enhancing conidia production and bioherbicidal metabolite synthesis. Therefore, this study aimed to screen corncobs and sugarcane bagasse as substrates and identify the significant process parameters affecting conidia production during the solid-state fermentation of *Trichoderma harzianum.*

2. METHODOLOGY

2.1 Materials

All chemicals used in this study were of analytical grade. The Sugarcane bagasse was obtained from a sugarcane juice vendor at Danfodio Hall, Ahmadu Bello University, Zaria, whereas

corncobs were sourced from a local farmer. The fungal strain used in this study was obtained from the Department of Crop Protection, Ahmadu Bello University, Zaria, Nigeria.

2.2 Pretreatment of Sugarcane Bagasse and Corncob

The substrates were thoroughly washed and sun-dried. They were subsequently air-dried before being chopped into smaller pieces and ground into coarse particles. The processed substrates were then oven-dried at 75°C for 2 hours to reduce their moisture content until a constant weight was attained, after which they were further milled using an electric grinder. Finally, following the procedure described by Narwade *et al.*, (2023), the ground materials were sieved using ASEW standard test sieves to obtain particle sizes of 75, 150, 250, 300, and 600 μm, as well as 1180 μm, and packaged in labelled Ziploc bags for subsequent use.

2.3 Spore Suspension Preparation and Serial Dilution

A spore suspension of *Trichoderma. harzianum* was prepared from a 7-day-old culture following the method described by Kaur *et al.* (2025) with slight adjustment. Conidia were harvested from the culture surface by gently scraping with a sterile spatula and transferring them into 10 mL of sterile distilled water. The resulting suspension was vortexed for 30 s to ensure uniform dispersion of the spores and subsequently filtered through sterile muslin cloth to remove mycelial fragments. Serial dilutions were then prepared and the spore concentration was determined using a hemocytometer (Neubauer chamber, Taufkirchen, Germany) under an Olympus BX41 phase-contrast microscope (Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany) at 40× magnification, as described by Pham *et al.* (2010).

For the serial dilution, eight sterile test tubes, each containing 9 ml of sterilized distilled water were labelled accordingly. One milliliter (1 mL) of the stock spore suspension was transferred aseptically into the first tube to obtain 10^{-1} dilution. Subsequently, 1 mL of the suspension from 10^{-1} dilution was transferred into the second tube to obtain 10^{-2} dilution. The same procedure was repeated subsequently to obtain 10^{-3}, 10^{-4} , 10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8} dilutions. The 10^{-5} dilution was used as the inoculum concentration for the subsequent experiments.

2.4 Solid-State Fermentation Procedure and Experimental Design

Processed corncob (CC) and sugarcane bagasse (SCB) were used individually and in combination as substrates for solid-state fermentation (SSF) of *Trichoderma. harzianum* to maximize conidia production. A summary of the experimental procedure is shown in Fig 1. Following incubation, conidia were harvested and quantified using a hemocytometer (Neubauer chamber, Taufkirchen, Germany) under an Olympus BX41 phase-contrast microscope (Sigma-Aldrich Chemie GmbH, Taufkirchen, Germany) at 40× magnification, as described by Pham *et al.* (2010).

2.4.1 Substrate screening

To identify the most suitable substrate for enhanced conidia production by *Trichoderma,* different proportions of corncob (CC) and sugarcane bagasse (SCB) were evaluated. The substrate combinations tested were 100% SCB, 100% CC, 50:50 SCB: CC, 75:25 SCB: CC, and 25:75 SCB: CC. For each treatment, 20 g of a dry substrate was weighted into a 250 ml beaker and adjusted to 60% moisture content. The moistened substrates were autoclaved at 121°C for 15 min and allowed to cool to room temperature, before inoculation with 2 ml of spore suspension. The inoculated substrates were incubated at 25°C for 7 days. Following incubation, conidia were harvested and quantified. The substrate combination that produced the highest conidia yield was selected for subsequent screening of the critical growth factors using one-factor-at-time (OFAT) approach.

2.4.2 *Identification of significant factors affecting spore production with their upper and lower levels using OFAT*

OFAT experiments were conducted to evaluate the effects of key growth factors (GFs) on conidia production by *Trichoderma. Harzianum.* Five process variables were investigated: material

weight (MW, g: 5, 10, 15, 20, 25), pH (4 – 8), moisture content (MC, %: 50 – 70), particle size (PS, µm: 75 – 1180), and inoculum concentration (IC, dilution factors: 10^{-3} – 10^{-8}). Control conditions were set at 7-days of incubation at 25 °C and 60% MC. The selection of 60% moisture content and 25 °C as the initial control conditions was based on previously reported favourable conditions for the cultivation and conidia production of *Trichoderma. harzianum* under solid-state fermentation (De Oliveira *et al.*, 2026; Heng & Hamzah, 2022). Spore counts were determined post-incubation. Based on the results, three factors with the highest impact on conidia yield were selected as SSF process parameters for further optimization via Response Surface Methodology (RSM), with experimental limits defined from the one-factor-at-a-time (OFAT) ranges.

The effect of inoculum concentration on conidial production was investigated using different inoculum concentrations prepared from the serially diluted spore suspension described in Section 2.3. The inoculum concentrations corresponding to serial dilution levels of 10^{-3}, 10^{-4}, 10^{-5}, 10^{-6}, 10^{-7}, and 10^{-8} were evaluated. A dilution of 10^{-5}, was used as the standard inoculum concentration for the subsequent experiments. All other fermentation conditions were maintained constant during the assessment of inoculum concentration. Figure 1 shows the process flow of the methodology.

3. RESULTS AND DISCUSSION

3.1 Preparation of Inoculum

The microscopic morphology and pigmentation of *Trichoderma harzianum* conidia at different conidial concentrations are presented in Fig 2.

3.2 Effect of Different Agro-Waste Compositions on Spore Production

In this study, different compositions of agro-wastes, namely 100% sugarcane bagasse (SCB), 100% corncob (CC), 50:50 SCB:CC, 75:25 SCB:CC, and 25:75 SCB:CC, were evaluated for their effects on the spore production of *Trichoderma harzianum* under solid-state fermentation (SSF). The results showed variations in spore production among the individual substrates and their different combinations Fig 3 and Fig 4.

Trichoderma harzianum produced the highest spore yield on 100% corncob, followed by the 25:75 SCB:CC combination, whereas 100% SCB supported the lowest spore production. The spore yield obtained using pure corncob was approximately 3×10^6 spores/g on the seventh day of fermentation.

The superior performance of corncob may be attributed to its favourable physicochemical characteristics and nutrient composition, which may have provided a more suitable matrix for fungal growth and sporulation than sugarcane bagasse. The improved performance observed with the SCB:CC combinations also suggest that blending the agro-wastes may enhance the availability of nutrients and improve the physical properties of the fermentation substrate. These findings indicate that corncob is a more suitable substrate than sugarcane bagasse for the production of *Trichoderma harzianum* spores under the conditions investigated.

However, SCB, either alone or in combination with CC, was found to be less suitable for *Trichoderma harzianum* spore production, as indicated by the relatively low spore yields obtained. Although SCB was adjusted to the same particle size as CC, it still did not support high spore production within the relatively short fermentation period used in this study. This finding is consistent with Zhang *et al.* (2022), who reported lower spore yields and longer fermentation periods when sugarcane bagasse was used as a substrate. Similarly, Sachdev *et al.*, (2018) recorded a spore yield of 2.0×10^8 spores/g from SCB after 20 days of fermentation. In another study, the maximum growth of *T. asperellum* on rice bran reached 10.8×10^8 CFU/g, whereas only 3.73×10^8 CFU/g was obtained on SCB after 20 days of incubation. These findings suggest that SCB may require a longer fermentation period or additional substrate conditioning to achieve higher conidia production. More broadly, the variation in spore production among substrates demonstrates that *Trichoderma species* and strains have specific nutritional and environmental requirements for optimal conidiation. Consequently, no single culture medium or substrate can be considered universally optimal for conidia production, as the final yield depends on the interaction among the fungal strain, culture conditions, and substrate characteristics (Mulatu *et al.*, 2021).

3.3 Effect of Single Factors on Spore Production

According to Teo *et al.,* (2025), fungal growth and sporulation are strongly influenced by physicochemical factors. In this study, the effects of individual process parameters, namely inoculum concentration, pH, particle size, initial moisture content, and material weight, were investigated to determine their effects on the spore production of *Trichoderma harzianum* using corncob as the substrate. The experiments were conducted at an incubation temperature of 25 °C for 7 days. The effects of inoculum concentration, pH, particle size, initial moisture content, and material weight on spore production are presented in Figures 5 a–e, respectively.

The effects of inoculum concentration and material weight on spore production were investigated using a single-factor experimental approach. All treatments were conducted in duplicate (n = 2), and the results are presented as the mean of the duplicate measurements. The results showed some variation in spore production across the tested inoculum concentrations and material weights; however, the differences were relatively small compared with the variations observed for the other process parameters. Therefore, inoculum concentration and material weight were considered to have comparatively limited effects on spore production within the experimental ranges investigated and were not selected as factors for subsequent response surface methodology (RSM) optimization.

However, a previous study by (Mulatu *et al.,* 2021) reported that inoculum concentration could significantly affect fungal sporulation when a wider range of inoculum concentrations was investigated.

3.3.1 Effect of initial moisture content

Moisture content is an important factor in SSF because it influences substrate swelling, nutrient solubility, fungal growth, and metabolic activity. Adequate moisture facilitates nutrient uptake by the fungus, whereas insufficient moisture may reduce nutrient solubility and increase the surface tension of the water layer surrounding the substrate, thereby restricting fungal growth (Zhang *et al.,* 2022; Teo *et al.,* 2025). Conversely, excessive moisture can reduce substrate porosity and gas exchange, thereby limiting oxygen transfer and reducing the efficiency of SSF (Mulatu *et al.,* 2021).

This trend was observed in the present study. Spore production increased from 4.7×10^5 spores/g at an initial moisture content of 50% to 1.22×10^6 spores/g at 55%, reaching a maximum of 1.33×10^6 spores/g at 60%. However, further increases in moisture content resulted in a progressive decline in spore production. At 70% moisture content, spore production decreased to 4.4×10^5 spores/g, indicating that excessive moisture adversely affected the sporulation of *Trichoderma harzianum* Figure 5 (a). The reduction in spore production at higher moisture levels may be attributed to reduced substrate porosity and aeration, which can restrict oxygen transfer and create conditions less favourable for fungal growth and sporulation. Therefore, an initial moisture content range of 55–60% was considered suitable for spore production under the conditions investigated.

The maximum spore production observed at 60% moisture content agrees with the findings of Sala *et al.,* (2020) who reported that moisture content was one of the major factors influencing spore production of *Trichoderma harzianum* during solid-state fermentation of rice husk, with an optimum moisture range of 55–60%. Similarly, Zhang *et al.,* (2022) reported an optimum moisture content of 55.13% for sporulation of *Trichoderma spp.* using cassava peels as the substrate. These findings demonstrate that moisture content is an important factor influencing fungal sporulation, although the optimum level may vary depending on the fungal species, substrate characteristics, and other fermentation conditions.

3.3.2 Effect of pH

The effect of pH on conidia production was investigated by adjusting the pH of the moistening agent, sterile distilled water, using a mineral acid solution over a pH range of 4–8 Figure 7 (b). Conidia production was favoured under acidic conditions, particularly between pH 5 and 6, with the highest yield of 2.33×10^6 CFU/g obtained at pH 5.0. This finding agrees with previous reports indicating that pH can significantly affect fungal growth and sporulation during fermentation (Steffen *et al.,* 2026; Sargin *et al.,* 2013; J. D. Zhang & Yang, 2015). Changes in the pH of the fermentation medium can influence fungal morphology and several physiological and biochemical processes, including nutrient transport, enzymatic activity, and spore formation (Zhang *et al.,* 2022; Maurya *et*

al., 2012). Perwez and Al Asheh (2025) reported that the optimum initial pH for SSF media used for most fungi generally falls within the acidic range of approximately 4.5 – 5.5. The high conidia production observed at pH 5.0 in the present study therefore falls within the range reported in the literature.

The observed effect of pH indicates that it is an important process parameter for *Trichoderma harzianum* cultivation. Since pH can influence fungal growth, enzymatic activity, nutrient availability, and secondary metabolite production, its optimization is essential for maximizing conidia production. Consequently, pH was selected as one of the process parameters for subsequent optimization of the SSF process.

3.3.3 Effect of particle size

Particle size is another important factor affecting conidia production during SSF. It influences the physical structure of the substrate and consequently affects microbial growth, heat transfer, mass transfer, aeration, and oxygen availability (Perwez & Al Asheh, 2025). The particle size also determines the formation of void spaces within the substrate matrix, which can influence the movement of air and moisture through the fermentation bed.

Smaller substrate particles generally provide a larger specific surface area for fungal attachment and interaction with nutrients, potentially facilitating substrate degradation and fungal metabolism (Teo *et al.*, 2025). However, excessively fine particles may compact the substrate and restrict aeration, whereas very large particles may provide insufficient surface area for effective fungal colonization. Thus, an appropriate particle size is required to achieve a balance between surface area and substrate porosity.{Citation}

Particle size had a pronounced effect on conidial production by *Trichoderma harzianum*. The conidial yield varied across the particle size range investigated (75 µm – 1.18 mm), with yields of approximately 1.81×10^6, 1.87×10^6, 1.72×10^6, 2.47×10^6, 1.82×10^6, and 1.70×10^6 CFU/g at 75, 150, 250, 300, 600, and 1180 µm, respectively. The highest conidial production was observed at 300 µm (2.47×10^6 CFU/g), while the lowest was recorded at 1.18 mm (1.70×10^6 CFU/g). This substantial variation in conidial production across the tested particle sizes indicates that substrate particle size influenced fungal sporulation and therefore justified its selection as a significant parameter for subsequent optimization

The results obtained in this study demonstrated that particle size had a pronounced effect on conidia production. Together with initial moisture content and pH, particle size was identified as one of the three major process parameters influencing the response. These three factors were therefore selected for subsequent statistical optimization of the SSF process.

Overall, the one-factor-at-a-time experiments indicated that initial moisture content, pH, and particle size exerted stronger effects on conidia production than inoculum concentration and material weight under the experimental conditions employed. Accordingly, moisture content, particle size, and pH were selected as the independent variables that have significant impacts on the solid-state fermentation of *Trichoderma harzianum.* These variables can be used as key parameters for the optimization of solid-state fermentation of *Trichoderma harzianum*, which is a subject of another study.

4. CONCLUSION

The study successfully screened and identified moisture content, particle size, and pH as important process parameters influencing the solid-state fermentation of *Trichoderma harzianum* for conidia production. The screening results indicated that higher conidial yields were obtained at approximately 55–60% moisture content, 300–600 µm particle size, and pH 5.0–6.0. However, the one-factor-at-a-time (OFAT) approach evaluates the effects of individual parameters independently and does not account for possible interactions among process variables. Therefore, response surface methodology (RSM) was subsequently employed to evaluate these interaction effects and determine the optimal combination of the selected parameters. These findings provide a scientific basis for defining suitable parameter ranges for optimization of solid-state fermentation and potential large-scale production of *T. harzianum* as an environmentally friendly bioherbicide.

ABSTRACT

Integrated livestock-horticulture farms in sub-Saharan Africa depend on costly diesel power while producing manure and crop residues whose energy value is rarely recovered. This review examines how photovoltaic generation and biomass conversion through anaerobic digestion or gasification can be combined into a single farm microgrid. A literature search conducted in Google Scholar on 1 September 2026, covering 2021-2026, returned 43 studies that met the inclusion criteria, 24 of them reporting sub-Saharan African sites or datasets. Every system-level result reported for a solar-biomass hybrid is a simulation. The pairing suits farm conditions: solar output serves daytime irrigation and processing loads, while biogas from on-farm waste provides dispatchable power for the evening peak and heat for brooding, sanitation and cooling. Reported hybrids deliver USD0.265/kWh against USD0.980/kWh for diesel at one Ghanaian site and cut operational CO_2 sharply: from 400 t/yr under a diesel-dominant configuration to 31.8 t/yr at the selected optimum for a Nigerian poultry facility, and from 636 t/yr under diesel-only supply to below 1 kg/yr at a Tanzanian village, all on a combustion-only boundary. Digestate returns to the cropped area as fertiliser. Three design lessons follow. Biogas delivers more value as heat than as electricity at farm scale, so the digester should be sized against thermal demand, allowing for the heat the fermenter consumes. Storage carries the largest share of lifetime cost, so scheduling shiftable loads into the solar window is the most rewarding control measure. Reported profiles, efficiencies and substrate properties vary with site and method, so local characterisation should precede sizing.

Keywords: *solar-biomass hybrid systems; anaerobic digestion; farm microgrid; dispatch strategy; techno-economic analysis; sub-Saharan Africa*

1. INTRODUCTION

Agriculture supports more than half the population of sub-Saharan Africa, smallholders account for roughly 80% of production and over 90% of cropland is rainfed, while about 75% of rural people and most rural enterprises lack reliable electricity (Falchetta *et al.*, 2023). Design practice compounds the deficit: rural generation studies address residential and institutional loads with little regard for productive uses, one Tanzanian village model entering agricultural demand as zero (Mwakitalima *et al.*, 2023) and Zambian fieldwork showing households acquiring capacity adequate for lighting but not income generation (Chanda *et al.*, 2026). Holdings combining livestock with horticulture fit neither template, yet are common: at Mankramso in Ghana, 89.8% of households farm crops and rear livestock (Odoi-Yorke, Abaase, *et al.*, 2022).

Where such holdings secure power off-grid it is predominantly diesel, consistently the costliest option: reviewed mini-grid studies place diesel at USD0.92-1.30/kWh (Zebra *et al.*, 2021), and community-scale examples reach USD0.980/kWh at Mankramso (Odoi-Yorke, Abaase, *et al.*, 2022). The environmental burden follows: at Abeokuta the diesel-containing optimum emits 31,840 kg of CO_2, against 15.8 kg for the diesel-free configuration retaining a 50 kW biomass generator (Emezirinwune *et al.*, 2024).

The resources to displace diesel are already on the holding. Photovoltaic pumping is economically feasible for smallholders at scale (Falchetta *et al.*, 2023), and biomass valorisation is a viable electrification route because agricultural and livestock waste accumulates wherever farming concentrates (Uzoagba *et al.*, 2024). Hybrids pairing renewables with storage or a dispatchable unit are

the established off-grid route (Zebra *et al.*, 2021), and solar-biomass suits farm conditions because photovoltaic output coincides with daytime irrigation and processing demand while a digester or gasifier is dispatchable to the evening peak and the thermal load (Diemuodeke *et al.*, 2024). Dispatchability has quantified value: removing bioenergy from a Ghanaian national pathway raises storage output by 37%, battery capacity by 29% and levelised cost by 27% (Mensah *et al.*, 2021).

This review treats the integrated holding as a single microgrid. Its objectives are to characterise the compound electrical and thermal load, review the conversion and power-conditioning subsystems, evaluate reported sizing and dispatch methods against standard reliability and cost metrics, and identify the empirical gaps obstructing design.

2. METHODOLOGY

2.1 Search Strategy and Study Selection

This is a narrative, conference-length review, illustrative of the current state of the art rather than exhaustive. Literature was identified by topic-based searching of Google Scholar, with full texts retrieved from the platforms it indexes, principally Elsevier, MDPI, Wiley, Frontiers, Springer Nature and Oxford University Press. Terms combined solar, photovoltaic, biomass, biogas, anaerobic digestion, gasification, agrivoltaic, hybrid renewable energy system, microgrid, livestock, poultry and cold storage with sub-Saharan Africa or individual country names; they were refined iteratively as the corpus developed, and the reference lists and related-article links of retained studies were followed. Records were eligible if published 2021-2026 in English in peer-reviewed journals or peer-reviewed conference proceedings, reporting original data, modelling or synthesis on: agrivoltaics and solar systems for irrigation, shading, grazing or farm electrification; digestion, co-digestion or gasification of manure or crop residue for farm energy; hybrid solar-biomass sizing, dispatch or techno-economic assessment in rural developing-country settings; post-harvest cold storage and precooling at farm scale; or microgrid coupling, power conditioning, energy management and metaheuristic sizing, subsystems sparsely treated in the agricultural literature. Utility-scale and urban work without an agricultural interface was excluded, as was any study stating no method or offering no extractable quantitative result. Studies outside the region were retained only for direct methodological relevance, such as the Fijian poultry-manure digestion trial, and are declared non-regional at each point of use. Claims resting on a single source triggered supplementary searching until corroborated or declared single-sourced where used. The search was conducted in Google Scholar and last updated on 1 September 2026, and resulted in 43 studies that met the inclusion criteria, of which 24 report sub-Saharan African sites or datasets.

2.2 Quality Appraisal and Character of the Evidence Base

Quality was appraised at point of use, and non-regional sources are declared at each use. The search was purposive rather than exhaustive and relied on openly retrievable English-language work, so the corpus is likely to under-represent unindexed, non-English or paywalled studies, a selection effect compounding the reporting bias considered in Section 3.7. Screening was carried out by a single reviewer, and stage-by-stage record counts were not retained. Two further features require statement: almost all system-level results are simulations, only Randle-Boggis *et al.* (2025) reporting operational agrivoltaic installations with measured multi-season output; and one reviewed study reports an itemised electrical and thermal breakdown (Baldi *et al.*, 2026), limiting how strongly the demand structure below can be asserted.

3. RESULTS AND DISCUSSION

3.1 Integrated Farm Load Characterisation

Livestock demands follow the animals' clock rather than the operator's: lighting, ventilation, feed preparation, water supply and, on dairy holdings, milking and chilling. Sub-metering of thirty German dairy farms shows these duties carry distinct load signatures (Vavouris *et al.*, 2025); no comparable African dataset was located, so structure is inferred from nameplate audits. Feed preparation is the largest discrete connected load on a poultry enterprise but not the largest consumer: a Nigerian layer audit at 25,000-bird scale reports a 16.5 kW hammer mill running briefly within

roughly 140 kWh/day dominated by pen-house lighting (Sasanya and Olaifa, 2022), while lighting on the Cameroonian broiler holding is minor at 2,418 kWh annually (Baldi *et al.*, 2026).

Irrigation is modelled rather than measured, and its character matters as much as its size: pumping is a deferrable motor load, flexible within the day because water can be stored, a mean smallholder system consuming about 255 kWh annually across roughly 75 operating days (Falchetta *et al.*, 2023).

Cold-chain demand is continuous and interruption-intolerant, so reliability rather than mean power drives design. Set points follow chilling-injury thresholds, 13 °C for banana and yam down to 7 °C for okra and pepper (Makule *et al.*, 2022), so a mixed tropical store runs near 13 °C rather than the sub-zero range of conventional cold storage. Solar cold stores run 5-10 kWp against 2-10 tons at COP 3.95, batteries taking 30-40% of cost (Amjad *et al.*, 2023). No reviewed source supplies a measured cooling profile for an African farm, the nearest entering refrigeration into the Mankramso model as a continuous 28.8 kWh/day load (Odoi-Yorke, Abaase, *et al.*, 2022): capacity can be inferred from tonnage, dispatch cannot, and dispatch determines storage.

Heat is a structural need: chicks held above ambient, wash water heated, harvests dried and produce cooled. On a three-house farm near Yaoundé producing roughly 72,000 birds annually, an 8 kW heater called below 27 °C consumes 57,744 kWh per year, about 94% of itemised farm energy (Baldi *et al.*, 2026); Emezirinwune *et al.* (2024) audit the same enterprise type but record electricity only, so the datasets cannot be compared. Non-regional broiler accounting agrees that brooding heat dominates total energy input, though ventilation dominates the electrical share as ambient temperature rises (Liang and Popp, 2025).

The cooling routes compare by coefficient of performance: a vapour-absorption cycle at COP 0.7 on 130 °C exhaust delivers 7.7 kW of cooling from 11 kW of heat (Diemuodeke *et al.*, 2024), a duty needing about 1.95 kW electrically at the vapour-compression COP of 3.95 (Amjad *et al.*, 2023), so absorption pays only where the heat would otherwise be rejected.

Aggregate figures allow sizing metrics to be derived. At Mankramso the load ranges 2.98-47.26 kW against 96 MWh annually, peaking 16:00-21:00 (Odoi-Yorke, Abaase, *et al.*, 2022). Taking the load factor as

$$LF = \frac{E_{ann}}{8760 \times P_{peak}} \tag{1}$$

gives a mean demand of 10.96 kW and a load factor near 0.23, which oversizes generation capacity, while the peak falling outside the generation window obliges energy to be time-shifted and so makes storage dominate lifetime cost. The audited Nigerian facility consumes 506,200 kWh annually, a mean of 57.8 kW, modelled as 527,250 kWh after a variability allowance (Emezirinwune *et al.*, 2024), against 3,544 kWh/yr at the Cameroonian farm, a caution against transferring published profiles. Table 1 assembles the load data reported.

Table 1: *Reported and derived farm load metrics across the reviewed studies*

Site	**Reported**	**Derived**
Yaoundé, Cameroon (Baldi *et al.*, 2026)	8 kW heater; 57,744 kWh/yr thermal; 3,544 kWh/yr electrical	Heating approximately 94% of itemised farm energy
Mankramso, Ghana (Odoi-Yorke, Abaase, *et al.*, 2022)	2.98-47.26 kW; 96 MWh/yr; peak 16:00-21:00	Mean 10.96 kW; load factor around 0.23
Abeokuta, Nigeria (Emezirinwune *et al.*, 2024)	Audited 1,386.85 kWh/day = 506,200 kWh/yr; modelled 1,444.52 kWh/day = 527,250 kWh/yr after a 5% variability setting, an increase of 4.2%; electrical only	Mean 57.8 kW audited (506,200 ÷ 8,760); 60.2 kW modelled; no thermal load recorded

3.2 Biomass Feedstock and Waste-to-Energy Conversion

Manure production per head differs by an order of magnitude between species (Kadam *et al.*, 2024), and threefold within one species by basis: poultry at 0.3 kg/head/day as excreted, 0.15 as collected litter and 0.09 as fresh manure (Baldi *et al.*, 2026; Naidu *et al.*, 2024). Poultry also gives the highest volumetric biogas yield among common manures, 231 Nm³ per tonne of dry manure against 60 for cattle manure (Augustyn *et al.*, 2021), and is the reference feedstock; its volatile fraction is reported between 0.61 and 0.85 on non-interchangeable bases (Ayantokun *et al.*, 2025), so the same yield spans 270-380 Nm³ per tonne of volatile solids. Blending streams of different character raises yield and stability (Kadam *et al.*, 2024), so the species mix is itself an asset. Supply is not constant: availability falls from 0.787 t/day in January to 0.315 t/day in July-October (Mwakitalima *et al.*, 2023), competing uses remove part of the residue stream (Adnane *et al.*, 2024), and about 6 of Ghana's 35 million tonnes of crop residue are unavailable for energy (Odoi-Yorke, Osei, *et al.*, 2022).

Biogas carries about 6 kWh/Nm³ at 55-65% methane (Naidu *et al.*, 2024). Stability is governed by the substrate carbon-to-nitrogen ratio, reported for poultry manure across a sevenfold range (Table 2) against a workable window given variously as 20-30, 16-25 or 20-35, optimal near 25, with ammonia inhibiting methanogenesis above 4 g/L (Adnane *et al.*, 2024; Ayantokun *et al.*, 2025); every entry in Table 2 except the Togolese and Nigerian measurements sits below it. The dispersion is not measurement error: nutrient content varies with region, diet and antibiotic use, bedding adds straw, feathers, lime or sawdust, and storage raises ammonia (Kadam *et al.*, 2024).

Table 2: *Reported carbon-to-nitrogen ratios for poultry manure*

Source	**C/N**	**Material as described**	**Basis**
Kadam *et al.* (2024)	Approx. 4.0	Chicken manure, elemental composition	Literature compilation; ultimate analysis depresses the ratio, the same source reporting 10.1
Baldi *et al.* (2026), Cameroon	6-12	Litter with bedding	Literature-derived
Naidu *et al.* (2024), Fiji	8	Manure with feathers, no sawdust	Calculator estimate
Brou *et al.* (2026), Togo	16.07	Manure with wood-chip bedding	Site measurement
Ayua *et al.* (2026), Nigeria	29.38	Dried droppings	Site measurement

Co-digestion brings the substrate into the window. Brou *et al.* (2026) report cumulative biogas rising from 210.73 to 348.65 mL/g VS at C/N 25 with cocoa pod husk, a 65.45% gain inside the 25-400% range reported generally (Adnane *et al.*, 2024). The second benefit is operational: in parallel reactors, a fall from 29 °C to 26 °C cut mono-digestion output by up to 80% while the co-digested reactor lost only 20% (Naidu *et al.*, 2024). The co-substrate is thus a stabiliser drawn from material already on a cropping holding, and mesophilic operation is the most widely adopted full-scale regime because it tolerates inhibitors and avoids thermophilic heating demand (Kadam *et al.*, 2024).

Uzoagba *et al.* (2024) assign low-moisture wastes to thermochemical and high-moisture waste to biochemical routes; Odoi-Yorke, Osei, *et al.* (2022) add scale, every gasification feedstock returning a negative net present value at 10 kW where every combustion feedstock was profitable, the two converging only at 100 kW because gasification carries the extra capital of gas cleaning and the gas engine. Integrated holdings sit at this scale, and fixed-bed downdraft reactors suit it best, yielding 0.1-1.2 g/Nm³ of tar against 20-100 from updraft units, but their window is narrow, 20-100 mm particles, ash near 0.5%, moisture below 20% (Ouedraogo, Sidibe, *et al.*, 2025), and most farm residues miss it: a West African trial on 25.2%-ash rice husk returned a cold gas efficiency of 36.6% against the 52.2-65% downdraft band (Ouedraogo, Richardson, *et al.*, 2025).

The electrical energy available from either route follows from

$$
\begin{aligned}
Q_{th} &= V_{gas} \times LHV_{gas}, \\
P_e &= \eta_e \times Q_{th}, \\
\eta_{cg} &= \frac{V_{gas} \times Y_{gas} \times LHV_{gas}}{LHV_{bio}}, \\
\eta_{overall} &= \eta_{cg} \times \eta_e
\end{aligned}
\tag{2}
$$

where Y_{gas} is specific gas production in Nm³/kg (Ouedraogo, Richardson, *et al.*, 2025). Applying (2) shows why efficiency figures must be read on a common basis: a gasifier consuming 25-30 kg/h and producing 60-65 Nm³/h at 4.5-5.0 MJ/Nm³ delivers roughly 82 kW of syngas thermal power against a genset rated 20 kWe and optimised to 24 kW, so the electrical efficiency near 24%, taken on the 20 kWe rating, is an engine figure, not a system one, and at the 16-20 MJ/kg typical of West African agro-residues cold gas efficiency is 54-68% and overall efficiency 13-16% (Diemuodeke *et al.*, 2024).

Yield figures can likewise mix bases. Augustyn *et al.* (2021) tabulate dry chicken manure at 381 kWh_e per tonne, implying 27% electrical efficiency, a full-scale cogeneration figure well above the 10-20% assumed for small farm gensets (Baldi *et al.*, 2026), so mixing the two over-predicts electrical output by roughly 1.4 to 2.8 times. At Tuna the same generator returns 140,661 kWh of recovered heat against 185,735 kWh of electricity (Diemuodeke *et al.*, 2024).

3.3 Microgrid Architecture, Power Electronics and Control

Among the off-grid reviewed systems only one describes a coupling arrangement, and then only as a nominal 12 V bus with no topology justification (Diemuodeke *et al.*, 2024), so guidance on the uncharacterised power-electronics layer comes from adjacent work. Jabari *et al.* (2025) describe the architecture as an AC subnet, a DC subnet and an interlinking converter, grid-forming units setting the voltage and frequency reference and grid-following units tracking it. An explicit two-bus arrangement is reported at Maizube farm, Sabon-daga, a 500 ha Nigerian holding carrying over 300 cattle alongside an orchard and drawing 980 kWh/day: Adetoro *et al.* (2023) place array, wind turbine and battery on a DC bus and the generators and heavy agricultural loads on an AC bus linked by a bidirectional converter, so rotary generators serve inductive machinery directly and inrush stress bypasses the power electronics. That system is grid-connected, an interconnection the islanded case does not carry, but the ordering of sources on the AC side is the one an off-grid farm faces.

For a farm microgrid whose largest loads are three-phase induction motors and whose biomass generator is an AC machine, AC coupling is the defensible default: the generator serves the motor loads directly, without a converter stage, at the cost of lower array-to-load efficiency. Classical droop assumes inductive line impedance, whereas in low-voltage networks resistance is comparable or larger, breaking active-reactive decoupling and causing inaccurate sharing and circulating currents (Jabari *et al.*, 2025), the case farm distribution presents and no reviewed study addresses. Inverter-connected photovoltaics contribute no rotational inertia, so sudden generation loss produces a faster rate of change of frequency unless grid-forming control emulates a synchronous response (Khan *et al.*, 2024); since thermal-first dispatch leaves the biomass generator off for most hours, a grid-forming battery inverter must hold the reference.

Converter ratings are reported in two of the reviewed systems on incompatible conventions: 81.4 kW against a 561 kW array, 6.9:1 against installed practice of 1.1-1.5:1 (Emezirinwune *et al.*, 2024), and 24.8 kW against a 20 kWp array at Tuna, 0.81:1 (Diemuodeke *et al.*, 2024). Neither states a rule, and no reviewed study reports inverter topology, harmonic distortion, regulation limits or protection coordination. Direct-on-line starting of mills and pelletisers imposes inrush currents of several times rated value, and a synchronous machine can supply roughly seven times rated current briefly where a grid-forming converter offers only about 20% overcurrent (Khan *et al.*, 2024). Machinery surveys reach the same requirement independently, reporting hammer mills at 2-15 kW and pelletisers from 3 kW upward and recommending variable-frequency drives for soft starting (Ogunobo and Onyenanu, 2025). A converter rated for motor starting rather than mean demand is therefore the implied requirement, which no reviewed sizing study addresses, and no measured power-quality data for an African farm microgrid was located.

Dispatch is either unspecified or set to the simulator's load-following rule (Emezirinwune *et al.*, 2024), whereas the evidence supports a thermal-first order of merit. Biogas converted to electricity at 10-20% engine efficiency discards most of its energy content against 90% in a gas heater (Baldi *et al.*, 2026); Naidu *et al.* (2024) reach the same ordering on emissions, 147.09 t CO2 avoided annually by cooking-fuel displacement against 55.98 t via electricity; Rezaei *et al.* (2024) reach it on capital grounds, an organic Rankine cycle entering the optimum only if the electricity price roughly triples; and Augustyn *et al.* (2021) close it from the supply side, 95-99% of generated heat being absorbable by building heating and fermentation support.

A general constraint makes this ordering unusually favourable here. A biogas plant on average uses only half the heat it produces, and in Germany only 10% of producers use more than half (Augustyn *et al.*, 2021): cogeneration disappoints because the heat has no destination, and on a holding combining brooding, sanitation, drying and absorption cooling one exists. Capturing 130 °C engine exhaust serves the thermal load without touching the electrical bus (Diemuodeke *et al.*, 2024), so heat met this way never draws on the battery, the dominant cost term (Table 3). Load scheduling is then the highest-value control objective: forced-air precooling completes in 1-10 hours against 20-100 for room cooling (Makule *et al.*, 2022), and feed processing admits the same treatment (Sasanya and Olaifa, 2022). The one reviewed design that schedules milling does so as an assumed rather than optimised pattern (Odoi-Yorke, Abaase, *et al.*, 2022), and machinery-level guidance likewise places grinding and pelleting in the solar window (Ogunobo and Onyenanu, 2025).

Producer gas carries only 4.2-5.7 MJ/Nm³ and engines burning it have strict purity requirements. Tar is the dominant reliability constraint: below 450 °C it condenses and polymerises, corroding and clogging downstream components, and for unattended small units mechanical cleaning is favoured over catalytic or wet routes, which displace the problem into liquid-waste handling (Ouedraogo, Sidibe, *et al.*, 2025). A gasifier-genset should therefore run near its rated point with the battery absorbing the mismatch, a constraint no reviewed farm-scale study incorporates, though the Tuna simulation agrees, average electricity cost falling as the minimum load ratio rises (Diemuodeke *et al.*, 2024).

3.4 Sizing and Optimisation Methodology

All but two of the reviewed systems were sized in HOMER, the exceptions using particle swarm optimisation and mixed-integer linear programming (Table 3). A comparison of ten sizing tools against fourteen criteria (Silinto *et al.*, 2025) ranks HOMER the highest-scoring conventional model and confirms it admits thermal and deferrable loads, a capability no reviewed HOMER-based farm study exercised though the mixed-integer formulation schedules both (Baldi *et al.*, 2026); the same review records two structural limits, no multi-objective formulation and aggregation of all components into a single node with no internal power flow.

The wider literature applies metaheuristic search to the same problem. One reviewed study coupled HOMER with a grey wolf optimiser, reducing levelised cost from USD0.1109/kWh to USD0.0887/kWh (Mwakitalima *et al.*, 2023), a margin reflecting a different search space, since HOMER enumerates near-exhaustively over its own. In multi-objective formulations cost, reliability and emissions genuinely conflict: on a grid-connected solar-biogas system with storage, a non-dominated sorting whale optimisation algorithm balanced net present cost against emissions with better convergence than grey wolf and particle swarm benchmarks (Agajie *et al.*, 2023). Every reviewed farm study nonetheless minimises a single cost objective, which conceals the trade-off rather than resolving it.

Reliability is expressed as loss of power supply probability,

$$LPSP = \frac{\sum E_{unmet}}{\sum E_{demand}} \tag{3}$$

and cost as the levelised cost of energy,

$$LCOE = \frac{C_{cap} \times CRF + C_{O\&M} + C_{rep} + C_{fuel}}{E_{served}} \tag{4}$$

where $CRF(i,n) = \frac{i(1+i)^n}{(1+i)^n - 1}$ at real discount rate i, replacements are present-worthed, salvage credited, and E_{served} is electricity delivered; crediting heat gives a cost of energy, not of electricity (Diemuodeke *et al.*, 2024). The reliability metric is not reported under a single name across the corpus, appearing as loss of energy probability in Emezirinwune *et al.* (2024) and as loss of energy probability of power in (Mwakitalima *et al.*, 2023); the quantity is identical and the studies are compared on that basis.

Applied to Abeokuta, the fully renewable configuration leaves 399 kWh/yr unserved against a 527,250 kWh modelled load, a ratio of 0.000757, at USD0.261/kWh against USD0.206/kWh for the diesel-containing optimum, a premium of 26.7% (Emezirinwune *et al.*, 2024): the premium buys the last fraction of a point of availability, a design choice rather than a technical limit. Each metric is reported in only two of the reviewed systems.

3.5 Techno-Economic, Environmental and Cogeneration Synthesis

Table 3 assembles the reviewed sub-Saharan solar-biomass systems; only one is sited on a holding combining livestock with a cropped area, and there the crop enterprise carries no modelled electrical load. The hybrids sit below diesel and above grid supply: Mankramso delivers USD0.265/kWh against USD0.980/kWh for diesel alone, 64% above Ghana's average tariff (Odoi-Yorke, Abaase, *et al.*, 2022). Where no grid exists the comparison inverts, break-even grid extension at Simboya being 0.19 km against a nearest connection 79.7 km away (Mwakitalima *et al.*, 2023).

Table 3: *Reported solar-biomass hybrid systems for sub-Saharan Africa*

Site	**Scope**	**Configuration**	**Method**	**LCOE**	**Discount rate / life**	**Storage share**
Mankramso, Ghana	Rural community	PV 50 kW; biogas 20 kW; battery 237 kWh	HOMER	$0.265/kWh	12% / 25 yr (batteries 5 yr)	45.6% of NPC
Simboya, Tanzania	Rural village	PV 40 kW; biogas 25 kW; battery 144 kWh	HOMER, then grey wolf	$0.1109/kWh (HOMER); $0.0887/kWh (grey wolf)	8% nominal, 4% inflation / 25 yr (batteries 10 yr)	45.9% of capital
Tuna, Ghana	School (CHP)	PV 20 kWp; gasifier-genset 24 kW; battery 78 kWh	HOMER Pro	€0.295/kWh	7.5% / 25 yr	Not reported
Abeokuta, Nigeria	Poultry facility	PV 561 kW; gasifier 10 kW; diesel 88 kW; converter 81.4 kW (the fully renewable case substitutes a 50-kW biomass generator)	HOMER	$0.206/kWh diesel-containing optimum; $0.261/kWh fully renewable	11.5% / 25 yr	Approx. 51% of NPC
Sabon-daga, Nigeria	Dairy farm with orchard; grid-connected, 20% availability	PV 248 kW; wind 2 kW; biogas 22 kW; diesel 92 kW; battery 658 kWh	PSO	$0.148/kWh	15% / 25 yr	Not reported
Yaoundé, Cameroon	Poultry farm	PV 70 kW; digester to 23.2 kW	MILP	€2,680-6,980/yr (annual cost)	Not reported / 20 yr (10 yr batteries)	Battery at farm only in unconstrained case

Note. Yaoundé reports a total annualised system cost, not a levelised cost, and is not comparable with the other rows. Costs are in the currency and year of the source study, without exchange-rate normalisation. The Sabon-daga levelised cost includes grid import at USD0.07/kWh and is not comparable with the off-grid rows.

The biomass share of generation spans more than an order of magnitude across the three hybrids reporting it, 49% at Mankramso, 9.6% at Simboya and 2.77% at Abeokuta, and the cause is allocation, not resource. At Simboya the biogas unit generates 7,707 kWh against 72,500 kWh from the array on 23.1 t of feedstock annually, about 63 kg/day against a collected availability of 0.315-0.787 t/day, a capacity factor of 3.52%: the constraint is how much manure is committed to the generator, the balance going to household cooking gas (Mwakitalima *et al.*, 2023). At Mankramso a 20 kW unit against a 50 kW array carries 49% because it runs when the array cannot (Odoi-Yorke, Abaase, *et al.*, 2022), a split independently tabulated by Overen *et al.* (2024). Any quoted biomass fraction therefore describes dispatch and allocation, not the farm's resource.

Storage dominates lifetime cost, the most consistently reproduced result: all three hybrids reporting a share place batteries at or above 45% of net present or capital cost, denominators that are not interchangeable, with a further 30-40% share in solar cold storage (Amjad *et al.*, 2023). Quadrupling feedstock price from USD2 to USD8 per tonne raises levelised cost by only 5% where manure is collected on site (Odoi-Yorke, Abaase, *et al.*, 2022), whereas cost is materially sensitive for purchased groundnut shells (Diemuodeke *et al.*, 2024), an argument for on-farm supply.

Diesel displacement is the principal environmental benefit reported: at Abeokuta annual emissions fall from 399,855 kg of CO2 under the diesel-dominant alternative to 31,840 kg at the optimum and 15.8 kg diesel-free (Emezirinwune *et al.*, 2024), and at Simboya from 635,966 kg under diesel-only supply to 0.531 kg fully renewable (Mwakitalima *et al.*, 2023). These are combustion figures at about 2.66 kg CO2/L, with biogenic carbon zero-rated and methane slip and digestate storage outside the boundary, so the residual kilogrammes measure diesel displaced rather than the farm's footprint. Open storage of manure loses up to 70% of its nitrogen within 24 hours in humid tropical conditions (Kadam *et al.*, 2024), so digestion conserves more than energy alone.

Thermal recovery is rarely evaluated: only the Tuna configuration, delivering 110.9 MWh of heat and 7.7 kW of cooling (Diemuodeke *et al.*, 2024), and the Yaoundé optimisation, where biogas serves brooding heat (Baldi *et al.*, 2026). Sizing either requires a correction the reviewed designs omit: Rezaei *et al.* (2024) report a fermenter consuming on average 45% of the heat produced, rising to about 60% in the cold season, so the heat available to the farm is

$$Q_{avail} = Q_{gross}(1 - f_{par}) \text{ is approximately 0.45-0.60} \quad (5)$$

The figure is a temperate input coefficient rather than a measurement, but the correction cannot be omitted: a digester sized by matching nominal production to brooding demand will under-deliver by roughly half. The tropical case is likely more favourable, ambient temperatures sitting closer to the mesophilic set point (Adnane *et al.*, 2024), and solar water heating raised a Nigerian pilot digester's average temperature 35% on sunny relative to rainy days (Ayua *et al.*, 2026), placing part of the parasitic demand on the solar side.

Digestate is usually presented as an environmental co-benefit and is closer to an economic foundation. Zielińska and Bułkowska (2024) state the constraint: nitrogen and phosphorus in the liquid fraction are simultaneously too concentrated for discharge standards and too dilute to serve as fertiliser, and the mature recovery routes stay viable only above roughly 50 mg P/L or 1,000-1,500 mg/L ammonia, below which, the smallholder case, the nutrients are effectively unrecoverable. Naidu *et al.* (2024) show the value where a market exists, payback falling from 16.8 years to under three once 5% of digestate is sold; where none exists, the correct valuation is the fertiliser purchase avoided on site. These are transaction constraints, which makes co-location decisive: applied where produced, digestate is neither upgraded, transported nor priced, and proximity of livestock and co-substrate to the digester is independently identified as a commercialisation requirement (Kadam *et al.*, 2024).

3.6 Field-Level Implementation Challenges

Four technical constraints recur. Feedstock volatility is seasonal (Mwakitalima *et al.*, 2023), so sizing against the minimum month is the defensible heuristic. Gasifier tar fouling limits engine life, and nearly all gasification plants deployed for heat and power in this region have failed (Ouedraogo, Sidibe, *et al.*, 2025). Photovoltaic soiling is more severe than global defaults allow, modelled West African losses exceeding 50% during the Harmattan (Isaacs *et al.*, 2023), and no reviewed farm study applies a region-specific derating, so reported yields are optimistic. Finally, storage is 51% of net present cost on a four-year battery life, replacement across all components 34% against 11% for fuel (Emezirinwune *et al.*, 2024).

Capital cost and credit access dominate the economic constraints, ranking above technical ones across the solar-cooling studies screened by Amjad *et al.* (2023). Pay-as-you-go and lease-to-own arrangements still require 20-25% upfront, and on one estimate only about 6% of the region's farmers could afford solar irrigation individually (Durga *et al.*, 2024); Tanzanian smallholders meet input costs only after sale, so cannot prepay for storage services (Rutta, 2022). Even a 100% capital subsidy leaves levelised cost 32% above Ghana's lifeline tariff, because capital is barely two-fifths of lifetime cost (Odoi-Yorke, Abaase, *et al.*, 2022), a result reproduced by Odoi-Yorke, Osei, *et al.* (2022) and by a South African design that turns loss-making without a 60% subsidy (Overen *et al.*, 2024), while in the

Yaoundé optimisation the digester enters only under a litter-disposal constraint or with external financing (Baldi *et al.*, 2026).

Targets exist without accountability: Nigeria set 90% electricity access by 2030 with no public progress reports (Uzoagba *et al.*, 2024), and Nyarko *et al.* (2023) find monitoring largely absent, a six-country inspection identifying projects with neither maintenance plans nor monitoring systems. A multi-regional review records the same pattern of weak policy frameworks and limited stakeholder coordination across Nigeria, Kenya and South Africa (Obuseh *et al.*, 2025).

3.7 Convergence, Divergence and Empirical Gaps

Table 4 separates claims supported by multiple independent sources from those resting on one study or stated on differing bases.

Table 4: *Points of convergence across the reviewed literature*

Claim	Status	Basis
Storage dominates lifetime cost	Convergent	All three hybrids reporting a share are at 45% or above of NPC or capital, denominators not interchangeable; 30-40% for solar cold storage
Thermal use before electrical conversion	Convergent	Engine efficiency, emissions, capital cost and heat-utilisation ceiling agree; emissions line contingent on displaced fuel
Co-digestion corrects C/N and raises yield	Convergent	Batch assay and reviews agree on yield; one pilot corroborates stability
Capital subsidy alone is insufficient	Convergent	Two studies sharing a lead author, plus independent cost-type and South African corroboration
Shiftable processing belongs in the generation window	Partially corroborated	One assumed schedule in a community model plus independent machinery-level design guidance; no optimised or measured demonstration
Thermal demand dominates poultry load	Partially corroborated	One itemised regional audit; direction supported by non-regional broiler accounting; a second regional audit records no thermal load
Digester parasitic heat at 45-60%	Single-sourced, non-regional	A single Swiss study, where the value is an input coefficient attributed to secondary CHP guidance rather than a measurement; alters sizing materially
Biogas yield per tonne vs. engine efficiency	Stated on different bases	Plant-level 1.65 kWhe/Nm^3 vs 10-20% genset efficiency; 231 Nm3/t dry manure = 0.27-0.38 m^3/kg VS across the reported volatile-solids range
Gasifier electrical efficiency	Single plant, two bases reconciled	24% engine and 13-16% overall are one plant on two bases
Bus architecture and power quality	Addressed once, outside the off-grid set	One grid-connected Nigerian farm study specifies a two-bus topology; no off-grid system justifies a coupling arrangement, states a converter sizing rule, or reports power-quality data

Five empirical gaps follow. First, the holding is not modelled as one system: the audited poultry facility reports no thermal demand (Emezirinwune *et al.*, 2024), agricultural load is entered as zero at village scale (Mwakitalima *et al.*, 2023), both village-scale solar-biogas designs size digesters from livestock censuses treating manure purely as fuel, and at Maizube farm the itemised load covers animal housing and milk handling only, with no irrigation or post-harvest demand in the optimisation (Adetoro *et al.*, 2023). That integrated configuration has not been examined. Second, demand is not disaggregated: with one itemised electrical and thermal breakdown available (Baldi *et al.*, 2026), the thermal-first order of merit rests on multiply-sourced efficiency arguments matched against a singly-

sourced demand structure. Third, cooling has capacity but no demand shape, leaving a schedulable load unschedulable. Fourth, the power-electronics layer is unspecified for the off-grid farm case (Table 4). Fifth, continuous farm-scale digestion is untested regionally, the reviewed pilots operating at 10 L in Nigeria (Ayua *et al.*, 2026) and 500 L in Fiji (Naidu *et al.*, 2024), and no African livestock agrivoltaic instance was located, the field studies identified being United States sheep systems (Bacon *et al.*, 2025) and the one financial analysis likewise North American (Gasch *et al.*, 2025).

A limitation of the evidence base qualifies these gaps and the convergence in Table 4. Every hybrid reviewed reports a cost advantage over diesel, and no reviewed study reports an uncompetitive configuration at farm scale. Simulation studies returning unfavourable outcomes are less likely to be submitted and published than favourable ones, so the absence of negative results is consistent with reporting practice as well as with system performance. Table 4 therefore indicates that these configurations perform under the modelling assumptions their authors adopted, not that a representative sample of sites would return equivalent results.

3.8 Recommendations for Future Sizing Models and Field Implementation

Four recommendations follow. First, instrument a working integrated holding for electrical and thermal demand at end-use resolution over a full agricultural cycle. Second, formulate sizing as a multi-objective problem over levelised cost, loss of power supply probability and renewable fraction, with the digester's unit-commitment decision represented explicitly and the fermenter parasitic fraction of (5) applied to gross thermal output; since that fraction rests on a single non-regional coefficient, establishing the regional value is part of the work. Third, specify the power-electronics interface against motor-starting duty rather than mean demand, and apply a region-specific soiling derating from local particulate data. Fourth, treat local characterisation as preceding sizing: panel densities associated with yield loss in temperate meta-analysis improved several crop yields at two East African sites (Randle-Boggis *et al.*, 2025), that expectation itself resting on coverage thresholds across fifty installations (Widmer *et al.*, 2024).

4. CONCLUSION

Integrated livestock-horticulture holdings resolve internally three constraints that limit on-farm digestion elsewhere: the substrate carbon-to-nitrogen imbalance, corrected by a co-substrate the cropping enterprise already produces; the thermal instability that co-substrate buffers; and the transaction cost of digestate, which disappears when the material is applied where it is produced. Co-location is therefore an economic precondition of the design, and the same reasoning governs heat.

Three design principles follow. Gas should be allocated to heat before conversion, and the digester sized against thermal demand referred to gross rather than net output, because the fermenter consumes a substantial share of the heat produced; the only quantification available, 45-60%, is a single non-regional input coefficient (Rezaei *et al.*, 2024), so the design carries forward its approximate magnitude, not its precise value. Storage is the dominant cost term, so scheduling shiftable load into the generation window is the control objective with the largest economic return. Published parameters are artefacts of the method and site that produced them, so local characterisation precedes sizing rather than refines it. The principal limitation is the evidence base itself: every system-level result reported for a solar-biomass hybrid is a simulation, digestion results are at bench and pilot scale, the cooling load is uncharacterised in time, the power-electronics layer is unspecified, the corpus contains no negative techno-economic result, and the demand structure has been itemised on a single farm. The configuration is well founded in its parts and unproven as a whole; an instrumented pilot is the next contribution needed.

ABSTRACT

The reliance of Nigeria's textile and cottage dyeing industries on imported synthetic colourants poses severe environmental hazards, while the importation of natural indigo dye from Europe and China continues to drain valuable foreign exchange reserves. To drive sustainable import substitution and foster local industrialization, this study presents the engineering design, fabrication, and physical performance evaluation of an indigenous, large-scale natural indigo extraction machine. Response surface methodology (RSM) based on a central composite design (CCD) was initially employed at bench scale to model process kinetics. Optimizing plant biomass fermentation (18 hours) and aeration duration (63 minutes at pH 12) predicted a maximum yield of 31.99 g/kg fresh biomass with a purity of 70.35%. Building upon these kinetic baselines, a mechanical extraction system was engineered to scale up the fermentation, liquid separation, and aeration phases into a controlled, high-efficiency mechanical process. Validation trials conducted across five operational runs processing 100 kg of fresh biomass per batch produced 3.21±0.7 kg of dry indigo flakes (equivalent to 32.13±0.7 g/kg biomass yield) with a purity of 71.12±1.3%, within 24-hour cycle. By replacing toxic synthetic dyes and bypassing expensive foreign colourant imports, this fabricated extraction system provides scalable, eco-friendly technological framework to revitalize Nigeria's historic textile clusters, directly supporting sustainable agricultural value addition and national economic self-reliance. (Note: In the first abstract submitted, the criteria set in the optimization software was "in range" for both fermentation time, pH and oxidation time and the predicted values were 26 hours fermentation time, pH 12, and 105-minutes oxidation time. After careful consideration, looking at Table 2, the highest crude yield was obtained at 18 hours fermentation time. Also, previous work reported that there is tendency for the fermented liquor to be contaminated after 24 hours fermentation thereby affecting pure yield. For this reason, the criteria for the fermentation time was changed from "in range" to "equals to 18". The software predicted a result where a combination of 18 hours fermentation time, pH 12 and oxidation for 63 minutes will result 31.99 g/kg and 70.35% crude and pure yield respectively as shown in Figure 3. It is a known fact that the ramp shown in the Figure 3 cannot be edited. It was copied directly from the software. With this development, large scale extraction using the fabricated machine had to be carried out using the new predicted parameters which resulted in different yields from the ones reported in the earlier abstract)

Keywords: *indigo extraction; machinery fabrication; import substitution; sustainable development; natural dyes; textile engineering*

INTRODUCTION

Accelerated depletion of fossil fuels and escalating environmental degradation necessitated intensified research into sustainable, renewable bio-resources (Cardon *et al.*, 2023). In the textile sector, global initiatives led by the European Union (EU) and international sustainability frameworks have actively sought to reintroduce efficient indigo-bearing crops into agricultural systems to develop scalable processes for natural dye production (Shin *et al.*, 2009; Mocquard *et al.*, 2022). Cultivating natural indigo (*Indigofera tinctoria*) supports sustainable agriculture by fixing atmospheric nitrogen restoring soil health in crop rotations, and yielding residual mass suitable for bio-fertilizers and biogas production, directly advancing Sustainable Development Goals (SDG) 12 (responsible consumption and production), SDG 13 (Climate Action) and SDG 15 (Life on Land) (Rao *et al.*, 2025). However, deploying natural dyes at an industrial scale requires overcoming key engineering bottlenecks,

particularly improving extraction kinetics and machinery efficiency to ensure economic viability (Pizzicato *et al.*, 2023).

Historically, nnatural indigo dyeing has been a prominent socio-economic enterprise across Northern Nigeria, centered in prominent urban hubs such as Kano, Sokoto, Zaria, and Bida (Akinbogun and Ogunduyile, 2009). Kano in particular, established regional prominence as early as the 14th century through its fine indigo-dyed textile products at traditional pit sites like Kofar Mata (Barau, 2007; Ezeanya-Esiobu, 2019P). Presently, most of the indigo dyers are out of business with only about 10 out of the 144 dye pits of "Kofar Mata" still functional (Abdullahi *et al.*, 2022). Despite this heritage, local dyeing operations have suffered a major decline, with remaining dyers relying on imported natural indigo powder from China, India, and Europe at exorbitant costs, reaching up to 350,000 per 25 kg container (personal communication). Local agricultural surveys in Kano state reveal an abundant, underutilized supply of Indigofera tinctoria biomass, with over 52 local farms producing an estimated 56,800 kg of fresh biomass per harvest cycle (Field work, 2022). Processing this local crop at an achievable 2% extraction yield could generate 1,136 kg of high-purity dye biannually (corresponding to 90.88 of 25 kg indigo bags), keeping nearly ₦32,000,000 (US$26,666.8) within the local economy.

Despite this agricultural potential, traditional bio-fermentation methods remain unviable for commercial scaling due to labour-intensive manual handling, slow liquid separation, uncalibrated aeration dynamics, and low overall dye recovery. Translating bench-scale chemical kinetics into pilot-scale production requires solving fluid mechanical mass transfer, and mechanical agitation challenges inherent in larger volumetric capacities. In alignment with the conference theme, "Innovating Tomorrow; Harnessing Engineering to Drive Nigeria's Growth for Sustainable Development", and specifically addressing the sub-theme "Sustainable Engineering Processes and Systems", this study bridges the gap between laboratory optimization and industrial implementation. By transitioning traditional bio-fermentation into automated, low-energy mechanical process, this research demonstrates how cleaner production technology can be localized. The primary objective of this research is to present the mechanical design, structural fabrication, and operational performance evaluation of an indigenous, inductive-scale natural indigo extraction machine engineered as a sustainable system to revitalize Nigeria's textile sector.

MATERIALS AND METHODS

Materials

Plant material (leaves and stems) of *Indigofera tinctoria* as identified by a taxonomist (Department of Biological Sciences, Ahmadu Bello University, Zaria), 3 months old (August to October), was harvested on 25th of October, 2023 from a farm in Yan Barau, Dawakin Kudu local government area of Kano State (see Figure A1 and A2, Appendix A), longitude 8.63^0 E and latitude 11.85^0 N with an altitude of 448 m above sea level. The plant biomass was cultivated under the following conditions: average daily air temperature, soil temperature, soil moisture, and rainfall were respectively 30.1 ^{o}C, 26.2 ^{o}C, 0.265 m^3/m^3 (28-100 cm), and 600 mm. Concentrated sulphuric acid, concentrated ammonia and standard synthetic indigo dye were purchased from Sigma Aldrich and used without purification. Coordinates of the farm were determined using hand-held Gamine78SC GPS receiver and pH was measured using Digital pH meter (Jenway 3310, UK).

Methods

Extraction of indigo dye

Fresh plant material with the leaves and stem (2 hours after harvest), 1 kg, was washed twice and placed in a transparent polyethene container and weigh down with 5 kg block to completely submerge the material in 10 l of water. The pH was adjusted to 3.5 using 20% concentrated sulphuric acid (this is to prevent indican from converting to indoxyl prematurely during fermentation). The container was covered to maintain anaerobic condition for fermentation to take place at different times. After a specified period of time, the pH of the fermented broth was measured, the solution was filtered and the pH was adjusted using concentrated ammonia (indoxyl forms indigo dye at an alkaline pH). The solution was then oxidized for a certain period of time using a blower at a flowrate of 3 l/min

(Figure A3, Appendix A). The solution was kept for 24 hours. to allow indigo slurry to settle at the bottom. The yellow green supernatant was gently drained (Figure A4, Appendix A) while the slurry was filtered using a 0.074 µm mesh (ASTM standard), placed on a tray (Figure A5, Appendix A) and allowed to dry at room temperature overnight in a cool dry place. After drying, the dye pellets were ground in to powder and washed with 2M HCl and then finally air dried.

Extraction experiments were designed with the aid of response surface methodology (RSM) using central composite design (CCD) which generated 15 runs in random order. The CCD is shown in Table 1. Crude dye (Figure A6, Appendix A) yield was calculated using Eq. 1. Crude indigo dye obtained from the 15 experiments is shown in Figure A7, Appendix A. To obtain the pure yield (dye content), standard synthetic indigo dye, 8 mg, was dissolved in 20 ml of concentrated sulphuric acid and then diluted to 500 ml with distilled water. The solution was then diluted to different concentrations viz., 0.1, 0.2, 0.4, 0.6, 0.8, 1.0 and 1.2 mg/l and the absorbance was measured at 610 nm to plot a standard curve. Crude indigo dye powder, 1 g, was dissolved in 20 ml concentrated sulphuric acid and diluted to 500 ml and the absorbance measured at 610 nm. From the standard curves, the pure yield (%) was calculated (Chanayath *et al.*, 2012). The data was analyzed using Design Expert® Software version 7 (DX7). After statistical analysis and optimization of extraction parameters using Desirability function, five sets of experiments were carried out at the optimized conditions to validate the results.

$$Crude\ yield\ \left(\frac{mg}{g}\right) = \frac{w1 - w2}{weight\ of\ the\ plant\ material} \ldots\ldots\ldots\ldots\ldots Eq.\ 1$$

where $w1$=weight of tray containing dried indigo dye and $w2$= weight of empty tray.

Table 1: Central composite design of extraction parameters

Variable	Unit	Level	
		Low (-1)	High (+1)
pH	-	9	13
Oxidation time	Minutes	30	120
Batching time	Hours	18	72

Fabrication of indigo extraction equipment

The equipment was designed to suit the purpose of the extraction process for indigo and other natural dyes. The extraction equipment was constructed using stainless steel and consists of 9 components including 2 steeping/soaking tanks, 1 oxidation tank, 1 filtration tank, and 2 evaporators, 2 condensers and a steam boiler. The whole equipment (Figure B1, Appendix B) is controlled by an electric panel. Each of the steeping tanks is of 1,000 litres capacity and is equipped with mechanical presser (diameter= 1.16 m, height= 1.22 m) whose purpose is to weigh down (submerge) the plant material completely inside water (see Figure B2, Appendix B). Direct steam can be injected into the tank through by a steam blower at a rate of 100 kg/hr. to raise temperature where necessary. The steeping/soaking tank is connected to an oxidizing tank via a 25 mm pipe in which the fermented broth is transferred with the aid of 1 HP pump.

The oxidizing tank is fitted with a stirrer controlled by a 1 HP electric gear motor which turns at 360 rpm (see Figure B3, Appendix B). At the bottom of the tank is a root blower controlled by a 3 HP electric motor. Valve, 25 mm, is fixed at the outlet of the blower to control the flowrate. For a batch process, liquid is siphoned off through an upper outlet and the sedimented indigo at the bottom is collected via a tap attached to the bottom of the oxidizing tank and a mesh just beneath the tap. For continuous process, the oxidized solution is pumped into a filtration tank where 3 filter cartridges trap the dye particles under pressure. The trapped dye is then collected and passed to the evaporators (equipped with a stirrer) to separate indigotin and indirubin. Steam is also passed through the evaporator to dry the final product. The solvent used to dissolve the crude indigo is recovered by the condensers. The flowchart showing the steeping and oxidizing tanks is shown in Figure 1.

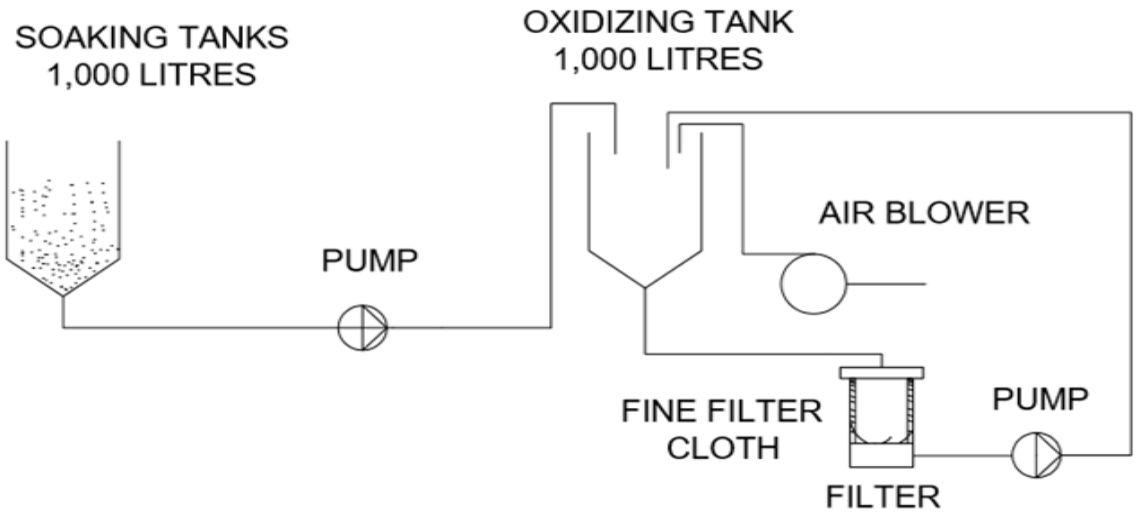

Figure 1: Flowchart showing soaking and oxidizing tanks

RESULTS AND DISCUSSION

Extraction and Yield of Indigo Dye

The extraction procedure was a modification of the method described by Stoker et al (1998) who used similar extraction technique to produce indigo on a large, commercial scale, from *Isatis tinctoria* leaves. Indigo precursor in *Indigofera tinctoria* is indican. The precursors are water soluble and on hydrolysis easily release free indoxyl which on aeration readily form indigo which is insoluble and therefore sedimentable. The identity of the extracted indigo was confirmed by UV-Visible spectroscopy, infrared spectroscopy, mass spectroscopy as well as proton and carbon nuclear magnetic resonance spectroscopy (not shown). Central composite design (containing 5 levels of each factor viz. low and high factorial, low and high axial, and centre) was used to fit a model, develop regression equations, and then optimize key factors influencing the quantity and quality (crude and pure yield) of the dye produced. The results obtained for crude and pure yield from different combinations of fermentation period as well as pH and oxidation time (Table 2).

Table 2: Crude and pure yield obtained from different combinations of fermentation time, pH and oxidation time

Run No.	Batching time (hr.)	pH	Oxidation time (min.)	Crude yield (g/kg)	Pure yield (%)
1	45	11	68	15	44.1
2	45	11	120	19	49.7
3	45	13	68	17	45.3
4	45	9	68	11	30.0
5	45	11	15	14	40.1
6	64	10	105	4	25.3
7	72	11	68	4	24.1
8	18	11	68	31	68.5
9	45	11	68	13	48.9
10	45	11	68	14	38.9
11	64	12	30	6	26.8
12	45	11	68	14	42.8
13	26	12	105	30	69.8
14	26	10	30	23	44.6
15	45	11	68	20	43.8

The highest crude yield, 31.0 g dye per kg of plant biomass (3.1%), was obtained when the batching/fermentation time was 18 hr. and where the pH was adjusted to 11 before oxidation for 68 min. The lowest yield, 4 g/kg, was obtained when the fermentation period was 64 hrs. (oxidation for 105 min. at pH 10) and 72 hrs. (oxidation for 68 min. at pH 11). The yield decreases with increase in fermentation time but increases with both increase in pH and oxidation time. Fermentation time for *Indigofera tinctoria* was suggested to be 15 to 16 hrs. as longer extraction time leads to contamination of the steep water with plant-derived materials (Pattanaik *et al.,* 2018; Pattanaik *et al.,* 2020a-b, Pattanaik *et al.,* 2021). The yield measured in this study, 3.1%, appears reasonable since John and Angelini (2023) reported that exceptional samples of *Indigofera tinctoria* might yield indigo to a value of 3.5%. Mussak and Bechtold (2009) also reported that traditional method of producing indigo has a maximum yield of 37 g/kg dry weight of leaf. Stoker et al (1998a) obtained a crude yield of 20 g/kg on a pilot scale from *Isatis tinctoria* leaves.

The purest sample among the 15 runs in the experiment has a purity of 69.8% which was obtained after 26 hrs. fermentation and oxidation for 105 min. at pH 12. The pure yield also shows the same trend as crude yield where lowest yield was obtained when the fermentation period was 64 hrs. (yield was 24.26.8%). The yield also increases with increase in pH and oxidation time but decreases with increase in fermentation period. Synthetic indigo is usually higher than 90% pure while natural indigo is 20-90% pure where a good sample of Bengal indigo was 61.4% (Perkin, 1900). Dutta et al (2017) obtained highest pure yield after 24 hrs. of fermentation. Natural indigo dye from Indigofera tinctoria plant biomass is believed to provide the highest purity of indigo dye (Pattanaik *et al.,* 2018). John (2004) obtained an average purity of 74±10% with an average yield of 0.5g/kg fresh leaves. Stoker et al (1998) achieved a pure yield of 20-40% from *Isatis tinctoria* leaves. Washing raw indigo in 2 M HCl after grinding the dried product could have improved the purity of the extracted dye. Dramatic increase in purity has been obtained from 3 large scale preparations of indigo by a wash with dilute HCl from 21-71%, 0.6-63%, and from 19-72% (John, 2004). Indigo can be extracted from woad with a purity of 90% if the leaves contain sufficiently high yield of indigo precursors and the leaves are rinsed free of soil (John, 2004; Garcia-Marias and John, 2004).

Model Fitting and Statistical Analysis

Analysis of variance (ANOVA) for the responses "crude yield" and "pure yield" was generated by Design Expert Software version 7 (DX7). Lack of fit shown in Tables 3 for both crude and pure

yeild compares residual error to the "pure error" from replicated design points. The selected model should have insignificant lack of fit. Lack of fit in this case is not significant and therefore the model can be used as a response predictor. The linear models selected exhibits low standard deviation, high coefficient of determination (94.72% and 93.69% respectively for crude and pure yield) and low PRESS. As shown in Tables 3, the model F-values imply that the selected models are significant. Values of "Prob>F" less than 0.05 will indicate that the model terms are significant.

Table 3: Analysis of variance (ANOVA) test for significance for crude yield and pure yield

Statistical Metric	Response 1: Crude yield	Response 2: Pure yield
Suggested model type	Linear	Linear
Model *p*-value	0.0001	0.0001
Ordinary R^2	0.9472	0.9369
Adjusted R^2	0.9328	0.9197
Predicted R^2	0.9190	0.8802
Lack of Fit (*p*-value)	0.8995	0.4373
Adequate Precision	26.321	24.373
Standard deviation	2.11	3.85
PRESS	75.24	309.67

$$\text{Crude yield} = +15.67 + 2.19 * A + 1.51 * B - 10.15 * C \quad \text{.....Eq. 2a}$$

$$\text{Pure yield} = +42.85 + 6.04 * A + 4.66 * B - 15.64 * C \quad \text{.....Eq 2b}$$

For both responses, the predicted determination coefficient (Pred R^2=0.9190 and R^2=0.8802 for crude and pure yield respectively) are in reasonable agreement with the adjusted determination coefficient (Adj R^2=0.9328 and R^2=0.9197 for crude and pure yield respectively) which is satisfactory to confirm the fitness of the model. The "Adeq Precision" ratios (26.321 and 24.373 for crude and pure yield respectively) indicates an adequate signal which implies that model for the responses could be used to navigate the design space. The negative sign in front of the terms in a first order regression model indicates antagonistic effect whereas a positive sign shows synergistic effect. The responses, crude and pure yield, increase with an increase in oxidation pH and oxidation time but decrease with increase in batching/fermentation time. There is however, no interaction among the extraction parameters investigated. Interaction occurs when the effect of one factor on the response variable depends on the level of another factor (Anderson and Whitcomb, 2007). The relationship between crude and pure yields with oxidation pH and time as well as fermentation time established in this study (Eq. 2a and 2b respectively in coded form) can be used as a model for indigo dye extraction from *Indigofera tinctoria* biomass.

The consistency of the data for responses "crude yield" and "pure yield" was confirmed from normal probability plot of residuals shown in Figures 2a and 2b respectively. In both cases, the points are fairly close to a straight line indicating the validity of the experimental data since the residuals are normally distributed. As shown in Tables 4, the value of residuals (difference between experimental data and the predicted value) is low showing the precision of the experiments (Wagaw and Chavan, 2012: Myers *et al.,* 2009).

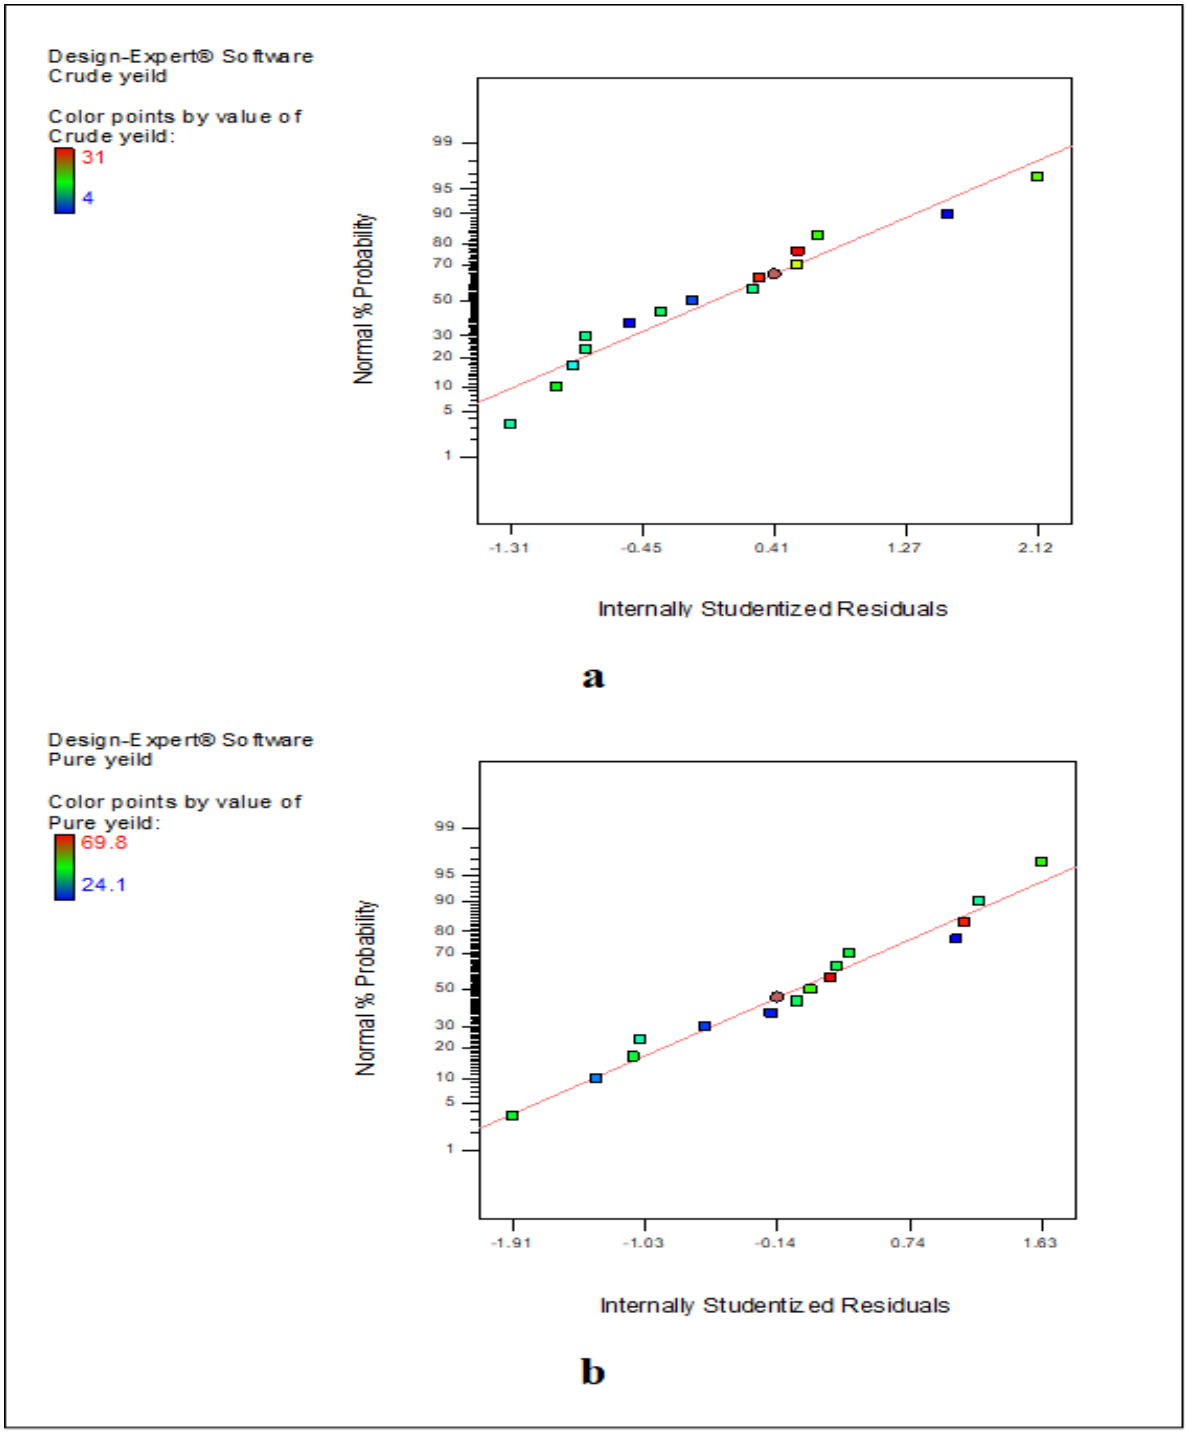

Figure 2: Normal probability plot of residuals (a) crude yield (b) pure yield

Table 4: Diagnostic case statistics showing residuals for crude and pure yield

Crude yield				Pure yield

13.00	15.67	-2.67	9	48.90	42.85	6.05	9
14.00	15.67	-1.67	12	42.80	42.85	-0.047	12
15.00	15.67	-0.67	1	44.10	42.85	1.25	1

Optimization of Extraction Parameters for Large Scale Production

The objective of this optimization is to simultaneously make crude and pure yield as high as possible. In numerical optimization, desired goal is chosen for each factor and response. A multiple response method was applied for optimization of combinations of three factors namely oxidation pH, oxidation time and batching time. The 2 responses optimized were average crude and pure yield. The criterion was set as follows: "in range" for pH, "equals to 18" for batching time (because 18 hours batching time resulted in the highest crude yield and fermentation for more than 24 hours results in microorganisms contaminating the liquor affecting pure yield), "in range" for oxidation time, "maximize" crude yield, and "maximize" pure yield. Figure 3 shows the ramp of optimal parameters for crude and pure yield. The dot on each ramp reflects the factor setting or response prediction for that solution. Batching for 18 hrs. and oxidizing for 63 min. at pH 12 will result in 31.99 g/kg crude yield and 70.35% pure yield with a desirability of 1.000. The optimum conditions predicted were checked experimentally on a large-scale extraction using 100 kg of plant biomass 5 times. The experimental values obtained for crude and pure yield (for five replicates) using the predicted values of the extraction parameters was respectively 32.13±0.7 g/kg and 71.12±1.3%. Small errors between these values indicated that the experimental values obtained were in good agreement with the values predicted from the models. Physicochemical parameters of indigo dye extraction including fermentation conditions such as temperature and time (Rahayuningsih *et al.,* 2022; Syafaatullah and Mahfud, 2020; Dutta *et al.,* 2017; Hidayati *et al.,* 2018) as well as oxidation conditions comprising of oxidation pH, oxidation time, and air flowrate (Pattanaik *et al.,* 2021) has been optimized previously using design of experiment to maximize indigo yield.

(Note: The software predicted the runs with combination of factors based on the information we provided in Table 1 as shown in Table 2. The columns crude and pure yield were originally empty with no values. After conducting 15 batch experiments and obtaining the samples shown in Figure A7, the crude and pure yields of each of the samples was determined and placed in the columns. It was after feeding the software with the results that statistical analysis and optimization were possible to obtain the predicted and optimized results).

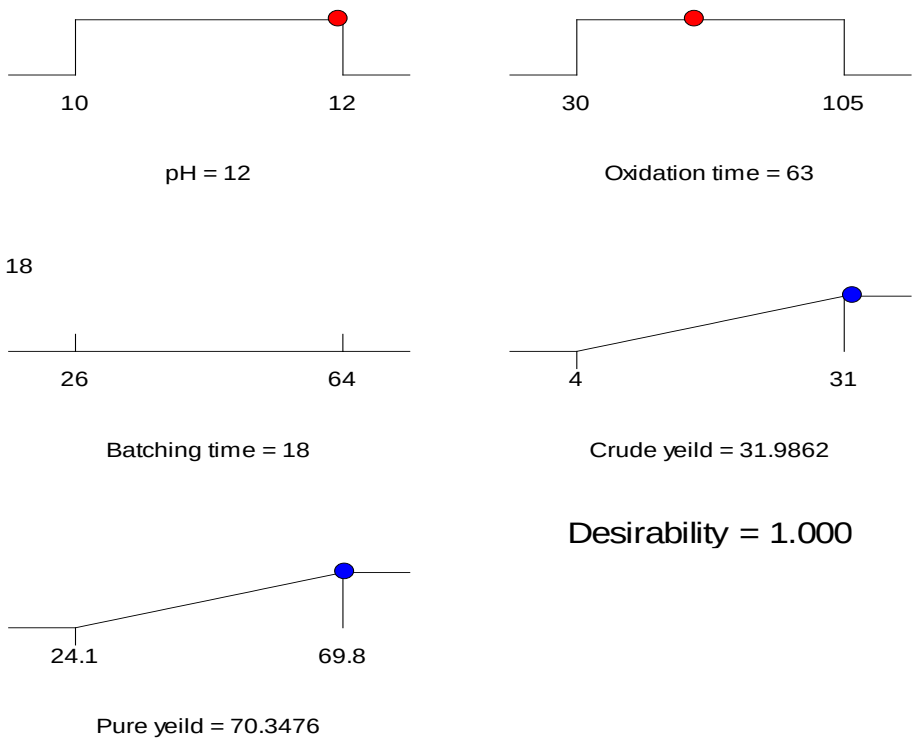

Figure 3: Ramp of optimal conditions for crude and pure yield

CONCLUSION

This study successfully designed, fabricated, and evaluated an inductive-scale natural indigo extraction machine, bridging the critical scale-up gap between laboratory-optimized bio-chemical kinetics and commercial pilot production. Tested across five consecutive validation runs under optimized operating conditions (18 hours fermentation, 63 minutes oxidation, and pH 12), the machine demonstrated exceptional operational fidelity and mass transfer efficiency. The inductive-scale unit achieved a crude pigment yield of 32.13 g/kg biomass and a pure yield of 71.12% (this progresses towards 90% purity obtainable with synthetic indigo and also the 90% purity sought by the European Union under sustainable production of plant-derived indigo), confirming that scaling up from bench parameters (31.99 g/kg crude yield and 70.35% pure yield) was accomplished without yield loss or kinetic degradation. The mechanical agitation, aeration dynamics, and volumetric mass transfer efficiency of the fabricated unit proved highly effective for pilot-scale processing. Furthermore, utilizing locally available engineering materials for construction demonstrates that sustainable industrial processing equipment can be manufactured cost-effectively within Nigeria, significantly reducing capital expenditure compared to foreign machinery imports. Industrially, this scalable extraction framework offers a viable technical pathway to commercialize natural indigo cultivation, substitute synthetic colourant imports, mitigate toxic effluent loading, and stimulate agrarian-industrial growth. Future iterations will focus on integrating automated pH monitoring and continuous-flow aeration controls.

It is recommended to incorporate a finer mesh than the one used in the fabricated equipment as this may likely enhance crude indigo yield. Indigo yield depends on climatic conditions which vary from season to season. It is therefore imperative to investigate seasonal variations and harvest time which could lead to changes in indigo yield. Indigo seed should be genetically modified and grown in the farms or in close proximity according to the principles of Good Agricultural and Collection Practices (GACP) which recommends on-farm production and post-production processes to address environmental, economic, and social sustainability. Considering the irregular power supply in the

country especially in remote areas like farms, solar panels are recommended to be installed on the equipment to have uninterrupted power supply which is mainly needed for the transfer of the fermentation broth from steeping to the oxidation tank and for blowing air into the oxidation tank.

ABSTRACT
Wastepaper is paper discarded after being used. Post-consumer paper, or wastepaper, is a vital renewable raw material source for the paper industry and can contribute substantially to the reduction in the importation of paper. With over 45,000 students, about 20,000 staff (academic and non-academic) and 106 departments, Ahmadu Bello University, Zaria, is the largest university in West Africa. With a population of about 200 million people, on the average, a Nigerian uses about 10 kg of paper per year. The result showed that for student respondents, 68% between 21-30, 59% are Postgraduate Diploma (PGD) students and 55% have been in ABU for 2-4 years. The demographic results for academic and non-academic staff respondents show that 72% are males, 50% of the respondents are single, 40% between 41-50 years and 62% have worked in ABU for 0 to 5 years. 62.4% of the staff and 54.2% of the students mentioned that reuse of wastepaper is what they do to curb wastepaper generation. The practice among the staff with the highest rank is the burning of wastepaper, while the activity with the least rank is sorting of waste before dumping them into the dustbins. The members of the university community should be encouraged to practice the 3Rs of waste management on waste more than is currently being practiced in the order of reduce, reuse and recycle. With 48.5% of the students Sometimes/Often/Always buy used textbooks, the Student Union can create a book buyback program as one of the methods of mitigating wastepaper generation on campus.

Keywords: *A.B.U; wastepaper; book buyback; reduce; reuse and recycle*

INTRODUCTION

Paper is a thin sheet material made from a combination of mechanical and chemical processes converting cellulose fibres derived from wood, rags, grasses or other vegetable sources. The raw materials are soaked in water, the water is then drained through a fine mesh, leaving the fibre evenly distributed on the surface of the mesh. This process is followed by pressing and drying. Paper is a versatile material used for several purposes such as books, printing, packaging, decorating, writing, cleaning, wallpaper, filter paper, conservation paper. laminated worktops, toilet tissue, currency, security paper and a number of industrial and construction processes (Hogben, 1951; Mann, 1952).

Wastepaper is paper discarded after being used. Wastepaper from scrap newspapers, books and periodicals, office paper, kraft paper, paper boxes and corrugated paper are all valuable fibrous raw materials (Worldwide Fund for Nature, 2019). Post-consumer paper, or wastepaper, is a vital renewable raw material source for the paper industry and can contribute substantially to the reduction in the importation of paper. Its recycling is also important from the environmental perspective, as systematic collection and recycling of wastepaper can greatly reduce the volume of municipal solid wastes. It has been estimated that recycling one ton of wastepaper results in a saving of 70% raw material, 60% coal, 70% water and 43% energy, as compared to making virgin paper from wood (Ministry of Environment and Forests Notification India, 2011; Devi and Sastry, 2017).

Wastepaper forms a certain percentage of waste stream that ends up in the dumpsite / landfill. According to Alim and Ahmed (2020), paper form about 18% of the waste stream in Gombe town, Gombe State Nigeria. This percentage is significant. If this percentage is reduced or removed from the waste stream, things such as cost of production of paper, land pollution, air pollution and water pollution would be effectively reduced. Nigerian Government policies towards waste sorting, reduce, reuse and recycle would also play an important role in reducing the overall waste stream that ends up dumpsite / landfill (Sridhar and Hammed, 2014).

The key causes of solid waste complications in Nigeria have been associated with large population, poverty and urbanization growth rates complicated by a weak and underfunded infrastructure (Ezeah and Roberts, 2012). The management of solid waste in Nigerian cities continues to pose serious challenges due to the absence of appropriate and organized waste management culture and technologies, arising from financial, political instability, technological constraints and poor implementation of policy (Afun, 2009; Ezerie, George, Chidi and John, 2017).

Ahmadu Bello University (ABU) is a public university founded on October 4, 1962, located in Zaria, Kaduna State in the Northern part of Nigeria. With over 45,000 students, about 20,000 staff (academic and non-academic) and 106 departments, it is the largest university in West Africa and the second largest on the African continent after the University of Cairo in Egypt. The university has two main campuses, the main campus located in Samaru and annex campus in Kongo, both in Zaria (ABU, 2021). With this large population of students enrolled in diploma, undergraduate and postgraduate programmes, there is a large usage of paper for various activities. The Samaru Campus which is the focus of this study has an estimated population of 16,150 people (staff, students and cleaners). A certain percentage of the paper used ends up as waste to the dumpsite. This article looks at the attitude, practices and knowledge of the ABU community towards paper after its use.

On the average, each person in the United States of America uses approximately 749 pounds (339.741 kg) of paper a year. Some the paper goes into things such as books, used in other permanent applications like insulation or roofing shingles for your home (Georgia-Pacific Corporation, 2011). In Nigeria however, the data available is on the quantity of paper imported into the country which is 2 million metric tons annually (Adunola, 2018) with almost zero local production. With a population of about 200 million people, on the average, a Nigerian uses about 10 kg of paper per year.

$$\text{average paper use per Nigerian} = \frac{\text{quantity of paper imported}}{\text{estimated total population}} = \frac{2{,}000{,}000{,}000}{200{,}000{,}000} \quad (1)$$

$$= 10\, kg/person$$

METHODOLOGY

A questionnaire was designed to obtain information from different categories of members of the university community. The respondents were categorized into three, namely staff (academic& non-academic), students and the casual staff who carry out the general cleaning within the university on daily basis. For the purpose of this study, the main campus in Samaru was the main focus. The population of study consists of students, academic & non-academic staff and other members of the university community within the Samaru campus, which is estimated 16,150. The sample size is 201 which was determined using Yamane's formula for determining samples size as seen in equation 1 below.

$$n = \frac{N}{1+N(e)^2} \quad (2)$$

where n is sample size, N is population size and e is sampling error (± 7%)

out of the 201 used as sample size, 101 questionnaires were administered to student and all were received back, while 50 questionnaires were administered to both academic and non-academic staff, while 50 questionnaires were administered to the cleaners. 48 questionnaires were received from the staff and 48 questionnaires were received from the cleaners. This distribution pattern is necessary because, out of the estimated 16,150 estimated people in the Samaru campus, the student are about half of this population. Based on the estimated population of Samaru campus, the average annual paper use is given by:

$$\text{estimated annual paper usage in ABU} = 16{,}150 \times 10\ kg/person \quad (3)$$

$$= 161{,}500\ \text{kg}$$

To achieve the aim of this study, a questionnaire was used to find out how wastepaper is managed in ABU. The questionnaire comprises of three different segments namely, for students (33 questions), academic and non-academic staff (30 questions), for casual workers (cleaners) and waste disposal truck drivers (28 questions) which was conducted by interview because most of them can only communicate in Hausa language. The response of each of the casual workers was filled on the

questionnaire as they responded. The questions for each group of respondents were categorized into parts consisting of information related to the sources of wastepaper, wastepaper reduction, wastepaper handling, uses of wastepaper and wastepaper disposal.

Questions on knowledge and awareness had an assign score, using Likert scale, 1-5 for "Never", "Seldom", "sometimes", "often", "always" respectively. The practice statements were scored based on negative or positive wording of the items. For every positive response (Yes) the respondent was scored 2 while every negative response (No) was scored 1. Questions on students practice on wastepaper management and what they will do in some certain situations were assigned a score of 0-4 for 'pass them to friends', 'sell them', 'throw them away', 'keep them', 'others' respectively (Vagias, 2006).

RESULTS AND DISCUSSION

The result showed that for student respondents, their age ranges are 27% below 20, 68% between 21-30, 4% between 31-40 and 1% above 41% respectively. 34% of the respondents are B.Sc. students, 59% are Postgraduate Diploma (PGD) students, 4% are M.Sc. students, 1% are M.Phil. students and 2% are Ph.D. students. on the number of years in ABU, 1% of the respondents have stayed more than 6 years in ABU, 12% have stayed between 4-6 years, 55% for 2-4 years and 32% between 0-2 years.

The demographic results for academic and non- academic staff respondents show that 72% are males while 28% are females. 50% of the respondents are single, 33% are married, 6% are divorced and 11% are widows. Their age ranges are 24% for below 30 years, 36% for 31-40 years, and 40% for 41-50 years. On their level of education, 50% are school certificate holders, 29% B.Sc. holders, 13% are M.Sc. holders and 8% are Ph.D. holders. On the number of years working in ABU, 62% have worked in ABU for 0 to 5 years, 29% for 6 to 10 years and 9% for 11 to 15 years.

The demographic results for cleaners and waste disposal truck drivers shows for their age distribution, 24% are below 30 years, 52% are between 31 to 40 years, 20% are between 41 to 50 years and 4% are above 51 years old. The males are 20% while the females are 80%. Most of the cleaners that are involved in cleaning the class rooms and offices are women, validating the fact that most of the cleaners are women. 13% are single, 54% are married, 4% are divorced, 29% are widows. 75% have been working in ABU between 0-5 years and 25% between 6-10 years.

Table 1: Approaches to wastepaper management by staff on campus

Methods	Frequency	Percentage (%)
Reduce	10	9.9
Recycle	20	19.8
Reuse	63	62.4
Others	8	7.9

Reduce 9.9%, Recycle 19.8%, Reuse 62.4%, Others 7.9%

Table 1 shows that 19.8% of the respondents agreed that recycling is the most common method used for wastepaper management in ABU Samaru campus. 62.4% mentioned that reuse of wastepaper is what they do to curb wastepaper generation within the campus while reducing wastepaper generation is the least method in use for wastepaper management in ABU because paper represent a huge resource used for academic and research activities on campus. It should be noted that 7.9% still adopt other methods such as burning and flushing in suck away are methods they in managing their wastepaper.

Table 2: Approaches to wastepaper management by students on campus

Methods	Frequency	Percentage (%)
Reduce	4	8.3
Recycle	18	37.5
Reuse	26	54.2

Using the percentages as shown in table 2, it can be seen that 54.2% of the students practice wastepaper reuse as wastepaper management method, 37.5% recycling and 8.3% use wastepaper reduction as a method of paper management. Similar to what is practiced by the staff as in table 1, reusing of wastepaper is the second used approach to wastepaper in campus. This is laudable; however, more efforts and awareness should be put into encouraging members of the university community to reduce paper usage as the best approach to wastepaper management.

Table 3: Sources of wastepaper among staff

Sources	**Frequency**	**Percentage (%)**
Newspaper	16	11.6
Flyers	12	8.7
Mails	18	13
Memos	12	8.7
Envelope	2	1.4
Seminar papers	18	13
Minutes of meetings	2	1.4
Result deliberations	6	4.3
Printed paper	26	18.8
Project report	12	8.7
Flyers	6	4.3
Minutes of meeting	8	5.8
Others	0	0

The major source of wastepaper among the staff by percentage as shown on table 3 are printed papers (18.8%), mail and seminar papers at (13%), newspaper (11.6%), memos, project report and flyers (8.7%) with files been the least source of wastepaper on campus. Printed paper usually come from request for staff information from individual staff by the university management, draft work of supervisee given to the supervisor, presentations at the departmental boards, faculty boards and senate standing committee meetings, printing of curriculum vitae and other supporting documents during promotion exercises etc.

Furthermore, seminar papers are the second main source of wastepaper due to regular seminars presented by postgraduate students. in this case, each student has to produce a significant number of copies of his/her work for the audience. Most of these seminar papers become waste as soon as the student finishes the presentation for that particular day. There is the need to seriously look into several ways of reducing paper consumption during the above-mentioned activities.

Table 4: Sources of wastepaper among students

Sources	**Frequency**	**Percentage (%)**
Lecture notes and course packs	39	38.7
Newspaper	6	5.9
Flyers	17	16.9
Mails	2	2
Cardboards	6	5.9
Printed paper	7	6.9
Textbooks	7	6.9
Seminar papers	8	7.9
Others	9	8.9

Table 4 shows the type of wastepaper generated on campus by students. The study revealed that lecture notes and course packs constitute the largest single source of wastepaper (38.7%) while mails constitute the least source of wastepaper among students on campus (2%). These lecture notes come in form of lecture materials issued by the course lecturer(s), solution to past questions, whole or part of textbook(s) etc, which are usually available at photocopy shops within the department or at other locations within the campus. In most cases, almost all the students in each of the courses procure some or all of these materials, of which they become wastepaper the moment the students conclude their examinations.

The various locations where wastepaper are collected on campus are senate building (10%), printing press (12%), classrooms (15%), staff offices (9%), departmental offices (21%), photocopy centers (12%), residential areas (16%) and other locations such as the field, basketball court and street are 5% respectively. As earlier mentioned, there is a great deal of wastepaper generated from the departmental offices. These usually comprises of request that have been attended to, excess submissions at the end of meetings, photocopies of documents during accreditation and promotion exercises, old documents that are disposed etc.

Table 5: Staff responses to items based on practice

	Never (1)	**Seldom (2)**	**Sometimes (3)**	**Often (4)**	**Always (5)**	**Mean**	**Rank**
Do you sort waste before dumping them into the dustbins?	14	4	18	8	4	2.67	6
Do you shred wastepaper before dumping it into the dustbin?	6	8	22	10	2	2.88	4
Do you work on draft documents electronically instead of on printed paper?	10	6	16	16	0	2.79	5
Do you use the second page of paper with printed materials on one page?	2	8	24	10	4	3.13	2
Do you print on both pages of sheet of paper to reduce paper wastage?	8	2	18	10	8	3.04	3
Do you burn wastepaper?	6	6	14	12	10	3.29	1

Table 5 shows the response of staff to practice on how they handle wastepaper generated in their domain. The practice with the highest rank is the burning of wastepaper, while the activity with the least rank is sorting of waste before dumping them into the dustbins. This is an indication that burning of wastepaper is a common practice which should be discouraged. There are numerous hazards associated with the burning of wastepaper such as air pollution and bush fires in the dry season which the members of the university community are exposed to. Whereas waste sorting that would encourage waste reuse and recycling is not a common practice.

Table 6: Student responses based on practice

	Never (1)	**Seldom (2)**	**Sometimes (3)**	**Often (4)**	**Always (5)**	**Mean**	**Rank**
Do you buy used textbooks?	48	4	38	3	8	2.20	6
Do you work on draft documents electronically instead of on printed paper?	18	10	57	14	2	2.72	3
Do you print on both pages of paper to reduce paper wastage?	4	4	51	22	20	3.50	1
Do you shred paper before dumping to the dustbin?	16	10	47	10	18	3.04	2
Do You burn wastepaper?	32	14	43	7	5	2.40	4
Do you reuse scrap paper?	36	4	52	6	3	2.37	5

Students usually print on both sides of paper in order to reduce paper wastage and to reduce the cost of printing and photocopying which has the highest rank among the activities done by students to reduce paper wastage. However, the least practiced activity is buying used textbooks. There is the need to encourage or come up with a book buyback program on our university campuses. This would help students have access to books at reduced price. Table 7 shows that 27% of academic and non-academic staff are familiar with print preview when working with Microsoft (MS) Word, 23% are familiar with paper settings, 20% are familiar with margin and layout settings, 6% are familiar with how to use comment in MS Word, and 2% can use track changes settings. Furthermore,

Table 7: Familiarity of Staff with MS Word Settings

MS Word Settings	**Percentage (%)**
Print Preview	27
Paper Settings	23
Margin And Layout Settings	20
Use Comment	6
Track Changes Settings	2
Compare Tab	6
Split Screen	8
Spelling And Grammar	8

Paper shredding machines should be provided at certain offices on campus and Academic staff should be encouraged to send and receive assignments, handouts and course materials using electronic drafted copies. 57% of students reuse scrap paper for calculations, 30% for jotting and 13% for revision in other to reduce wastepaper.

Table 8: Items based on the level of knowledge for staff

	Yes	**No**
Do you have a dustbin in your office?	40 (83%)	8 (17%)
Do you know what happens to wastepaper after you dump them in dustbin?	20 (42%)	28 (58%)
Do you know that wastepaper can be recycled to get new paper?	46 (96%)	2 (4%)

In table 8, 96% of the respondents have knowledge that waste paper can be recycled to get new paper, 17% do not have a dustbin in their offices and 58% of the academic staff and non-academic staff

do not know what happens to the wastepaper after they are dumped. The mean score shows that they are knowledgeable about common environment friendly wastepaper reduction practice.

Table 9: Application of wastepaper according to staff and students

Application	**Frequency**	**Percentage (%)**
Recycled paper bags	24	14
Recycled paper basket	10	6
Paper mâché	30	17
Pen stand	12	7
Recycled paper wall hangings	10	6
Origami crafts	4	2
Egg tray	32	19
Tissue/ toilet / napkin paper	36	21
Others (Packaging and ceiling)	13	8

Table 9 shows the potential application of wastepaper, 21% of respondents have knowledge that recycled paper can be used to make Tissue/ Toilet / Napkin papers while only 2% have knowledge on the use of wastepaper for origami crafts. Other application of wastepaper include used as roof ceiling and common practice is the use for packaging certain

items such as bean cakes, Suya meat, and most fries within and outside the campus.

Table 10: Wastepaper application according to cleaners

Application	**Frequency**	**Percentage (%)**
Recycled paper bags	14	12
Recycled paper basket	14	12
Paper mâché	16	14
Pen stand	4	3
Recycled paper wall hangings	6	5
Origami crafts	4	3
Egg tray	26	22
Tissue/ toilet / napkin paper	24	20
Others (Packaging and ceiling)	10	9

Table 10 shows the various application of recycled wastepaper. 22% are aware of egg tray as a major application of wastepaper, 20% are use as tissue/toilet/ and napkin paper within and around the campus. The least used is origami craft which are mostly used by kids in their craft works and assignments. With 9% of the respondents using these recycled papers for packaging and also as ceiling in rooms around campus. Most of the cleaners and waste collects generate some amount of money for the sale of these papers which encourages them to sort out the one-sided printed paper from other papers for the purpose of reuse.

76% of both academic and non-academic staff, cleaners/waste collectors and truck drivers sort their waste before disposing it. There are enough waste bins within the campus but 82% of the cleaner respondents suggested having points for some waste categories which will discourage indiscriminate waste disposal and also encourage the practice of waste sorting generally. The findings of this project revealed that major source of paper waste is printed paper and with the departments being the highest producers of wastepaper (21%), 19% from residential, 15% from classes, 12% from printing and photocopying centers, 10% senate, 9% staff offices and 5% other locations on campus.

The 3Rs of waste management are reduce, reuse and recycle. However, from the responses of both the staff and students, it would be observed that waste reduction is the least practiced approach with 9.9% and 8% for staff and students respectively. There is the need to imbibe the attitude of reducing waste as the most important approach to waste reduction. The main source of wastepaper among staff is printed paper (18.8%), followed by seminar papers and mails (13%) each. Additionally, the main sources of wastepaper among students are Lecture notes and course packs, flyers and others with 38.7%, 16.9% and 8.9% respectively. This corroborates the earlier assertion that if wastepaper is reduced, it would significantly reduce the sources of wastepaper.

On the knowledge of what happens to wastepaper after it has been disposed into the waste bins, the staff and students are aware that wastepaper can be used in applications such as tissue/ toilet / napkin paper — 21%, egg tray — 19% and paper mâché -17%. While in the responses of the cleaners, they are also aware that wastepaper can be used in applications such as egg tray — 22%, tissue/ toilet / napkin paper — 20% and paper mâché -14%.

Finally, a book buyback program is one in which used textbooks and course packs are bought from student who no longer need them at a reduced rate. These books are then sold to students who now need them. This gives a win-win scenario to both the initial owner of the book, as he can still make some money from selling his old books, and to the buyer who would get a fairly new book at a reduced price rather than buying a new book. If the second user is able to take proper care of the book, he may still be able to sell the book through the book buyback program. Such books can be used by as many people as possible until it is defaced.

CONCLUSION

The members of the university community should be encouraged to practice the 3Rs of waste management on waste more than is currently being practiced in the order of reduce, reuse and recycle. With 48.5% of the students Sometimes/Often/Always buy used textbooks, the Student Union can create a book buyback program as one of the methods of mitigating wastepaper generation on campus. The book buyback program is expected to target textbooks and other lecture materials which forms about 45.6% of waste materials generated by the students. 78% academic and non-academic staff respondents are familiar with MS Word features such as print preview, paper settings, how to use comment, margin and layout settings and use track changes settings. This is a significant percentage, which the university management can leverage on to ensure that more staff use these features to save paper. Additionally, 73.7% of wastepaper generated by the staff can be reduced drastically if these features of MS word can be put to use. With the increasing level of global warming there is need for school authority and government to create more room for research, workshops and seminars on ways to better improve our immediate environment and also increase the level of awareness on wastepaper management and promote environment friendly practices.

ABSTRACT

The increasing accumulation of polystyrene waste and the environmental impact associated with cement production have necessitated the search for sustainable alternatives in the construction industry. The study evaluated the properties of sandcrete mortar containing polystyrene waste and fly ash with a view to developing a lightweight and environmentally friendly material for potential use in non-load-bearing sandcrete blocks. A cement-to-sand mix ratio of 1:6 and a constant water-cement ratio of 0.50 were used to produce the sandcrete mortar cubes of 50x50x50 mm and cylinders of 70mm diameter x100mm height. Fine aggregate was replaced with polystyrene at 0, 5, 10, 15, 20, and 25% by volume, while fly ash was maintained at a replacement level of 10% of cement. In the fresh state, the mixes were tested for consistency using a flow test, while in the hardened state, the sandcrete mortar samples were tested for compressive strength, tensile strength, and density. Furthermore, the morphology of the sandcrete mortar specimens was assessed using Scanning Electron Microscopy (SEM). The results show that the compressive strength of the specimens decreased as the polystyrene content increased from 5 to 25%. However, the mix containing 5% polystyrene and 10% fly ash achieved a compressive strength of 3.125 N/mm² at 90 days, compared with 3.375 N/mm² for the control mix, representing a 7.4% reduction in compressive strength. SEM analysis confirmed a denser cementitious matrix in fly ash-modified mixes due to secondary calcium silicate hydrate (C–S–H) formation, while higher polystyrene contents produced larger interfacial voids that contributed to strength reduction. The 5% polystyrene and 10% fly ash mix was identified as the optimum modified mix, achieving a compressive strength of 3.125 N/mm², exceeding the 2.5 N/mm² minimum requirement reported for non-load-bearing sandcrete blocks under NIS 87:2007, indicating its potential suitability for non-load-bearing applications.

Keywords: *fly ash; sandcrete blocks; polystyrene waste; mechanical properties*

1.0 INTRODUCTION

The construction industry is increasingly seeking sustainable methods of producing building materials without compromising performance. The utilization of industrial by-products and waste materials in construction can reduce dependence on natural resources while providing useful applications for materials that would otherwise contribute to environmental pollution. The use of waste materials as lightweight aggregates has therefore received increasing attention because of their availability and potential to reduce the weight of construction products (Arshad, 2014; Khatib, 2009). Polystyrene is a lightweight, non-biodegradable thermoplastic commonly used for food packaging, disposable cups, cartons, and other consumer products. Its closed-cell structure and low density make it attractive as a lightweight material for cement-based products (Kan, 2009). However, its widespread disposal creates environmental challenges. Polystyrene waste can accumulate in drainage systems, streets, and disposal sites, while inappropriate disposal and burning may contribute to environmental pollution (Murana, 2020; Kehinde & Babatunde, 2020; Olutoye et al., 2022).

The incorporation of polystyrene waste into construction materials offers an alternative approach to managing this waste. Previous studies have indicated that polystyrene can reduce the density of cement-based materials; however, increasing its content may reduce mechanical strength due to its low density and relatively weak bonding with the cementitious matrix (Haidar & Khalil, 2002; Babu & Babu, 2003; Kehinde & Babatunde, 2020).

Fly ash is an industrial by-product with pozzolanic characteristics. Its silica and alumina content allows it to react with calcium hydroxide produced during cement hydration to form additional calcium silicate hydrate (C–S–H), which can contribute to strength and matrix densification (Mehta & Monteiro, 2020; Abbas et al., 2021). Studies revealed that fly ash can improve the performance of cement-based materials and provide environmental benefits by reducing cement consumption (Freeda, 2010; Zhang et al., 2022; Olutoge et al., 2023).

In Nigeria, sandcrete blocks are widely used for external and internal wall construction because of their availability and affordability (Anosike, 2012). However, their relatively high density contributes to the dead load of buildings. The use of polystyrene as a partial replacement for fine aggregate can reduce this weight, while fly ash can be used as a partial cement replacement to improve the sustainability of the material (Dadu, 2020; Akinyele & Adedeji, 2021).

Although studies have separately investigated polystyrene and fly ash in cement-based materials, few studies have examined their combined application in sandcrete mortar under local Nigerian conditions. The present study therefore evaluates the mechanical properties of sandcrete mortar blocks containing polystyrene waste as a partial replacement for fine aggregate and fly ash as a partial replacement for cement.

2.0 MATERIALS AND METHODS

2.1 Materials

2.1.1 *Fine Aggregate*

The fine aggregate used for the experiment was river sand sourced from Zaria metropolis, Kaduna State, Nigeria. The sand was sieved through a 4.75 mm sieve to remove large particles and impurities.

2.1.2 *Polystyrene Waste*

Polystyrene waste was collected from dump sites, event centres, and drainage channels within Zaria metropolis. The collected waste was manually sorted to remove contaminants such as paper, soil, and organic materials. It was then shredded using a locally fabricated grinder into particle sizes not exceeding 4.75 mm. Sieve analysis was subsequently conducted to establish the particle-size distribution.

2.1.3 *Cement*

Limestone Portland Cement of Dangote brand conforming to BS EN 197-1:2011 specifications was used.

2.1.4 *Fly Ash*

Fly ash was obtained from BUA Cement Plant, Okpella, Edo State. It was stored in airtight containers to prevent moisture contamination and sieved through 45 μm before use. The physical and chemical characteristics of fly ash are important in determining its suitability and performance as a supplementary cementitious material in cement-based materials (Akhatar & Tarannum, 2018).

2.1.5 *Water*

Portable water fit for drinking was used for both mixing and curing

2.2 Mix Proportioning

A cement-to-sand mix ratio of 1:6 was adopted, representing one part cement to six parts fine aggregate, in accordance with the provisions of NIS 87:2004. A constant water-cement ratio of 0.50 was maintained for all mixes. Fly ash was incorporated as a 10% replacement of cement, while polystyrene waste was used to replace fine aggregate at 0%, 5%, 10%, 15%, 20%, and 25% by volume. The summary of the materials used to produce the samples is presented in Table 1.

2.3 Preparation of Samples

The constituent materials were thoroughly mixed using a mortar mixer to achieve a uniform mixture. The fresh mixes were subsequently cast into 50 × 50 × 50 mm cube molds and 70mm diameter x100mm height cylindrical molds and compacted manually to ensure adequate consolidation. After setting and hardening, the specimens were demolded and fully immersed in a water-curing tank until the specified testing ages.

Table 1: Mix Proportioning of Materials

Polystyrene repl. (%)	**Cement (kg/batch)**	**Fly Ash (kg/ batch)**	**Fine Agg. (kg/ batch)**	**Polystyrene (kg/batch)**
0	3.243	0.00	19.46	0.00
5	2.908	0.323	18.413	0.00493
10	2.908	0.323	17.445	0.00985
15	2.908	0.323	16.476	0.01478
20	2.908	0.323	15.507	0.01971
25	2.908	0.323	14.538	0.024633

2.4 Testing of Samples

In the fresh state, the mortar mixes were evaluated for consistency using the flow-table test in accordance with the procedure outlined in BS EN 1015-3:1999. The measured spread diameters were subsequently classified based on the consistency criteria adopted from the relevant provision of IS 4031. At the hardened state, Density, compressive strength, and splitting tensile strength were measured at 7, 14, 28, 56, and 90 days in compliance with the provisions of BS EN 12390-3 (2002) and BS EN 12390-6 (2009), Three replicate samples were tested for each mixture at each curing age for compressive strength, splitting tensile strength, and density. The results were expressed as the mean value of the three replicates, together with the corresponding standard deviation. Furthermore, the morphology of the mortar cubes were assessed using a scanning electron microscope (SEM).

3.0 RESULTS AND DISCUSSION

3.1 Chemical Composition of Fly Ash

Table 2: Chemical Composition of Fly Ash

S/no.	**Constituent**	**Elements**	**Test Result (% by mass)**	**ASTM C618 Requirement**
1	Silicon Dioxide	SiO_2	53.42	—
2	Aluminum Oxide	Al_2O_3	27.18	—
3	Iron Oxide	Fe_2O_3	8.63	—
Sub-total	**(SiO_2 + Al_2O_3 + Fe_2O_3)**	—	**89.23**	**≥ 70.0%**
4	Calcium Oxide	CaO	5.36	—
5	Magnesium Oxide	MgO	1.45	≤ 5.0%
6	Sulfur Trioxide	SO_3	1.10	≤ 5.0%
7	Sodium Oxide	Na_2O	0.76	—
8	Potassium Oxide	K_2O	1.45	—
9	Titanium Dioxide	TiO_2	1.10	—
10	Phosphorus Pentoxide	P_2O_5	0.12	—
11	Loss on Ignition (LOI)	—	1.85	≤ 6.0%

Table 2 shows the chemical composition analysis of fly ash. It can be observed that the combined proportions of SiO_2, Al_2O_3, and Fe_2O_3 are 89.23%**,** which exceeds the minimum value of 70%

prescribed by ASTM C618 for the classification of fly ash. The loss on ignition (LOI) was 1.85%, which is also within the recommended limit. This implies that the fly ash was suitable for use as pozzolanic material.

3.2 Consistency of Fresh Mortar

Table 3: Flow of Mortar Mixes

Fresh Mixes Samples	Spread Diameter (mm)	Remark
0%	125mm	High consistency
5%	123mm	High consistency
10%	114mm	Moderate consistency
15%	110mm	Moderate consistency
20%	105mm	Moderate consistency
25%	100mm	Stiff

Source: Experiment (2025)

Table 3 presents the consistency of the fresh mortar mixes containing polystyrene and fly ash. It was observed that the flow of the mixes decreased with an increase in polystyrene content. The control mixture recorded a spread diameter of approximately 125 mm, while the spread decreased slightly with increasing polystyrene replacement, reaching approximately 100 mm at 25% replacement.

This represents a reduction of approximately 20% between the control and the 25% polystyrene mixture. The reduction in consistency is associated with the physical characteristics of the polystyrene particles and their influence on particle packing within the fresh mortar. Based on IS 4031, the spread values of the mortar mixes obtained fall within the range of high to moderate consistency, except for the 25% polystyrene sample. This implies that 5-20% polystyrene mortar mixes will be easy to work with. However, the consistency of the 25% polystyrene mixes could be improved by the use of water-reducing admixtures.

3.3 Density

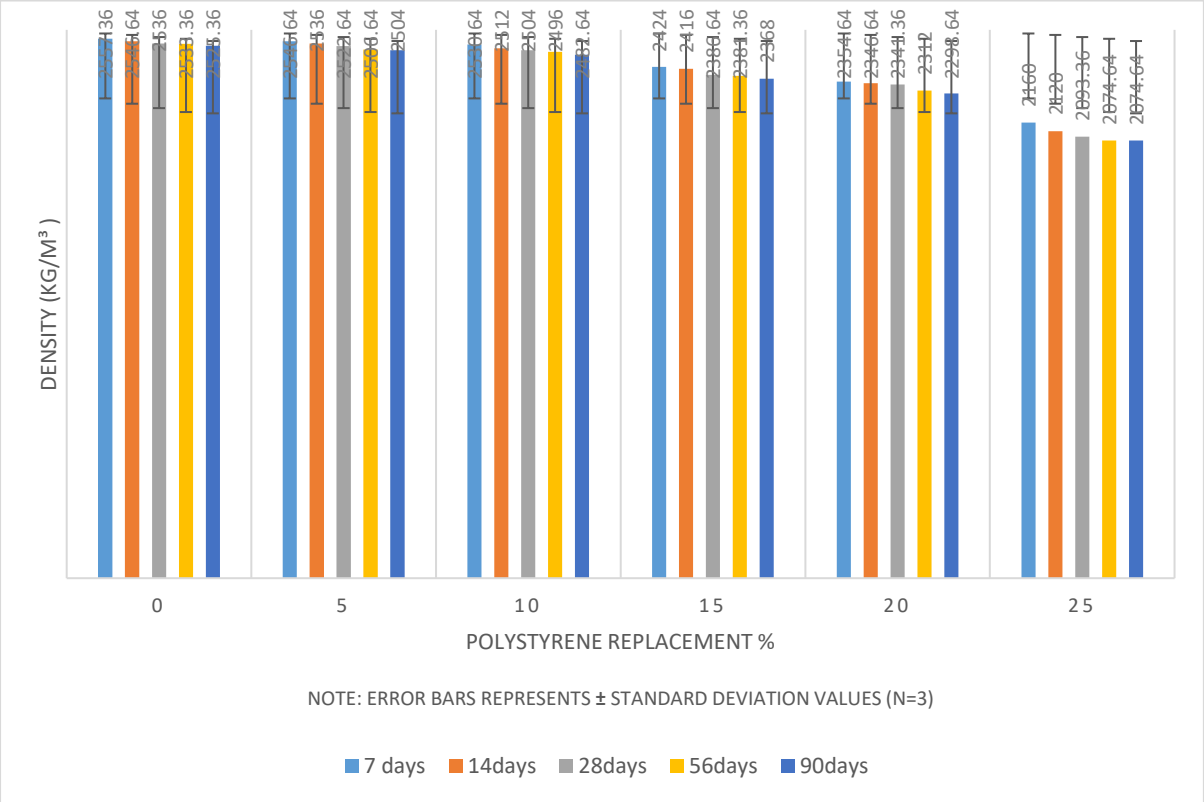

Figure 1: Density

Figure 1 presents the dry density of the hardened sandcrete mortar samples at curing ages of 7, 14, 28, 56, and 90 days. The results show that dry density generally decreased with increasing polystyrene replacement, particularly at replacement levels above 10%. At 7 days, the density decreased from 2557.36 kg/m³ for the control mix to 2160.00 kg/m³ at 25% polystyrene replacement. Similarly, at 14 days, the density decreased from 2546.64 kg/m³ to 2120.00 kg/m³ for the control and 25% replacement mixes, respectively. At 28 days, the density decreased from 2536.00 kg/m³ to 2093.36 kg/m³, while at 56 days, it decreased from 2533.36 kg/m³ to 2074.64 kg/m³ for the control and 25% replacement mixes, respectively. At 90 days, the density further decreased from 2525.36 kg/m³ for the control mix to 2074.64 kg/m³ at 25% polystyrene replacement.

The reduction in density is attributed to the significantly lower density of polystyrene compared with natural fine aggregate. The effect of curing age on density was relatively small compared with the effect of polystyrene replacement. At lower replacement levels of 5% and 10%, only slight reductions in density were observed, whereas higher replacement levels of 15–25% produced more substantial reductions. The findings demonstrate that increasing polystyrene content is effective in reducing the unit weight of the hardened mortar, supporting its potential application in lightweight construction.

The large difference between the densities of polystyrene and sand explains the reduction in the unit weight of the resulting mortar as the replacement percentage increased. This finding supports previous research identifying polystyrene as a suitable lightweight material for cement-based construction products (Kan, 2009; Miled & Boulay, 2004; Khatib, 2009).

3.4 Compressive Strength

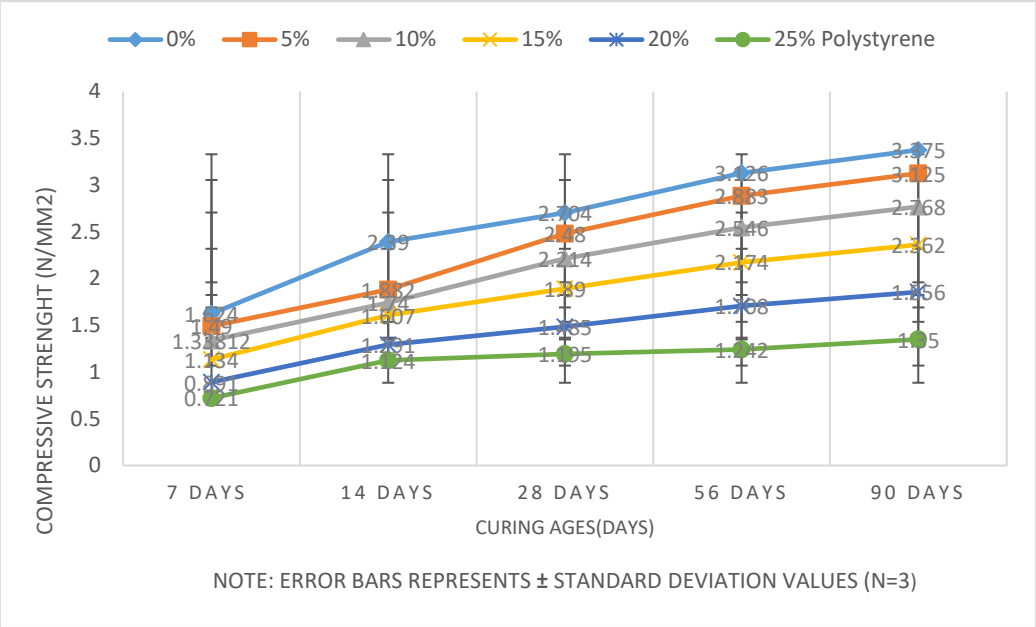

Figure 2: Compressive Strength of Sandcrete Mortar Samples at Different Curing Ages

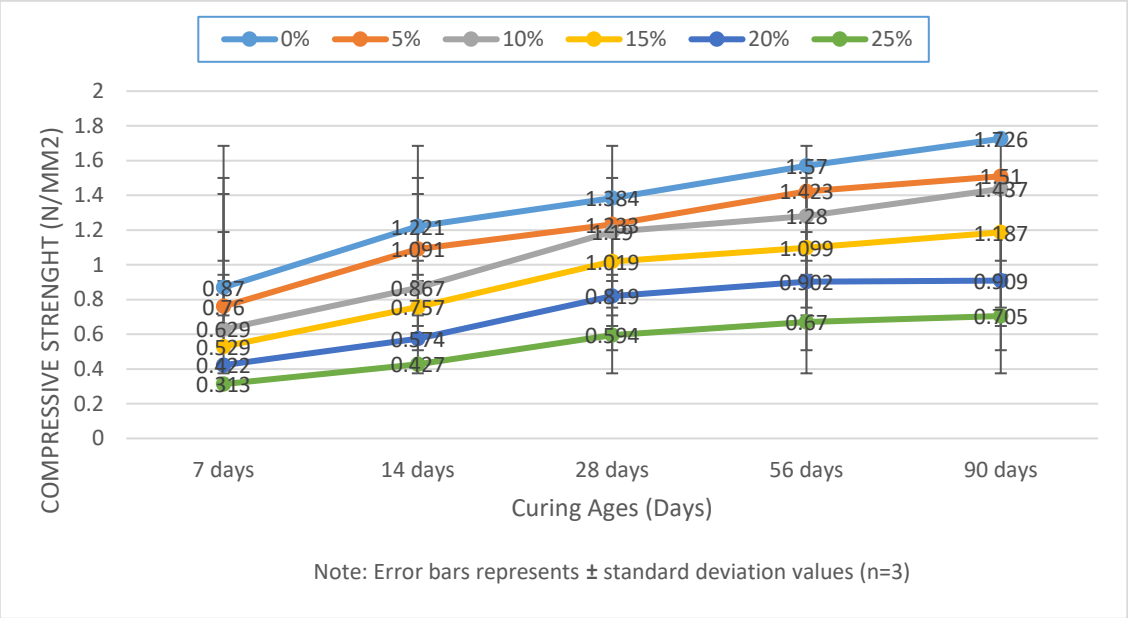
Figure 2 shows the compressive strength of the mortar samples at different polystyrene replacement levels. The compressive strength increases with age. At 90 days, the control sample recorded a compressive strength of 3.375 N/mm², while the values decreased to 3.125, 2.805, 2.445, 2.085, and 1.725 N/mm² for 5%, 10%, 15%, 20%, and 25% polystyrene replacement, respectively. Compared to the control sample, these values represent reductions of approximately 7.4%, 16.9%, 27.6%, 38.2%, and 48.9%, respectively. The results indicate that although prolonged curing improved the strength of all samples, increasing the proportion of polystyrene progressively reduced compressive strength. The relatively small reduction observed at 5% replacement indicates that a low level of polystyrene can be incorporated while retaining a substantial proportion of the control samples' strength. However, higher replacement levels resulted in progressively greater strength reductions. The reduction can be attributed mainly to the low density and relatively weak bonding of polystyrene particles within the cementitious matrix. Similar observations have been reported in studies of polystyrene-containing

cement-based materials (Haidar & Khalil, 2002; Kehinde & Babatunde, 2020). The continuous increase in strength with curing age is associated with continued cement hydration and the contribution of fly ash through pozzolanic reactions.

3.5 Splitting Tensile Strength



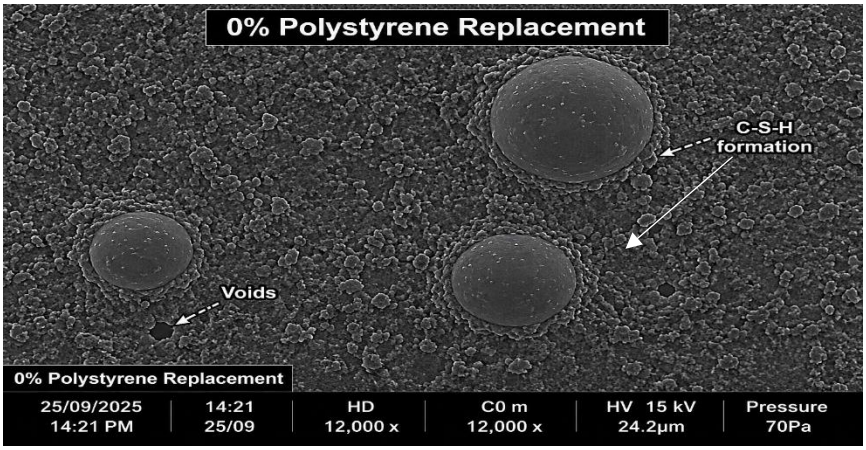


Figure 3: Split Tensile Strength of Sandcrete Mortar Sample at Different Curing Ages

Figure 3 presents the split tensile strength of the mortar samples containing polystyrene and fly ash. The tensile strength of the mortar samples exhibited a trend similar to that of compressive strength, whereby increasing polystyrene replacement resulted in progressive reductions in tensile strength. At 90 days, the control mix recorded a tensile strength of 1.726 N/mm², while the 5%, 10%, 15%, 20%, and 25% polystyrene mixes attained tensile strengths of 1.510, 1.437, 1.187, 0.909, and 0.705 N/mm², respectively. Compared to the control sample, these values represent reductions of 12.51%, 16.74%, 31.23%, 47.28%, and 59.15%, respectively. This indicates that increasing the proportion of polystyrene progressively reduced the mortar's tensile performance. The reduction may be attributed to the low density and weak mechanical properties of polystyrene particles, which can increase void spaces within the matrix and reduce the bond between the cement paste and aggregate particles. The observed decrease in tensile strength agrees with the findings of Ya'u et al. (2024), who reported that the mechanical properties decreased with an increase in polystyrene content

Despite the reduction in tensile strength with increasing polystyrene content, all mixes exhibited continuous strength development with curing age. For instance, the 25% polystyrene mix increased from 0.313 N/mm² at 7 days to 0.705 N/mm² at 90 days. The continuous increase in strength with curing age may be associated with the ongoing hydration of cement and the contribution of fly ash content to the development of the cementitious matrix through pozzolanic reactions.

3.6 Scanning Electron Microscopy Analysis (SEM)

Vods

Plate I: Sample A (Control Mix containing 0% Polystyrene Replacement and 0% fly ash replacement)

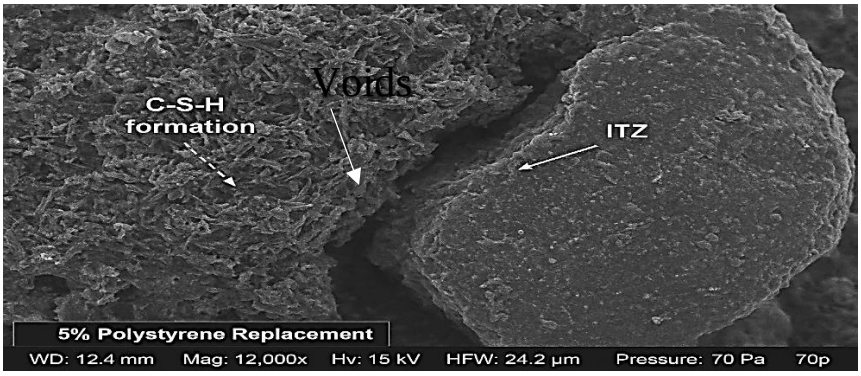

Plate II: Sample B (5% Polystyrene Replacement and 10% fly ash Replacement)

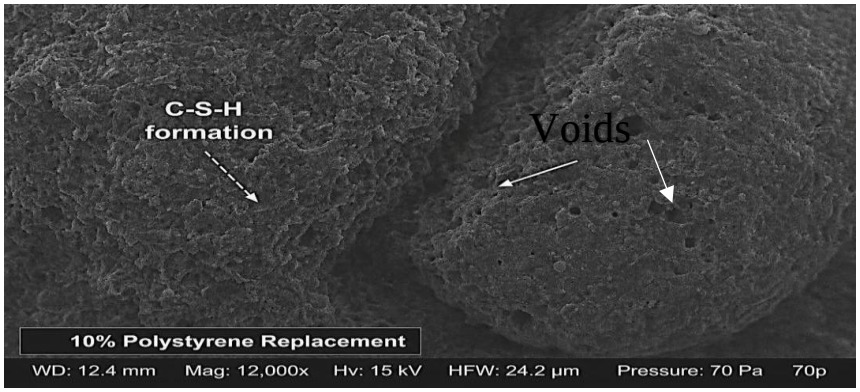

Plate III: Sample C 10% Polystyrene Replacement and 10% fly ash replacement

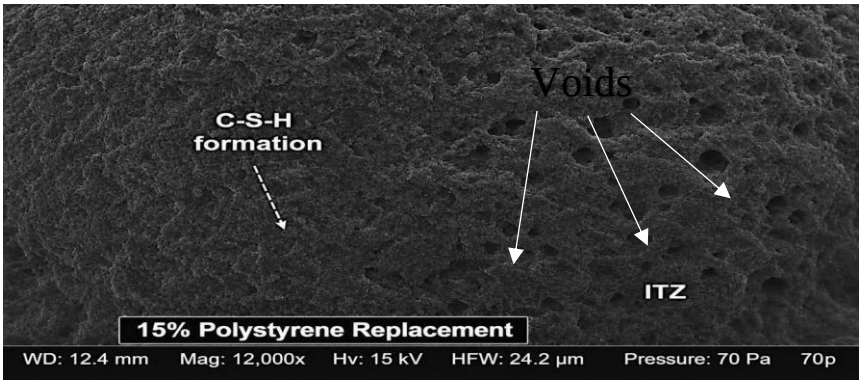

Plate IV: Sample D (15% Polystyrene Replacement and 10% fly ash replacement)

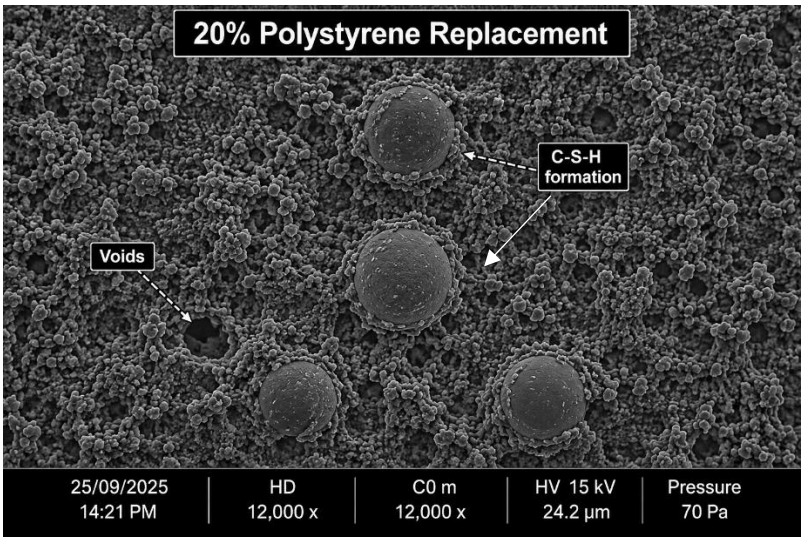

Plate V: Sample E (20% Polystyrene Replacement and 10% fly ash replacement)

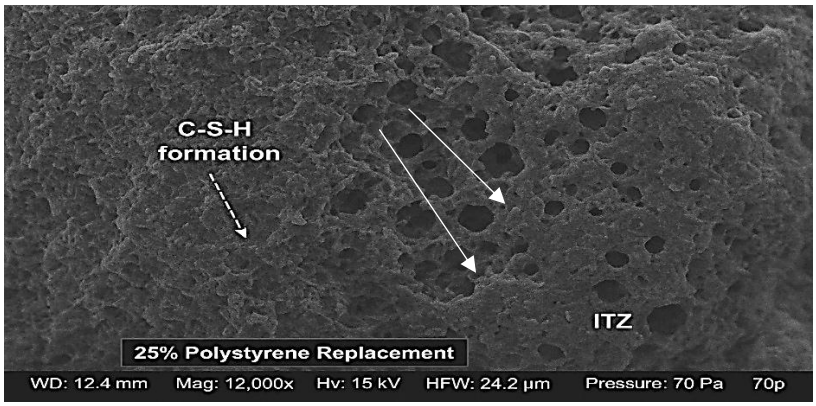

Plate VI: Sample F (25% Polystyrene Replacement and 10% fly ash replacement)

The microstructural properties of the mortar samples were evaluated using Scanning Electron Microscopy (SEM) at 12,000× magnification as shown in Plates I-VI. The SEM observations provided microstructural evidence supporting the mechanical-strength results. The control specimen exhibited a relatively dense and compact microstructure with extensive C–S–H gel formation and a well-bonded interfacial transition zone. The limited number of voids and microcracks corresponded with the relatively high mechanical strength of the control specimen.

At 5% polystyrene and 10% fly ash, small spherical voids associated with the polystyrene particles were observed. However, the matrix remained relatively dense because of the pozzolanic activity of the fly ash, which promoted secondary C–S–H formation. This helped maintain relatively good microstructural integrity.

At 10% polystyrene, the number of voids increased, and the interfacial transition zone became less compact. At 15 to 25% replacement, the microstructure became progressively more porous and discontinuous, with larger voids, weak interfacial zones, and localized microcracking. The 20% and 25% specimens exhibited highly porous matrices with poor particle bonding and fragmented hydration products.

The SEM results therefore support the observed reduction in compressive and tensile strength with increasing polystyrene content. They also provide evidence for the improved performance of the 5% polystyrene + 10% fly ash specimen.

4.0 CONCLUSION

i. The 5–20% replacement levels exhibited high to moderate consistency and were considered workable, whereas the 25% mix became relatively stiff.

ii. Based on the density results, increasing polystyrene content can be effectively used to produce lighter mortar suitable for non-structural applications.

iii. Compressive and tensile strength decreased with increasing polystyrene content. However, 5% polystyrene and 10% fly ash specimens retained 92.6% of their strength. Therefore, 5% polystyrene and 10% fly ash is the optimum for producing cement mortar

iv. Increasing polystyrene content resulted in greater porosity, larger voids, weaker interfacial zones, and localized microcracking. In contrast, the lower polystyrene replacement level exhibited a relatively denser matrix with improved C–S–H gel formation associated with the presence of fly ash.

ABSTRACT

The development of sustainable, low-carbon construction materials has become a major priority in the construction industry. In response, this study evaluates the effectiveness of metakaolin-based geopolymer (MBG) as a modifier for improving the physical properties of asphalt binder. MBG was incorporated into a 60/70 penetration-grade asphalt binder at dosages ranging from 2% to 10% (by weight of binder, at 2% intervals). The effects on key physical properties including penetration, softening point, ductility, flash point, solubility, and storage stability were systematically investigated. Results showed that MBG addition produced a desirable hardening effect. Penetration decreased by an average of 17.94%, while the softening point increased by 6%, resulting in an improved penetration index. Ductility decreased by 39%, indicating reduced flexibility, whereas the flash point showed a marginal 1% increase. Solubility remained essentially unchanged, and storage stability was satisfactory across the tested range. These enhancements are attributed to strong interfacial interactions between the geopolymer particles and the asphalt matrix, leading to a stiffer and more stable binder structure. Overall, the findings demonstrate the potential of MBG as a sustainable, low-carbon modifier capable of enhancing asphalt binder performance. Based on the results, a 2% MBG dosage is recommended as the optimal level for effectively improving the physical properties without excessive compromise to ductility.

1. INTRODUCTION

Several studies have demonstrated that polymer modification of asphaltic binders significantly enhances the performance of asphalt mixtures. For example, rubber-modified asphalt binders have been shown to improve toughness, low-temperature performance, and elastic properties, while ethylene-vinyl acetate (EVA) and high-density polyethylene (HDPE) reduce temperature susceptibility, and polyvinyl chloride (PVC) enhances heat resistance (Murana *et al*., 2018; Murana *et al.*, 2020; Murana *et al.*, 2023; Abah *et al.*, 2024). In addition, polymer-modified asphalt contributes to notable environmental benefits by reducing pavement maintenance and repair frequency as well as lowering traffic noise (Hamid *et al.*, 2020). As a result, interest has increasingly shifted toward recycled polymers as modifiers. These materials offer clear environmental and economic advantages while often delivering superior performance compared to unmodified binders. Consequently, polymer modification of asphalt has become a highly promising approach for designing high-performance flexible pavements, with important implications for the engineering properties and long-term durability of road infrastructure.

Building on these developments, geopolymers have emerged as a promising alternative to conventional and recycled polymers for asphalt modification. Geopolymers are inorganic materials capable of delivering higher strength and superior performance in asphalt mixtures (Milad *et al*., 2021). They are produced through geopolymerization, a reaction between alkaline activators and

aluminosilicate-rich precursors. A wide range of industrial by-products and wastes can serve as source materials, including metakaolin (Ibedu *et al*., 2026), fly ash (Hamid *et al.,* 2020), bentonite (Jaimes *et al*., 2020), rice husk ash (Thirukumaran *et al*., 2023), mine waste, and blast furnace slag (Milad *et al.,* 2021; Amran *et al.,* 2021). Due to their low-CO_2 production process and utilization of waste materials that would otherwise require disposal, geopolymers are widely recognized as a greener, more environmentally friendly alternative to traditional binders and polymers. Their production significantly reduces greenhouse gas emissions compared to conventional materials, while also conserving natural resources and mitigating the environmental burdens of waste accumulation. This combination of technical performance, economic viability, and sustainability makes geopolymers highly attractive for advancing sustainable development in civil engineering. They hold strong potential for applications in asphalt concrete, pavement engineering, geotechnical engineering, and broader construction works.

However, a notable theoretical and experimental knowledge gap remains regarding the influence of metakaolin-based geopolymers on the physical properties of asphalt binders. The present study seeks to address this gap through a systematic evaluation of the physical performance of metakaolin-based geopolymer-modified asphalt binders. Such an assessment is essential to determine their suitability as a sustainable alternative to traditional bituminous binders. Bridging this gap will not only support the development of greener pavements but also provide deeper insights into the material's behavior under real-world service conditions.

2. METHODOLOGY

2.1 Materials

Metakaolin ($SiO_2 \cdot 2Al_2O_3$) was processed from Kankara kaolin. The metakaolin was used as precursor. The Alkali (Sodium Hydroxide and Sodium Silicate) were sourced from Cardinal Scientific Shop, Samaru Zaria. The NaOH was in pellet form (98.9% purity) and the Na_2SiO_3 was used for the alkali activation. The 60/70 asphalt binder was sourced at Gradient Emulsions and Polymers Limited, Located at kilometer 8, Abuja-Kaduna Expressway, Kakau Chikun LGA Kaduna State.

2.1.1 Geopolymer Synthesis

The geopolymer consists of metakaolin, and the alkaline activator. Due to the fact that there is no standard geopolymer mix design, the optimal molarity and mix ratio was adopted from Hamid, *et al.,* (2020) and further corroborated in the studies of Hauruna, *et al.,* (2018); Gambo, e*t al.,* 2020). Sodium hydroxide (NaOH) pellet was diluted in water to produce 8 Molar (8M) NaoH solution and combined with the alkaline activator solution (Na_2SiO_3). The ratio of sodium hydroxide to sodium silicate (NaOH /Na_2SiO_3) was 2:1. A mixture of the sodium hydroxide solution and sodium silicate solution was prepared and stirred for 5 minutes to activate the alumino-silicate precursors in metakaolin. In this study, metakaolin with Class F which satisfies the chemical composition of SiO_2+ Al_2O_3+ Fe_2O_3 as stipulated by ASTM C168-19, (2019). The formed homogenous slurry geopolymer were poured into a size 75 cm x 75cm x 75 cm mold, the product was called metakaolin-based geopolymer. All samples were cured at room temperature for 24 hours and then further cured in the oven at 60ºC for 24 hours. Generally, the process of geopolymerisation depends on the curing mode. The samples were cured at room temperature (25ºC-26ºC), to minimize moisture loss, allow for proper gelation. At higher temperature in the oven, the excess water is given out during this process, the reaction of geopolymerisation accelerates leading to faster setting and hardening. This improves the mechanical properties of geopolymer such as strength and durability. Plate I shows the mixing process to produce the geopolymer.

Plate I: Geopolymerisation process: (a) mixing at room temperatures (b) geopolymer paste (c) geopolymer cubes

2.1.2 Production of Metakaolin-Based Geopolymer Modified Asphalt Binder

To produce the metakaolin-based geopolymer modified asphalt binder, a two-stage mixing process was employed using high shear and low shear mixers. Initially, 3000g of pristine asphalt binder was heated to 180°C for 4 hours in an oven to achieve optimal fluidity. Subsequently, metakaolin-based geopolymer was added to the heated asphalt binder at varying concentrations (2, 4, 6, 8, and 10% by weight of bitumen). The mixture was then blended using a high shear mixer (Model Fluko SK560) at 4000 r/min for 30 minutes at 180°C. To ensure homogeneity, the blended asphalt was further mixed using a low shear mixer (Model Fluko FW30 electric stirrer) at 2000 r/min for 40 minutes at 180°C. The detailed mixing process is illustrated in Plate II.

(a) (b)

Plate II: Production of metakaolin-based geopolymer modified asphalt binder (a) high shear mixing (b) low shear mixing

2.2 Methods

Test on Asphalt Binder

i. Fourier Transform Infra-Red (FTI-R) Spectroscopy

FTI-R spectroscopy was used to identify functional groups of metakaolin and metakaolin-based geopolymer. The wavelength were recorded from 4000 - 650 cm^{-1}. This was carried out in accordance with (ASTM D6348-12, 2020)

ii. Penetration

The penetration grade is a measure of the asphalt binder's consistency and stiffness, which correlates with its viscosity. This was conducted in accordance with ASTM standard (ASTM D5/D5M-20, 2020).

iii. Ductility

Ductility, a critical property of asphalt binders, refers to their ability to deform under tensile stress without cracking, reflecting the material's internal cohesion. The test was conducted following the guidelines outlined in the relevant ASTM standard (ASTM D113-17, 2017).

iv. Softening Point

Softening point of asphalt binders is used to grade asphalt binder and ensure performance in road construction. This was carried out in accordance with ASTM standard (ASTM D36/D36M-14, 2020).

v. Solubility

The solubility of asphalt binder was performed to determine the extent of asphalt binder solubility, having little or no organic impurities other than recovered asphalt binders in a specific solvent. For this study, Toluene was used as the solvent. This test was conducted in accordance with relevant ASTM standard (ASTM D2042-15, 2015).

vi. Flash point

The flash point of an asphalt binder is defined as the lowest temperature at which its vapors, when heated under specified conditions, will momentarily ignite (flash) upon application of a small test flame. The flash point testing was performed in accordance with the relevant ASTM standard (ASTM D92-18, 2018).

vii. Storage stability

The storage stability test measure or what extent a polymer stays mixed with asphalt binder under static storage conditions. This was conducted per ASTM Standard (ASTM D7173, 2020). Storage stability process is depicted in Plate 7.

3. RESULTS AND DISCUSSION

3.1 FTIR Spectra of Pristine Asphalt Binder

The FTIR spectrum of the pristine asphalt binder is shown in Figure 1. The major peaks characteristic of typical asphalt binders include: 2920.4 cm^{-1} and 2851.4 cm^{-1}, attributed to C–H stretching vibrations of aliphatic methylene (CH_2) groups. 1653.1 cm^{-1}, corresponding to C=C stretching of aromatic rings. 1459.3 cm^{-1} and 1375 cm^{-1}, assigned to C–H bending vibrations of aliphatic (CH_2 and CH_3) groups. In the fingerprint region, peaks at 864.7 cm^{-1}, 810.7 cm^{-1}, and 743.6 cm^{-1} indicate out-of-plane C–H bending of aromatic rings. These assignments align well with established literature on pristine asphalt binder characterization including studies by Weigel & Stephan, (2018); Yaro, *et al.,* (2021). Additionally, several less common peaks were observed, suggesting possible variations due to the specific source or crude oil origin of the asphalt binder: Weak bands at 2376.2 cm^{-1} and 2344.5 cm^{-1}, likely corresponding to S–H stretching (thiols). A peak at 2084.7 cm^{-1}, assignable to –N=C=S stretching of isothiocyanate groups (–NCS). Bands at 1597.2 cm^{-1}, 1541.3 cm^{-1}, and 1507.7 cm^{-1}, linked to –N=N– stretching in open-chain azo compounds connected to acyclic hydrocarbyl (alkyl or aryl) groups. A peak at 1032.5 cm^{-1}, attributed to P–O–C stretching of aliphatic phosphates. A band at 723.1 cm^{-1}, characteristic of out-of-plane aromatic C–H bending (Coates, 2000).

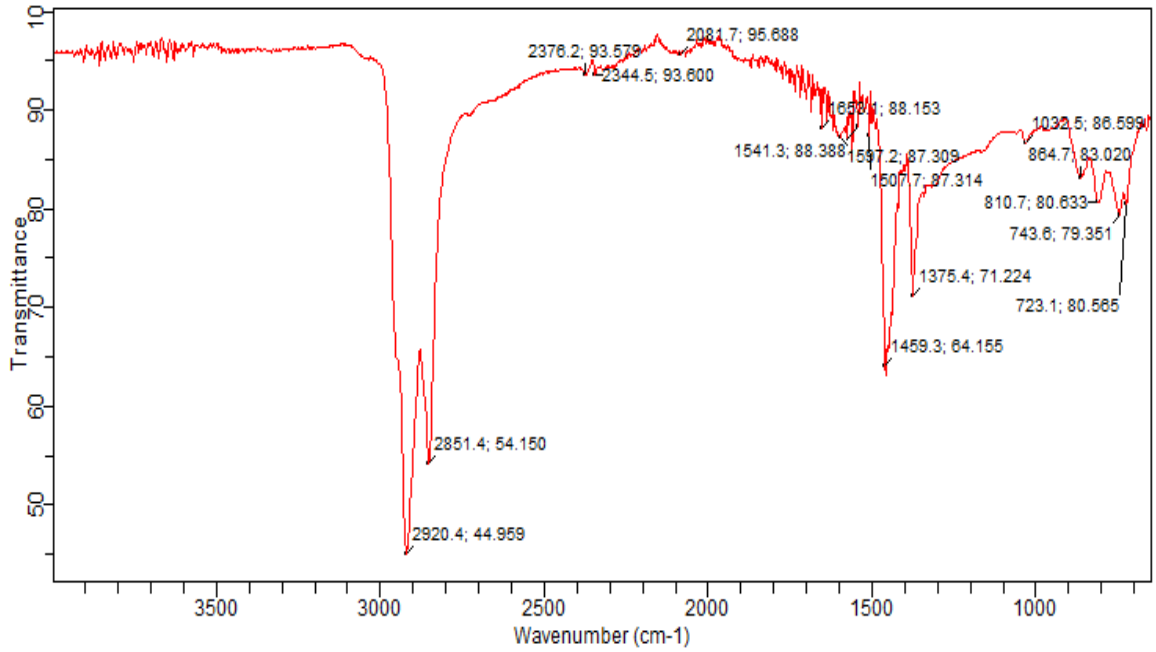

Figure 1: Infrared Spectra of Pristine Asphalt Binder

3.2 FTIR on Metakaolin-Based Geopolymer Asphalt Binder

Characteristic absorption bands at 2920.4 cm^{-1} and 2851.4 cm^{-1}, attributed to C–H stretching vibrations of methylene (CH_2-) groups in saturated aliphatic chains (Silverstein, *et al.*, 2014), remained unchanged across all metakaolin-based geopolymer contents. Similarly, peaks at 1459.3 cm^{-1}, 1375.4 cm^{-1}, and 721.2 cm^{-1}, corresponding to C–H bending and rocking modes of aromatic rings, showed no significant shift, confirming the persistence of aromatic structures typically present in base asphalt binder (Lin-Vien, *et al.*, 1991; Coates, 2000). Weak bands observed at 2374.3 cm^{-1} and 2344.5 cm^{-1} are attributed to atmospheric CO_2 interference and are not indicative of sample composition (Smith, 2011). Several new or shifted absorption bands appeared with increasing geopolymer content, indicating chemical interaction between the metakaolin-based geopolymer and the asphalt binder. New peaks in the 2090–2165 cm^{-1} region (e.g., 2111.5, 2145.1, 2104.1, 2161.5, and 2092.1 cm^{-1}) suggest the formation of terminal and internal alkyne (C≡C) groups. The band originally at 1601.7 cm^{-1} in the neat asphalt binder shifted to higher (1658.1 and 1654.9 cm^{-1}) and lower (1541.3 cm^{-1}) wavenumbers, consistent with N–H bending in primary and secondary amines (Silverstein, *et al.*, 2014). A new band at 1155.5 cm^{-1} indicates C–N stretching of tertiary amines. Bands near 1994–1997 cm^{-1} may arise from transition metal carbonyls or cumulene (C=C) structures (Coates, 2000). Peaks in the 1000–1030 cm^{-1} region (1030.6, 1006.4, 1004.5, and 1020.6 cm^{-1}) are assigned to C–H vibrations in cyclohexane ring structures or methyne groups. Additional aromatic C=C stretching bands emerged at 1597.2, 1522.6, and 1507.7 cm^{-1} (Silverstein, *et al.*, 2014),. In the fingerprint region (650–900 cm^{-1}), multiple new peaks (864.7, 862.9, 810.7, 808.8, 807.0, 745.5, 743.6, 659.7, and 657.9 cm^{-1}) correspond to aromatic C–H out-of-plane bending vibrations (Lin-Vien, *et al.*, 1991). These observations demonstrate that incorporation of metakaolin-based geopolymer induces chemical modifications in the asphalt binder, resulting in the formation of new functional groups (particularly amines, alkynes, and additional aromatic structures) while core aliphatic and aromatic hydrocarbon features of the asphalt are largely retained. The FTIR spectra of metakaolin-based geopolymer asphalt binders (2–10% by weight of asphalt binder) in the range of 400–4000 cm^{-1} are presented in Figure 2(a–e),

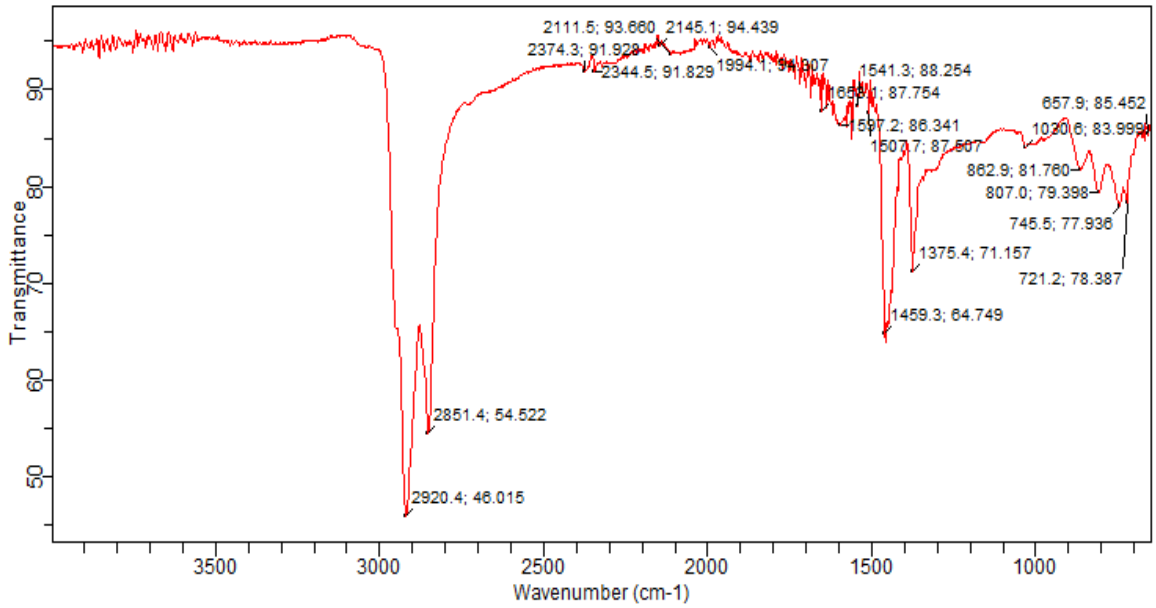

Figure 2a: Infrared Spectra of 2% Metakaolin-Based Geopolymer Asphalt Binder

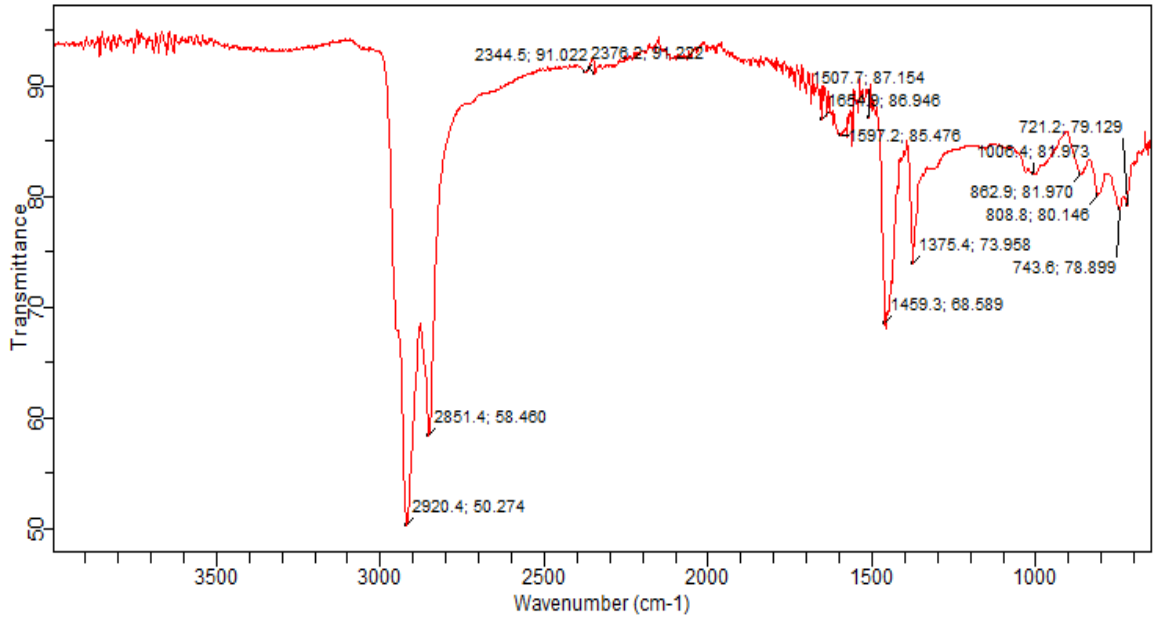

Figure 2b: Infrared Spectra of 4% Metakaolin-Based Geopolymer Asphalt Binder

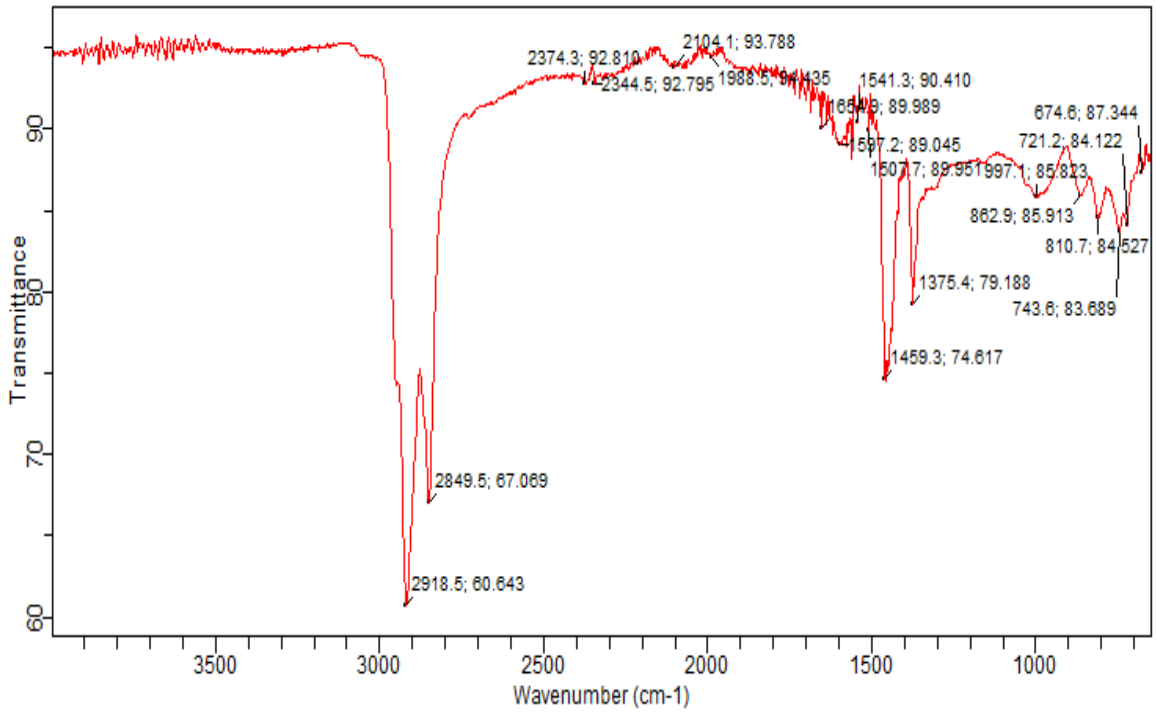

Figure 2c: Infrared Spectra of 6% Metakaolin-Based Geopolymer Asphalt Binder

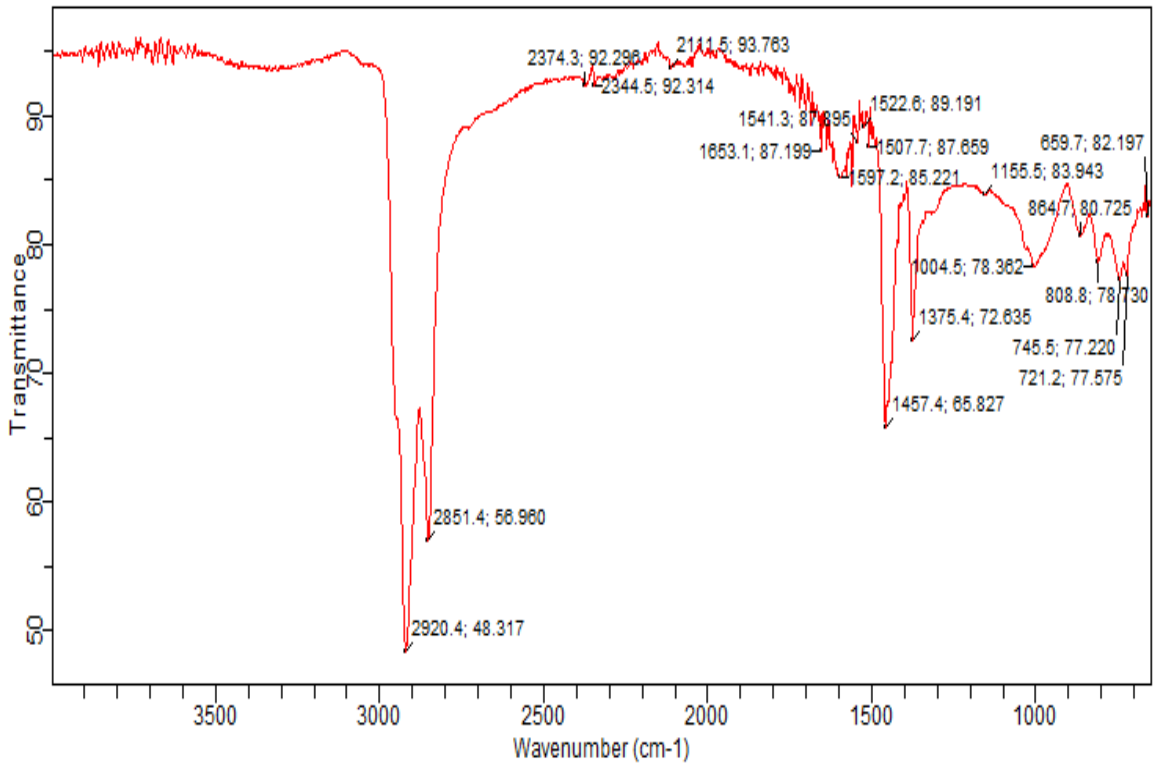

Figure 2d: Infrared Spectra of 8% Metakaolin-Based Geopolymer Asphalt Binder

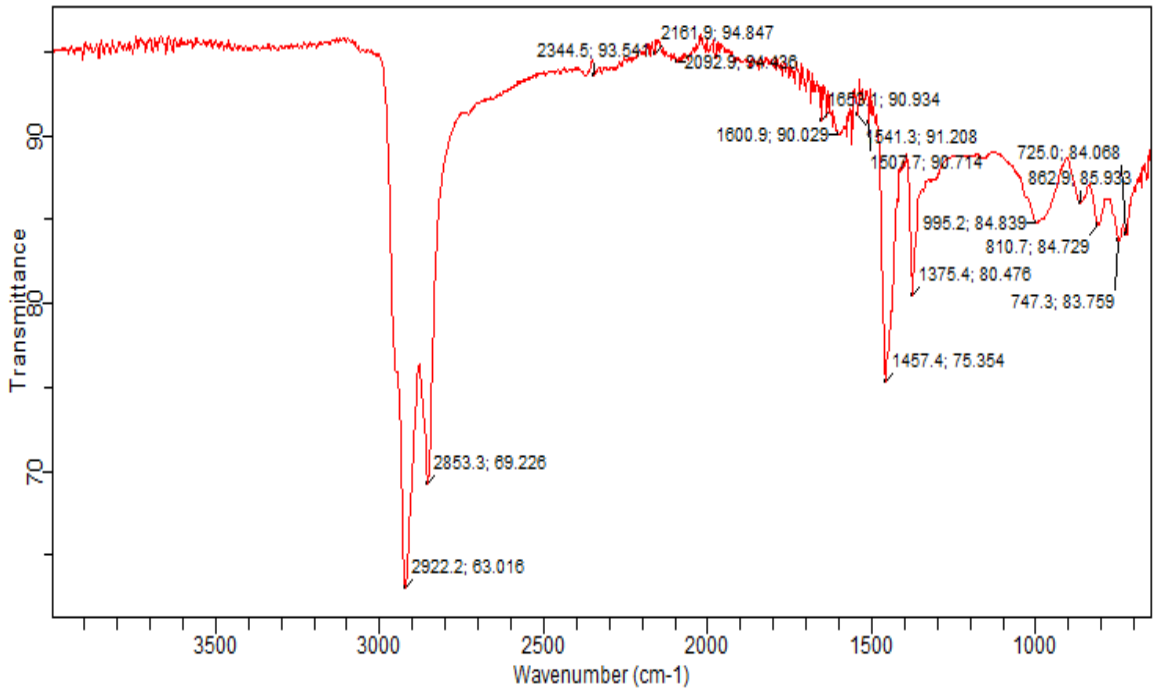

Figure 2e: Infrared Spectra of 10% Metakaolin-Based Geopolymer Asphalt Binder

3.3 Influence of Metakaolin-Based Geopolymer on the Properties of Asphalt Binder

3.3.1 Penetration

The results presented in Figure 4 demonstrate that increasing the content of metakaolin-based geopolymer (MBG) in the asphalt binder leads to a progressive decrease in penetration. This hardening effect can be primarily attributed to the strong interactions between the geopolymer particles and the asphaltene fraction of the binder, coupled with the absorption of lighter molecular components onto the geopolymer porous structure. All penetration values obtained for both pristine and MBG-modified asphalt binder fall within the penetration limits specified by (FMWH, 2016). These mechanisms reduce the mobility of the binder matrix, resulting in enhanced rigidity and stiffness, this is corroborated in the FTIR analysis by the appearance of extra aliphatic and aromatic bands in the infrared spectrum of modified asphalt binder. These findings align with previous studies on geopolymer-modified asphalt binders, including those by Yaro, *et al*., (2023); Rosyidi, *et al.*, (2020); Tang, *et al.*, (2018). The outcome of this finding shows that MBG can effectively be used to modify conventional asphalt binder to lower penetration grades. The engineering implication of reduced penetration are enhanced asphalt binder's resistance to permanent deformation (rutting) and thermal susceptibility of asphalt mixtures produced with such asphalt binders, particularly in high-temperature climates, such as those prevalent in Nigeria. Reduced penetration also implies, reduced moisture infiltration, improved skid resistance and overall longer lifespan and durability of pavement.

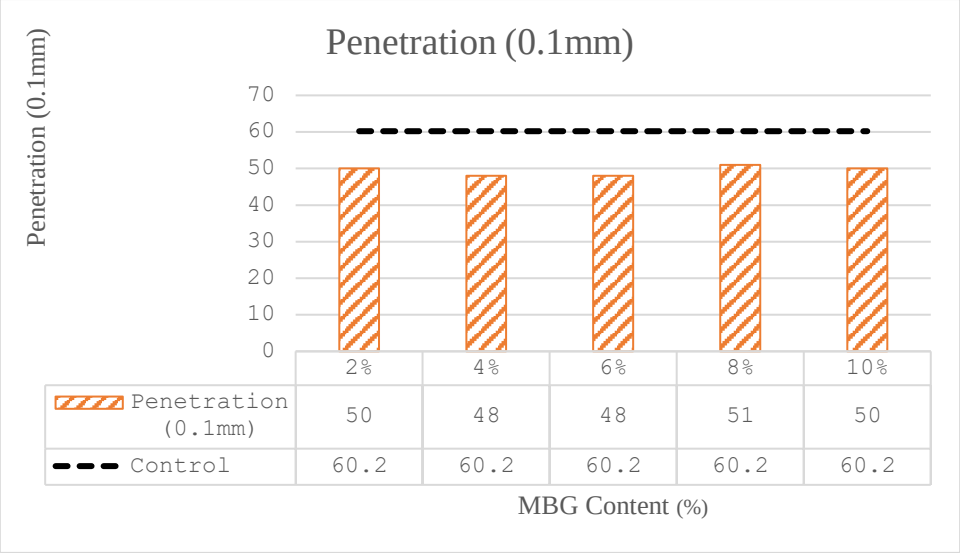

Figure 4: Influence of MBG on Penetration of Asphalt Binder

3.3.2 Softening Point

The results illustrated in Figure 5 indicate that incorporating MBG into the unmodified asphalt binder results in a significant increase in the softening point compared to the control. This trend shows the typical inverse relationship between softening point and penetration: lower penetration yields a higher softening point. All softening point values obtained are within the limits stipulated by FMWH (2016). The increased softening point can be attributed to the stiffening mechanisms induced by the MBG modifier. The geopolymer particles interact with the binder's components particularly by bonding with the aliphatic fractions leading to enhanced dispersion stability, reduced molecular mobility, and the formation of additional aromatic and aliphatic structures within the matrix. These observations are in agreement with prior research on geopolymer-modified asphalt binders, studies include those by Yaro, *et al.*, (2023); Rosyidi, *et al.*, (2020); Tang, *et al.*, (2018). From an engineering perspective, the higher softening point enhances the binder's resistance to permanent deformation (rutting) under elevated service temperatures.

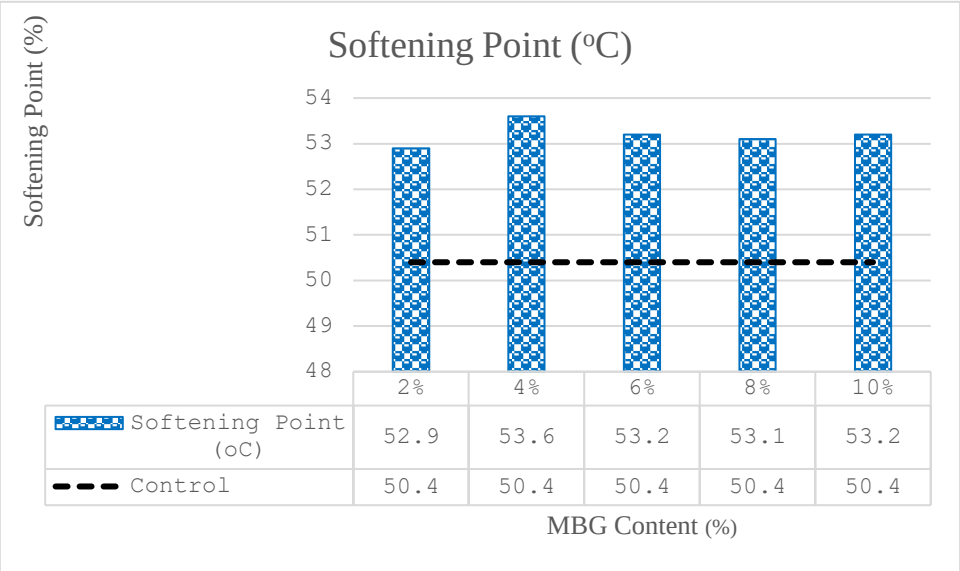

Figure 5: Influence of MBG on Softening Point of Asphalt Binder

3.3.3 Penetration Index

The penetration indices (PI) of the pristine (0%) and MBG-modified asphalt binders are presented in Table 1. The penetration index serves as a key indicator of the binder's temperature susceptibility. For conventional paving-grade asphalt binders, the acceptable PI range is typically < -2 to > +2. A PI of < -2 signifies high temperature susceptibility, while a PI of > +2 indicates low susceptibility. The calculated PI values decreased from the 0% binder to the MBG-modified binders. The observed reduction in PI for MBG-modified asphalt binder suggests improved overall temperature resistance. The MBG enhanced the binder's ability to resist both rutting (at high temperatures) and thermal cracking (at low temperatures). This improvement in temperature susceptibility can be attributed to the intermolecular interactions between dispersed MBG particles and the asphalt matrix, which stiffen the binder structure, reduce thermal volatility, and improve rheological property. These mechanisms are further supported by the FTIR results. From an engineering implication, the enhanced temperature performance of MBG modified asphalt binders is suitable for use in hot climate regions. This result is in align with the study by Yaro, *et al.*, (2021).

Table 1: Penetration indices of Pristine and MBG-modified asphalt binder

MBG Content	Penetration	Softening Point	Penetration index
0%	60.2	50.4	-0.666
2%	50	52.9	-0.574
4%	48	53.6	-0.439
6%	48	53.6	-0.532
8%	51	53.2	-0.413
10%	50	53.2	-0.436

3.3.4 Ductility

The results in Figure 6 indicate a decrease in ductility of MBG asphalt binder compared to the control. This reduction is linked to the increased stiffness observed in the penetration test, likely due to interactions between resins (carbonyl) and aromatic functional groups within the internal structure of the molecules. Only the control and the 2% MBG-modified asphalt binder satisfied the minimum 100 mm requirement specified by FMWH (2016). The higher dosages of MBG resulted in reduced ductility values that fell below the specified limit. However, despite the reduction in ductility with higher MBG dosages, the results suggest that the modified binders retain adequate adhesive and tensile properties. These characteristics are crucial for proper bonding between the asphalt binder and aggregates, indicating promising performance of the asphalt mixtures. This is consistent with findings from Yaro, *et al.*, (2023); Rosyidi, *et al.*, (2020); Tang, *et al.*, (2018).

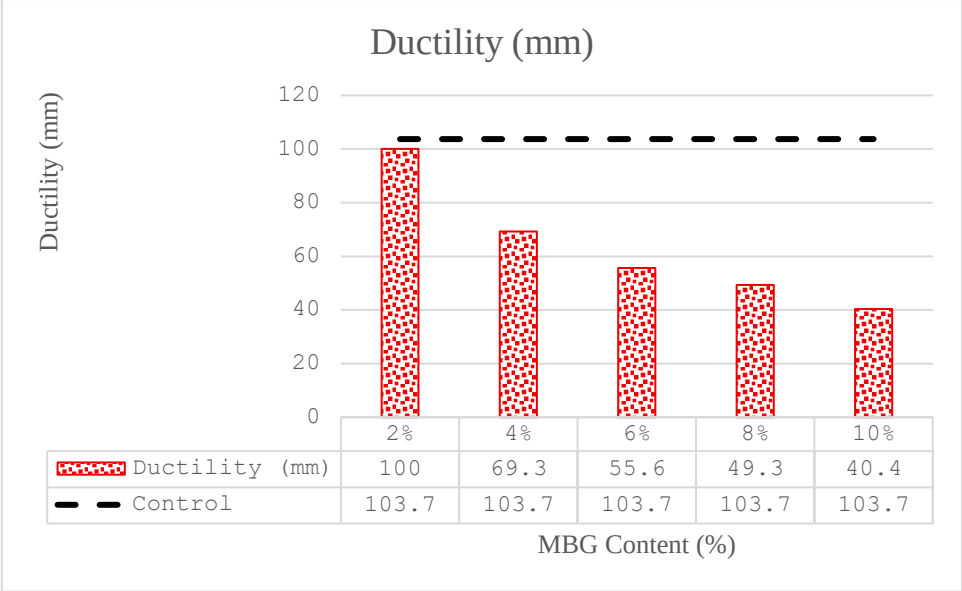

Figure 6: Influence of MBG on Ductility of Asphalt Binder

3.3.5 Flash point

The results from Figure 7 show that the flash point of the MBG-modified asphalt binder marginal increased by 1% with respect to the control binder. Nevertheless, the flash points of all MBG asphalt binders remain compliant the minimum requirement of 230 °C specified in AASHTO M 320 and higher than 250 °C by FMWH, (2016). The observed increase in flash point temperature for MBG-modified binders can be attributed to the dispersion of MBG particles within the asphalt matrix. These particles enhance the binder's thermal stability, thereby delaying the onset of flammability by reducing the volatility of lighter fractions and improving overall resistance to ignition. These findings suggest that MBG-modified asphalt binders exhibit reduced flammability compared to the control, offering a safety advantage. From an engineering perspective, a higher flash point enhances operational safety: the binder can be handled, stored, and transported at elevated temperatures with a significantly lower risk of fire hazards during production, mixing, or field application.

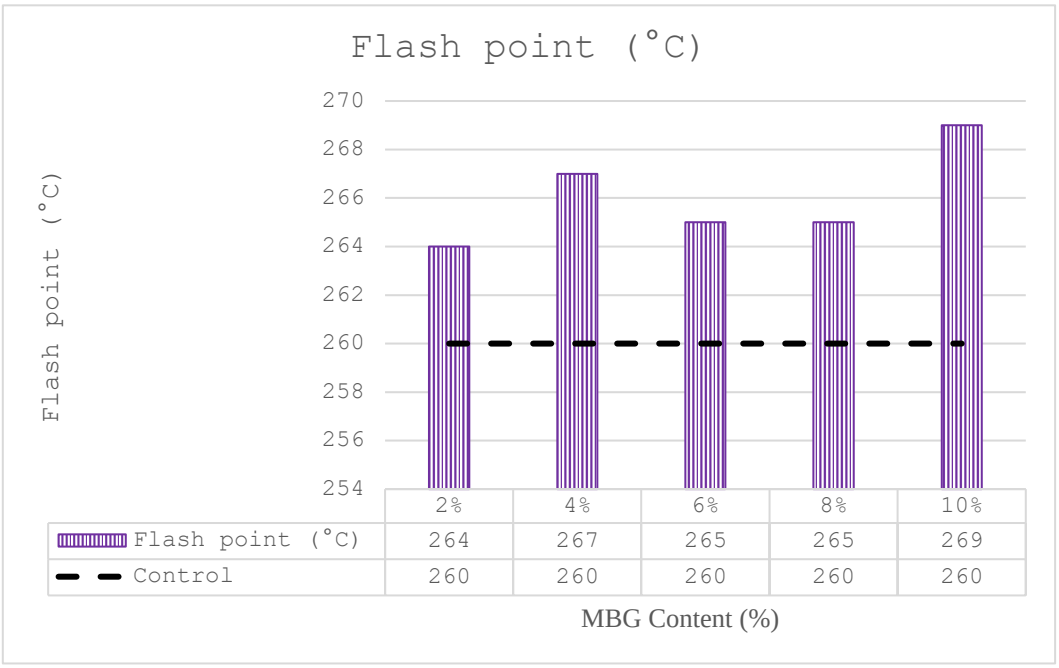

Figure 7: Influence of MBG on Flash Point of Asphalt Binder

3.3.6 Solubility

Solubility serves as an important indicator of asphalt binder purity. As shown in Figure 8, the solubility of the MBG-modified asphalt binders was lower than that of the control sample and decreased progressively with increasing MBG content. The control, 2 - 6% MBG-modified asphalt binder satisfied the minimum 99% requirement specified by FMWH (2016). The higher dosages of MBG fell below the specified limit. This reduction suggests the presence of minor insoluble organic impurities introduced by the modifier. Supporting evidence from FTIR analyses of metakaolin, as well as the FTIR spectra of the metakaolin-based geopolymer, confirmed the existence of such impurities. However, these impurities are present in minute quantities and are expected to have negligible effects on the overall performance of the asphalt binder. Therefore, their impact can be reasonably disregarded

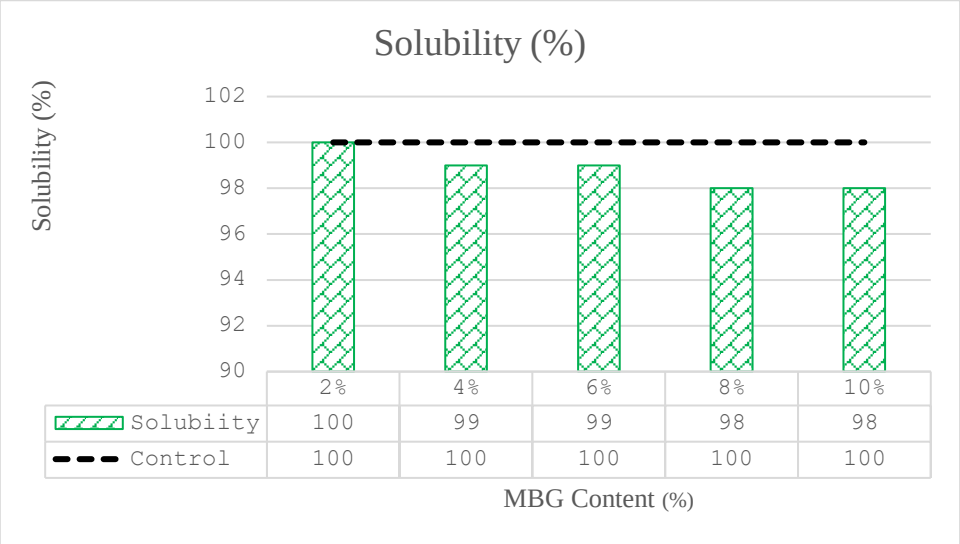

Figure 8: Influence of MBG on Solubility of Asphalt Binder

3.3.7 Storage Stability

The storage stability (also referred to as phase separation resistance or compatibility) of the asphalt binder was evaluated by measuring the difference in softening point between the top and bottom sections of a vertically stored sample tube after high-temperature conditioning. The results, as presented in Figure 9 showed that the storage stability for the pristine (0% MBG) asphalt binder, as well as the MBG modified asphalt binders at 2, 6, 8, and 10% dosages, remained below 2.5 °C (code acceptance criterion). This storage stability demonstrates excellent compatibility between the pristine asphalt binder and the MBG modifier, with negligible phase separation. Such performance is critical for preventing segregation during hot storage, transportation, and application, ensuring uniform binder properties in the field. From an engineering standpoint, this high temperature storage stability enhances operational reliability, reduces the risk of inconsistent binder behavior during mixing and paving, and supports practical handling in asphalt plants. Consequently, both the pristine and MBG-modified asphalt binders can be stored at elevated temperatures for extended periods, reheated, and reused without significant loss of homogeneity or performance. A similar trend of good storage stability with geopolymer based modifiers in asphalt was reported by Yaro *et al.*, (2021).

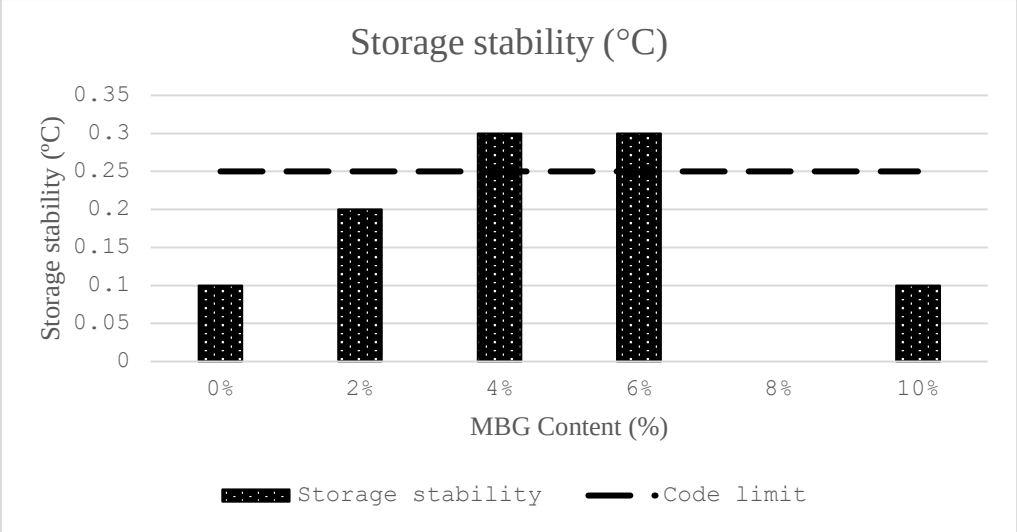

Figure 9: Storage stability of Asphalt Binders

4. CONCLUSION

This study presents the investigation on the physical properties of metakaolin-based geopolymer modified asphalt binder. The following conclusions were drawn based on the results of the research.

i. FTIR spectroscopy of the pristine asphalt binder revealed the presence of characteristic functional groups, including C–H stretching (aliphatic methylene), C=C stretching (aromatic rings). Less prominent peaks corresponding to –N=N– (alkyl or aryl), S–H (isothiocyanate), and P–O–C (alkyl) were also identified. Upon incorporation of metakaolin-based geopolymer (MBG), the original functional groups in the asphalt binder remained largely unchanged, while new peaks emerged, notably C≡C (internal alkyne), additional C=C (associated with metal carbonyls or cumulene), and C–H (cyclohexane or methine structures). These spectral changes confirm the successful incorporation of MBG into the asphalt binder and indicate the formation of new chemical interactions. The resulting functional groups influenced the physical properties of the modified asphalt binder

ii. The physical properties of the MBG-modified asphalt binders, when compared to the pristine binder, exhibited a typical pattern of effective stiffening modifications: decreased penetration, reduced ductility, and slightly lower solubility, accompanied by increases in softening point and flash point

ABSTRACT

Silica aerogels are ultra-lightweight, highly porous nanostructured materials with high specific surface area, properties that make them attractive adsorbents for water and wastewater treatment. However, conventional silica aerogels are commonly produced from costly precursors such as tetraethyl orthosilicate (TEOS), limiting their large-scale application, particularly in resource-constrained settings. This study reports the development of a hydrophobic silica aerogel from rice husk, an abundant and low-cost agricultural by-product, and its comprehensive physicochemical characterization. Silica was extracted from rice husk via acid leaching and calcination, converted to sodium silicate through alkaline digestion, and processed into a gel via acid-catalyzed sol-gel synthesis. The resulting hydrogel beads were solvent-exchanged into ethanol, surface-modified with trimethylchlorosilane (TMCS) to confer hydrophobicity, and dried at ambient pressure. The synthesized aerogel was characterized using nitrogen adsorption-desorption (BET/BJH/t-plot), Fourier-transform infrared spectroscopy (FTIR), water contact-angle goniometry, bulk density/porosity determination, and scanning electron microscopy (SEM). The aerogel exhibited a BET specific surface area of 303.60 m²/g, a mesoporous structure with pore diameters of 3.37–3.40 nm and pore volume of 0.52 cm³/g, negligible microporosity, a superhydrophobic water contact angle of 155.70° ± 1.34°, a bulk density of 0.18 g/cm³, and porosity of approximately 92%. FTIR confirmed characteristic Si-O-Si and Si-OH functional groups, while SEM revealed a rough, porous, agglomerated morphology consistent with an ambient-pressure-dried aerogel network. These results demonstrate that rice husk is a viable, sustainable precursor for producing hydrophobic, mesoporous silica aerogel with textural and surface properties consistent with materials reported to be effective for adsorption applications and recommend future adsorption studies.

Keywords: *silica aerogel; rice husk; sol-gel synthesis; ambient pressure drying; hydrophobicity*

1. INTRODUCTION

Silica aerogel is a nanostructured material characterized by high specific surface area, high porosity, and low density, properties that have made it the subject of extensive research as an adsorbent for organic and inorganic contaminants in water and wastewater treatment (Standeker et al., 2007, 2011; Wang et al., 2011, 2012). Compared with conventional adsorbents such as granular activated carbon, silica aerogels offer a more open, foam-like pore network, tunable hydrophobicity, and reusability, which together have been reported to improve adsorption performance for organic contaminants (Rahmani et al., 2018).

A major limitation to the wider adoption of silica aerogels, however, is that they are conventionally synthesized from relatively expensive precursors such as tetraethyl orthosilicate (TEOS) or commercial sodium silicate, which constrains cost-effective, large-scale production, particularly in

low- and middle-income settings. Agricultural by-products rich in amorphous silica, such as rice husk, offer a low-cost, abundant, and environmentally sustainable alternative precursor. Rice husk is generated in large quantities wherever rice is cultivated and is otherwise a largely underutilized waste stream; converting it into a valuable silica precursor therefore carries both economic and environmental benefits, avoiding the carbon burden associated with uncontrolled disposal or open burning.

Although several studies have reported the synthesis of silica aerogels from rice husk ash using sol-gel processing and ambient pressure drying (Deng et al., 2025; Halim et al., 2021; Ochoa-Munoz et al., 2025), reported textural and surface properties vary considerably depending on the specific extraction route, gelation conditions, solvent-exchange protocol, silylating agent, and drying method used. This variability underscores the need for detailed, route-specific characterization of any newly developed rice-husk-derived aerogel before its adsorption performance can be meaningfully evaluated or compared with other adsorbents.

This study reports the development of a hydrophobic silica aerogel from rice husk via acid leaching, calcination, alkaline extraction to sodium silicate, acid-catalyzed sol-gel synthesis, solvent exchange, and trimethylchlorosilane (TMCS) surface modification, followed by ambient pressure drying. The resulting material was comprehensively characterized in terms of its textural properties (BET/BJH/t-plot), functional chemistry (FTIR), hydrophobicity (water contact angle), bulk density and porosity, and surface morphology (SEM), to establish its suitability as an adsorbent for water treatment applications.

2. MATERIALS AND METHODS

2.1 Materials

Rice husk used in this study was purchased from a commercial vendor in Johor Bahru, Malaysia, and supplied in 10 kg polythene bags. The chemicals, reagents, and equipment used for silica aerogel synthesis and characterization are summarized in Tables 1 and 2.

Table 1: Chemicals, Reagents and Eqipments for Silica Aerogel Synthesis and Characterization

Material / Reagent	Function
Rice husk	Silica precursor source
Hydrochloric acid (HCl)	Acid leaching of rice husk prior to calcination
Sodium hydroxide (NaOH)	Alkaline dissolution of rice husk ash to sodium silicate
Acetic acid	pH adjustment for gel formation
Hexane	Top layer for bead-shape preservation during gelation
Aqueous ammonia (5%)	Bottom layer for gelation of sol droplets
Ethanol	Solvent exchange (pore-water removal)
Trimethylchlorosilane (TMCS)	Silylating agent for surface (hydrophobic) modification
n-Hexane	Washing modified aerogel beads
Equipment	**Purpose**
Muffle furnace	Calcination of rice husk to ash
Brunauer–Emmett–Teller (BET) analyzer, NOVA touch 4LX	Specific surface area, pore size and pore volume (BJH, t-plot)
Perkin Elmer Frontier FTIR	Functional-group identification (650–4000 cm^{-1})
DataPhysics OCA 15EC–Series	Water contact-angle (hydrophobicity) measurement
JEOL JSM-IT300LV Scanning Electron Microscope	Surface morphology (10, 20, 30, 100 μm)

2.2 Silica Extraction from Rice Husk

Amorphous silica was produced from rice husk by first washing the husk with distilled water and oven-drying it for 24 h at 100°C. Acid leaching was then carried out, since it has been reported to increase silica yield (Azat et al., 2019; Bakar et al., 2016). Leaching was performed by treating the rice husk with 0.5 M hydrochloric acid (HCl) on a hot plate at 60°C for 30 minutes under constant stirring, after which the husk was rinsed three times with distilled water to remove residual acid, air-dried, and oven-dried for a further 24 hours.

Calcination was carried out using a muffle furnace capable of reaching 1000°C. Complete calcination of rice husk has been reported to occur at temperatures between 500°C and 900°C (Bakar et al., 2016). Controlled combustion of acid-treated rice husk at approximately 600 °C has been widely reported to produce silica-rich rice husk ash with predominantly amorphous characteristics, while higher calcination temperatures may promote sintering and, depending on impurity content and pretreatment, transformation toward crystalline silica phases (Bakar et al., 2016; Azat et al., 2019). Bakar et al. (2016), for example, evaluated acid-leached rice husk calcined between 500 and 900 °C for 2 h and demonstrated the production of amorphous silica, with relatively limited improvement in silica production above approximately 600 °C. Therefore, in this study, the acid-leached rice husk was calcined at 600°C for 2 hours. After the furnace cooled, the resulting rice husk ash (RHA) was carefully collected and sieved.

2.3 Sodium Silicate Preparation

Sodium silicate ($Na_2O:SiO_2$), also known as water glass, was produced by dissolving RHA in sodium hydroxide (NaOH) solution. Thirty (30) g of RHA was added to 200 mL of 1 M NaOH solution,

and the mixture was heated on a hot plate under constant stirring at 120°C for 3.5 hours. The mixture was then cooled to room temperature and filtered using Whatman No. 1 filter paper (110–125 mm diameter, particle retention ~11 μm) to obtain a clear sodium silicate solution.

2.4 Silica Aerogel Synthesis, Surface Modification, and Drying

Silica aerogel was produced from the sodium silicate solution by first adjusting its pH to between 4 and 5 through the dropwise addition of acetic acid under gentle stirring, stopping just before gel formation began. Gelation was carried out by dropping the acidified sol into a beaker containing hexane as the top layer and 5% aqueous ammonia as the bottom layer; the resulting gel beads were left for 10 minutes to strengthen before being transferred to warm water for further ageing. The aged beads were then soaked in ethanol for 24 hours to exchange the pore water with ethanol, and this solvent-exchange step was repeated for a further 24 hours to ensure complete exchange.

Surface Modification of aerogel beads was carried out to introduce or improve its hydrophobicity. It was achieved using a silylating agent where in this study Trimethylchlorosilane (TMCS) together with ethanol and n-hexane using in the following proportion: 25% ethanol, 25% TMCS and 50% n-hexane by volume (ratio of ethanol: TMCS: n-hexane = 1:1:2). The gel beads were soaked in each silylating mixture with gentle mixing for 3.5 hours in sealed containers at ambient pressure. After silylation, the beads were washed three times with n-hexane to remove residual TMCS and finally dried on a hot plate at 80°C for 1 hour, yielding the finished silica aerogel at ambient pressure (i.e., without supercritical drying). The overall process, from raw rice husk to the surface-modified, dried silica aerogel, is summarized in Figure 1.

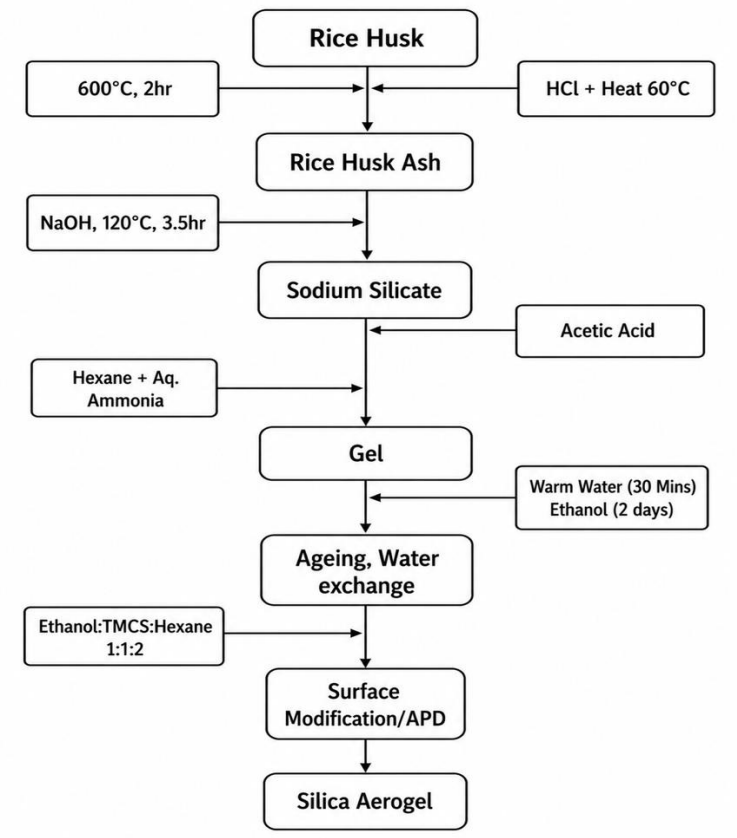

Figure 1: Process flow for the development of hydrophobic silica aerogel from rice husk.

2.5 Characterization of Silica Aerogel

Surface area was determined using the Brunauer–Emmett–Teller (BET) multipoint method, and pore size and pore volume were determined using the Barrett–Joyner–Halenda (BJH) method, both on a NOVA touch 4LX instrument. Prior to analysis, the aerogel was degassed at 200°C for 4 hours, and nitrogen adsorption-desorption isotherms were obtained at 77.3 K. Moreover, functional groups present

in the aerogel were identified by Fourier-transform infrared spectroscopy (FTIR) using a Perkin Elmer Frontier FTIR spectrometer (mid-IR: 8300–350 cm^{-1}; far-IR: 700–30 cm^{-1}; best resolution 0.4 cm^{-1}), scanning the wavenumber range 650–4000 cm^{-1}.

Hydrophobicity was assessed from the water contact angle of a droplet placed on the horizontally positioned aerogel surface, measured with a DataPhysics OCA 15EC–Series instrument and its high-resolution camera; this property has been reported to increase with the amount of silylating agent used and the soaking time in the silylating mixture (Khedkar et al., 2019). Also, bulk density was determined by weighing an empty 50 cm^3 glass flask, filling it with aerogel particles (tapping seven times until no further volume reduction occurred), and reweighing it. Bulk density (g/cm^3) was calculated as the ratio of aerogel mass to flask volume (Equation 1). Porosity was then calculated from the bulk density using Equation 2, assuming a standard amorphous silica density of 2.2 g/cm^3.

$$Density = {(M_1 - M_0)}/{V_a} \quad (1)$$

where M_0 = mass of the empty flask (g); M_1 = mass of flask and aerogel (g); V_a = volume of the flask (cm^3).

$$Porosity = \left(1 - {\rho_a}/{\rho_{st}}\right) \times 100 \quad (2)$$

where ρ_a = density of the developed aerogel (g/cm^3); ρ_{st} = standard density of amorphous silica (g/cm^3).

Finally, surface morphology was examined using a JEOL JSM-IT300LV scanning electron microscope (SEM) at magnifications corresponding to 10, 20, 30, and 100 µm resolutions.

3. RESULTS AND DISCUSSION

3.1 Visual Transformation During Synthesis

The visual appearance of the intermediate products obtained during synthesis (Figure 2) supports successful conversion of rice husk into silica aerogel at each processing stage. The rice husk ash (RHA) obtained after calcination appeared as a fine white powder, indicating effective combustion of the husk and near-complete removal of carbonaceous matter. Recent reviews identify rice husk as an abundant agro-industrial by-product with a composition well suited to conversion into silica and other advanced materials (Hamidu et al., 2025), and rice husk ash has been widely reported to contain a high proportion of amorphous SiO_2 usable as a low-cost aerogel precursor (Deng et al., 2025).

The sodium silicate solution obtained after alkaline digestion of the RHA was golden-brown and slightly transparent, consistent with dissolution of silica into the alkaline medium, although the colour may partly reflect trace impurities carried over from the RHA. The use of RHA-derived sodium silicate, rather than commercial silicate or alkoxide precursors, is significant because it provides a cheaper, more sustainable route to aerogel synthesis (Ochoa-Munoz et al., 2025); similarly, waste-derived sodium silicate has been highlighted as a pathway to more scalable, less energy-intensive aerogel production (Borzova et al., 2024).

Upon acidification, white gel particles formed, confirming conversion of soluble silicate species into a hydrated silica gel network via hydrolysis and condensation. This wet-gel stage is critical, as the final aerogel structure depends on preserving the gel network through ageing, solvent exchange, surface modification, and drying; rice husk ash-derived sodium silicate has similarly been reported to convert into hydrogels and then alcogels via solvent exchange prior to ambient pressure drying (Halim et al., 2021). After drying, the finished aerogel appeared as fragile, extremely light, irregular particles, consistent with the low-density, highly porous nature expected of silica aerogels and confirming successful synthesis via the ambient-pressure-drying route (Deng et al., 2025; Halim et al., 2021; Ochoa-Munoz et al., 2025).

3.2 Textural Properties (BET, BJH, and t-Plot Analysis)

Nitrogen adsorption-desorption analysis was used to evaluate the textural properties of the synthesized aerogel, including BET specific surface area, BJH pore size and pore volume, and t-plot microporosity and external surface area, since these parameters are central to evaluating silica aerogels as environmental adsorbents (Goryunova et al., 2023).

The nitrogen adsorption-desorption isotherm (Figure 3) showed a gradual increase in adsorbed volume at low-to-intermediate relative pressure followed by a sharp rise at high relative pressure, typical of a mesoporous material in which multilayer adsorption and capillary condensation dominate. The separation between the adsorption and desorption branches indicates hysteresis, commonly associated with mesopore filling/emptying (Thommes et al., 2015), while the sharp rise at high relative pressure suggests the presence of larger mesopores and interparticle voids.

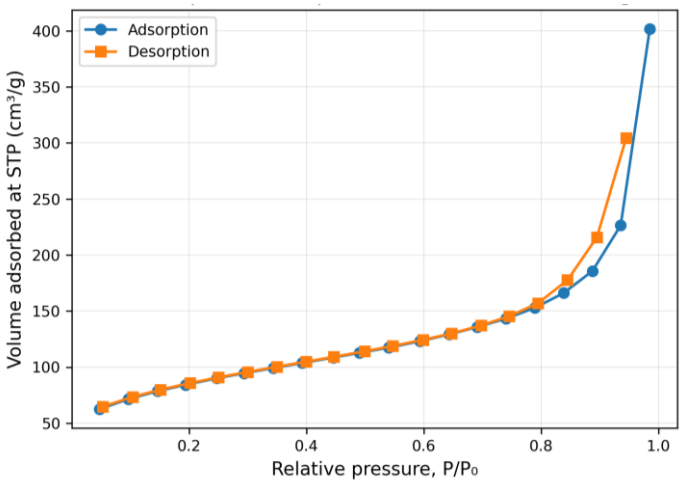

Figure 3: Nitrogen adsorption-desorption isotherm of the silica aerogel.

BET analysis (Figure 4) gave a specific surface area of 303.60 m²/g with a correlation coefficient of r = 0.999915 and a BET C constant of 124.16, indicating strong linearity in the fitting range and favourable interaction between nitrogen molecules and the aerogel surface. This value is

comparable with recent rice husk-derived silica aerogel studies reporting surface areas of 312 and 298 m²/g (Akhter, Soomro, and Inglezakis 2023) and TEOS-doped/non-TEOS-doped aerogels of 296.18 and 267.06 m²/g (Soylu et al., 2025), placing the present material within the range expected for mesoporous silica aerogels, notwithstanding known sensitivity of surface area to precursor chemistry, ageing, solvent exchange, and drying method.

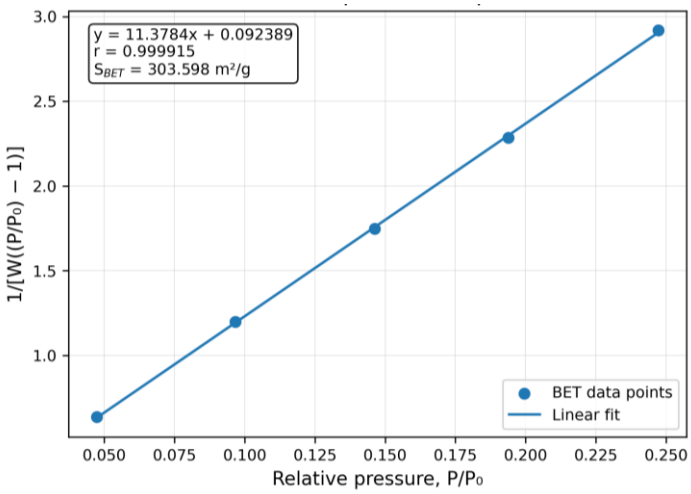

Figure 4: BET multipoint linear plot used to calculate specific surface area.

The t-plot analysis gave an external surface area of 303.60 m²/g, essentially identical to the BET value, indicating that the measured surface area is associated mainly with mesopores and external surface rather than micropores.

From the BJH analysis (Figure 5), the adsorption and desorption branches gave pore radii of 1.687 and 1.701 nm respectively, corresponding to pore diameters of approximately 3.37 and 3.40 nm. Under the IUPAC pore classification (pores < 2 nm: micropores; 2–50 nm: mesopores; > 50 nm: macropores) (Thommes et al., 2015), the aerogel is therefore classified as mesoporous, a structure expected to provide favourable diffusion pathways for adsorbate access to internal sites.

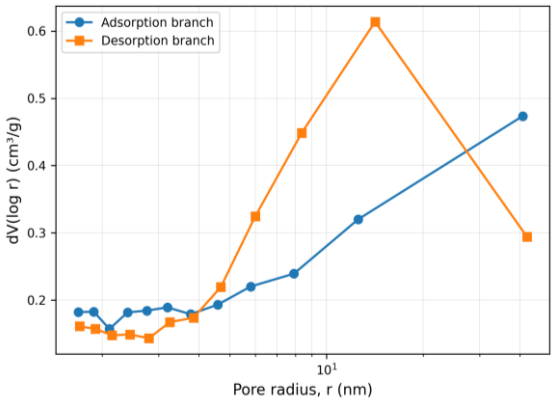

Figure 5: BJH pore size distribution based on adsorption and desorption branches.

The BJH pore volume (Figure 6) was 0.520 cm³/g from the adsorption branch and 0.525 cm³/g from the desorption branch, confirming an appreciable void network for adsorbate accommodation; the corresponding BJH surface areas were 111.55 and 121.82 m²/g, lower than the BET value because BJH analysis captures only pore-size-related surface area from capillary condensation, whereas BET reflects total specific surface area from multilayer nitrogen adsorption. This pore volume is somewhat lower than the 0.85 and 0.75 cm³/g reported for some rice husk-derived silica aerogels (Akhter et al., 2023), a difference attributable to variation in synthesis route, precursor source, gel ageing, solvent exchange, surface modification, and drying conditions across studies.

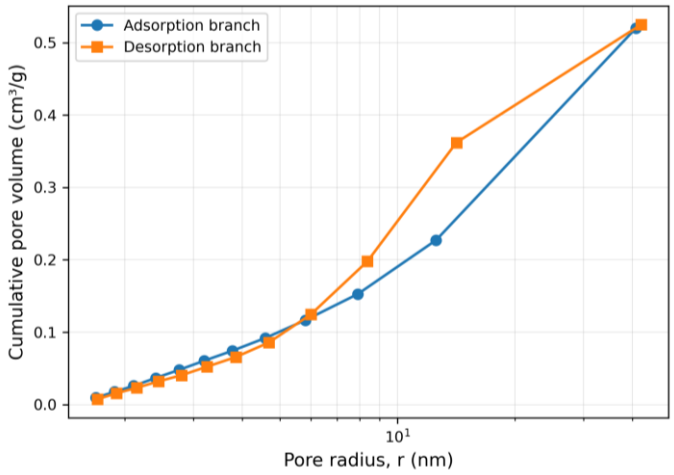

Figure 6: BJH cumulative pore volume of the silica aerogel.

The t-plot analysis (Figure 7) gave a micropore volume of 0 cm³/g and micropore area of 0.000 m²/g, confirming that the material is not micropore-dominated and that its surface area arises mainly from mesopores and external surfaces, consistent with the BJH pore-diameter results.

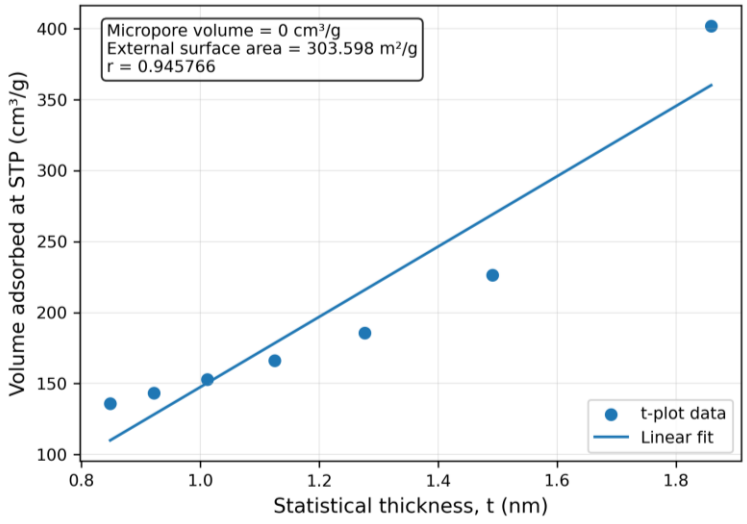

Figure 7. t-plot showing the absence of measurable micropore volume.

Collectively, the BET, BJH, and t-plot results indicate a mesoporous silica aerogel with a moderately high surface area (303.60 m²/g), pore diameter of 3.37–3.40 nm, and pore volume of 0.520–0.525 cm³/g — properties favourable for adsorption, since high surface area provides adsorption sites, mesoporosity supports accessibility and mass transfer, and pore volume accommodates adsorbate molecules, consistent with the general characterization of silica aerogels as highly porous adsorbents for environmental applications (Goryunova et al., 2023).

3.3 Fourier-Transform Infrared Spectroscopy (FTIR)

FTIR spectra of the synthesized aerogel (Figure 8) showed a broad band near 3359.03 cm^{-1} attributed to O-H stretching from surface silanol groups and adsorbed water, and a band at 1627 cm^{-1} corresponding to O-H bending. A weak band near 2964.14 cm^{-1} suggested residual aliphatic C-H groups from the precursor or surface-modification step. A strong absorption at approximately 1065.82 cm^{-1} was assigned to asymmetric Si-O-Si stretching, confirming formation of the silica network, while the band near 945.66 cm^{-1} was associated with Si-OH stretching, indicating surface silanol groups. Additional bands at 848.6, 758.95, and 668.83 cm^{-1} were attributed to symmetric stretching, bending, or related silica-network/surface-group vibrations. Overall, the spectrum confirms successful formation of a silica aerogel bearing siloxane and silanol functional groups that may contribute to adsorption via surface interaction with contaminants (Ma et al., 2025; Minju et al., 2021; Ransing et al., 2023).

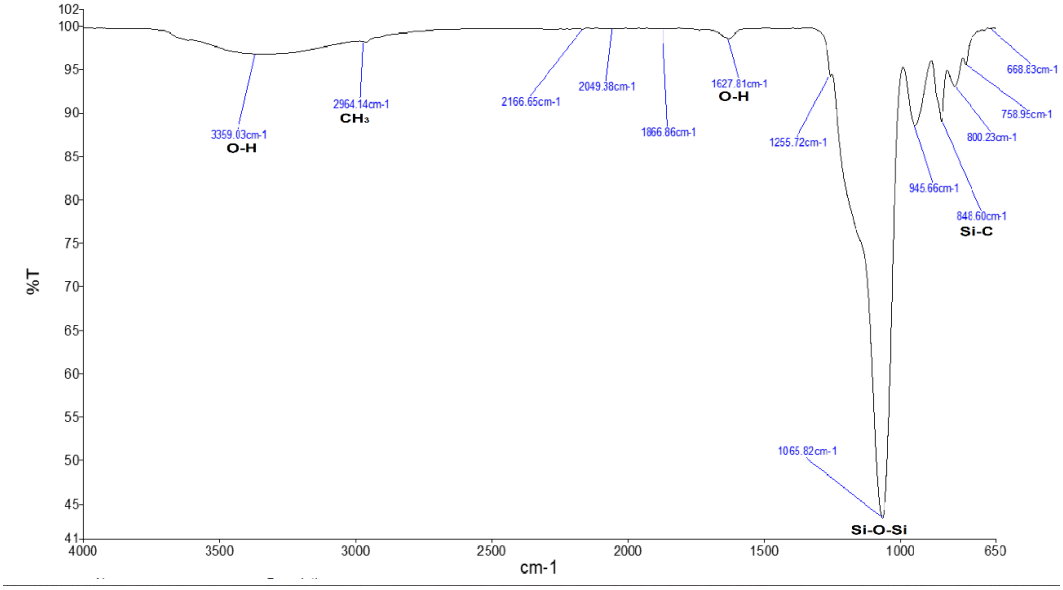

Figure 8: FTIR spectrum of the synthesized silica aerogel.

3.4 Hydrophobicity

Water contact-angle analysis on duplicate aerogel samples (Figure 9) gave contact angles of 156.7°/157.0° and 154.4°/154.7° (means of 156.85° and 154.55°), yielding an overall mean of 155.70° ± 1.34°. The small difference of approximately 2° between the duplicate samples is considered minor and may be attributed to local variations in surface roughness, pore distribution, and the uniformity of TMCS coverage across the aerogel surface. Because contact-angle measurement is highly sensitive to the exact location at which the water droplet is deposited, small differences in surface texture and chemical heterogeneity can influence the measured value. Additional experimental factors, including droplet volume, sample levelling, baseline selection, and image-fitting during contact-angle determination, may also contribute to slight variations. Nevertheless, both duplicate samples consistently exhibited contact angles well above 150°, indicating good reproducibility of the surface modification and confirming the superhydrophobic character of the prepared silica aerogel (Akbari et al., 2025; Tian et al., 2015).

Since surfaces with contact angles above 150° are generally classified as superhydrophobic (Wu et al., 2024), the TMCS-modified aerogel is confirmed to be superhydrophobic. This high contact angle likely reflects the combined effect of low surface energy from the silylating treatment and the porous micro/nano-rough structure of the aerogel, which together limit contact between water droplets and the solid surface. Comparable superhydrophobic contact angles have been reported for rice husk-derived silica aerogel (up to 159.5°) and silica-polyimide aerogel blankets (≈ 153°) (Deng et al., 2025; Liu et al., 2021), suggesting that the surface modification applied in this study was effective and may enhance the aerogel's interaction with hydrophobic organic contaminants during adsorption.

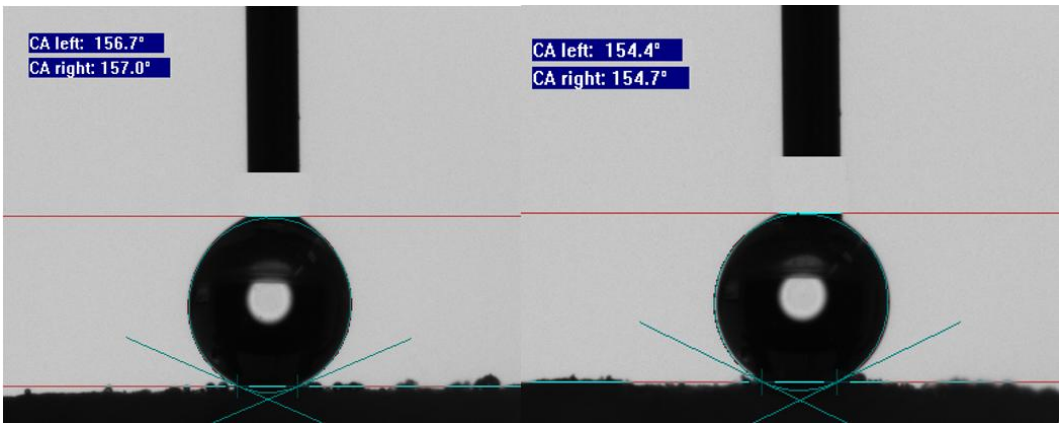

Figure 9: Water contact angles of the silica aerogel.

3.5 Density and Porosity

The bulk density and porosity of the developed aerogel were calculated as 0.18 g/cm³ and approximately 92%, respectively. The low bulk density confirms the lightweight nature of the aerogel and indicates that its porous network was largely retained after ambient pressure drying, while the high porosity shows that roughly 92% of the aerogel volume is void space, with only about 8% occupied by the solid silica framework. This is consistent with the characteristic low-density, highly porous structure of silica aerogels generally (Payanda Konuk et al., 2023), and the porosity value obtained here is comparable to porosities exceeding 90% reported for other rice husk-derived silica aerogels (Ochoa-Munoz et al., 2025). The developed material can therefore be considered highly porous and structurally suited to adsorption, as its open pore network should support mass transfer and access to internal adsorption sites.

3.6 Surface Morphology (SEM)

SEM micrographs at 10, 20, 30, and 100 µm resolutions (Figure 10) revealed an irregular, rough, agglomerated structure with visible interparticle voids across all magnifications. Lower magnification showed larger porous clusters, while higher magnification revealed finer silica particles and rough micro-domains forming the aerogel network, confirming that the synthesized material is a porous aerogel-like structure rather than a dense silica solid. The agglomerated morphology may partly reflect capillary stress during ambient pressure drying, which can induce shrinkage and local structural rearrangement; nonetheless, the persistence of visible pores and rough texture indicates that the porous framework was substantially retained. Similar porous, mesoporous morphology has been reported for other rice husk ash-derived silica aerogels prepared by sol-gel synthesis and ambient pressure drying (Akhter, Soomro, Jamali, et al. 2023; Deng et al., 2025; Ochoa-Munoz et al., 2025). The rough, porous surface observed here is favourable for adsorption, as it provides accessible surface sites and diffusion pathways for contaminant molecules, supporting the suitability of this rice husk-derived silica aerogel as an adsorbent for water treatment.

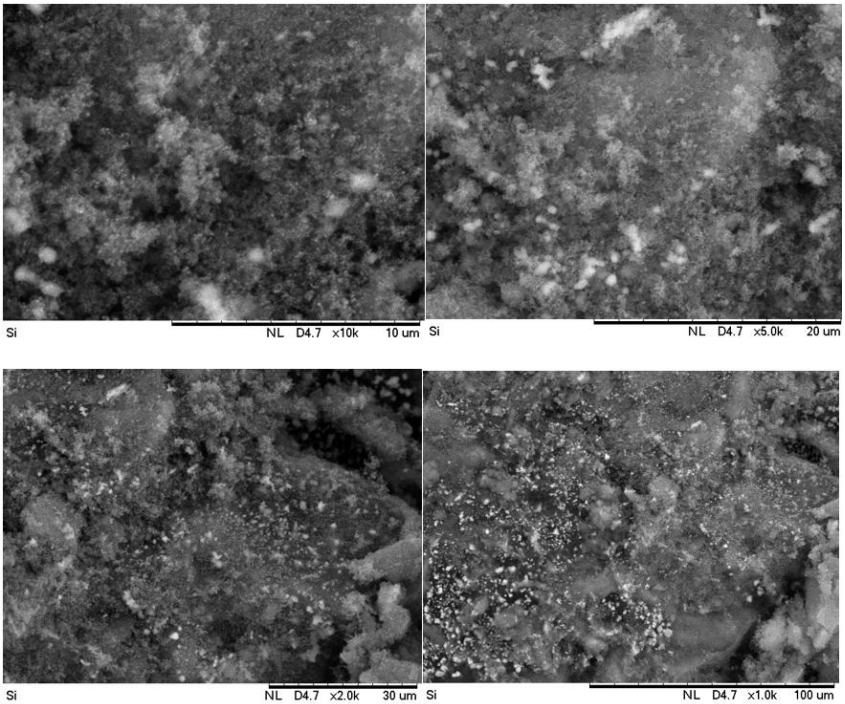

Figure 10: SEM images of the silica aerogel at 10, 20, 30, and 100 µm resolutions.

Table 2: Summary of textural, chemical, and physical properties of the synthesized silica aerogel

Property	Result
BET specific surface area	303.60 m^2/g (r = 0.999915; BET C = 124.16)
External surface area (t-plot)	303.60 m^2/g
BJH pore radius (adsorption / desorption)	1.687 nm / 1.701 nm (≈ 3.37–3.40 nm diameter)
BJH pore volume (adsorption / desorption)	0.520 cm^3/g / 0.525 cm^3/g
Water contact angle (mean ± SD)	155.70° ± 1.34° (superhydrophobic)
Bulk density	0.18 g/cm^3
Porosity	≈ 92%

4. CONCLUSION

Hydrophobic silica aerogel was successfully synthesized from rice husk via acid leaching, calcination, alkaline extraction to sodium silicate, acid-catalyzed sol-gel synthesis, ethanol solvent exchange, TMCS surface modification, and ambient pressure drying. The resulting material exhibited a mesoporous structure with a BET specific surface area of 303.60 m^2/g, pore diameter of 3.37–3.40 nm, and pore volume of 0.52 cm^3/g, alongside negligible microporosity. FTIR confirmed the presence of Si-O-Si and Si-OH functional groups characteristic of a silica network. Water contact-angle measurements (155.70° ± 1.34°) confirmed superhydrophobic behaviour, while low bulk density (0.18 g/cm^3) and high porosity (≈92%) confirmed the characteristic lightweight, open-pore structure of silica aerogels. SEM further revealed a rough, porous, agglomerated surface morphology consistent with these bulk properties. Taken together, these results demonstrate that rice husk, an abundant, low-cost, and environmentally sustainable agricultural by-product, can be converted into a hydrophobic, mesoporous silica aerogel with textural and surface properties consistent with materials reported to be effective for adsorption applications and recommend future adsorption studies

ABSTRACT

This study investigated the dynamic mechanical behaviour of blended low-density polyethylene (LDPE) and high-density polyethylene (HDPE) waste plastics using Dynamic Mechanical Analysis (DMA). The aim was to evaluate the effect of HDPE loading on the viscoelastic and damping properties of LDPE/HDPE blends. Samples with varying HDPE loadings (0–50 wt.%) were prepared by melt compounding on a two-roll mill machine, followed by compression moulding. DMA was conducted at a frequency of 1 Hz over a temperature range of 30–120 °C at a heating rate of 6 K/min. The results showed that increasing HDPE content significantly improved the mechanical performance of the blends. Relative to pure LDPE, the storage modulus increased by approximately 573.4%, while the loss modulus increased by approximately 426% at 50 wt.% HDPE loading. The tan δ values ranged from 0.13 to 0.27 across all blends within the investigated temperature range of 30–120 °C, indicating good damping characteristics. The findings demonstrate that HDPE incorporation enhances the stiffness and mechanical strength of LDPE-based blends, indicating the potential of recycled LDPE/HDPE waste plastics for engineering and structural material applications.

Keywords: *High-density polyethylene (HDPE); low-density polyethylene (LDPE); plastics; polymer blend; Dynamic mechanical Analysis (DMA)*

1. INTRODUCTION

Polyethylene-based plastics have become highly valued in modern engineering and industrial systems owing to their lightweight, chemical inertness, ease of processing, and low production cost. Among the various polyolefins currently in circulation, Low-density polyethylene (LDPE) and high-density polyethylene (HDPE) contribute to a much larger share of global plastic production and waste than most other plastics (Vannessa, 2004).

In 2023, global plastic production was estimated at around 415 million metric tons, roughly double the amount produced at the beginning of the 21st century, yet only approximately 9% of all plastic waste generated to date has been successfully recycled (Surendarnath et al., 2025). This is a challenging situation in Nigeria, where limited waste sorting and recycling infrastructure results in LDPE and HDPE being dumped together with other waste materials, worsening environmental pollution (Akan et al., 2021). A cost-effective method for recovering value from mixed polyethylene waste is heat blending, where LDPE and HDPE are processed together in the molten state to give a material with properties that can be tailored by adjusting the blend ratio.

Evaluating the mechanical behaviour of polymer blends under real service conditions requires more than conventional tensile or flexural tests, since polymers exhibit viscoelastic behaviour influenced by temperature, loading frequency, and the duration of deformation. Dynamic Mechanical Analysis (DMA) is widely used to investigate this behaviour, providing key parameters including the storage modulus (E′), the loss modulus (E″), and the damping factor, tan δ, expressed as the ratio of E″ to E′ (Chartoff et al., 2009).

Although interest in recycled polyolefin blends has increased in recent years, several important gaps still exist in the available literature. Most studies on LDPE/HDPE blends have used virgin polymers with controlled and well-defined properties (Schyns & Shaver, 2021). In contrast, recycled plastics are often more complex, containing impurities and variations in composition and quality (Nagy & Weltsch, 2023). Previous research has also focused largely on the tensile, thermal, and rheological

properties of LDPE/HDPE blends, with comparatively few studies examining their dynamic mechanical behaviour, particularly for materials derived from post-consumer plastic waste, and information is especially limited over the temperature range commonly encountered in service conditions (30–120 °C).

To help address these gaps, the present study investigates the dynamic mechanical behaviour of binary LDPE/HDPE blends prepared from post-consumer plastic waste collected in Zaria, Nigeria. The blends were produced with HDPE contents of 0wt.%, 10wt.%, 20wt.%, 30wt.%, 40wt.%, and 50 wt.% using a melt-compounding process. The specific objectives of the study are to:

1. Examine the effect of increasing HDPE content on the storage modulus (E′), loss modulus (E″), and damping factor (tan δ) of recycled LDPE/HDPE blends over the temperature range of 30–120 °C at a frequency of 1 Hz and a heating rate of 6 K/min.
2. Determine how blend composition affects key thermomechanical transition temperatures, including the onset, peak, and offset temperatures.
3. Evaluate whether the dynamic mechanical properties of the blends make them suitable for engineering and structural applications.

2. METHODOLOGY

2.1 Materials

Post-consumer low-density polyethylene (LDPE) waste used in this study was obtained from discarded sachet water packaging films collected within Samaru, Zaria, Kaduna State, Nigeria. High-density polyethylene (HDPE) waste was sourced from used yoghurt packaging containers ("San yoghurt" plastic) collected from the same location.

It is acknowledged that the use of post-consumer waste plastics introduces inherent variability that virgin polymer studies do not face. In this study, material identity was inferred from the known source of the plastics, such as sachet water films (LDPE) and yoghurt containers (HDPE). These are commonly used product categories with well-documented polymer types in the Nigerian context. However, formal characterisation of the raw materials using techniques such as Fourier-transform infrared spectroscopy (FTIR), differential scanning calorimetry (DSC), or melt flow index (MFI) testing was not conducted in this study. This represents a limitation, as residual contamination from labels, adhesives, or mixed plastics cannot be completely ruled out despite the washing procedure employed. Future work should incorporate material characterisation of the recycled feedstock before blending to quantify contamination levels and confirm polymer identity, allowing a more definitive interpretation of the dynamic mechanical results.

2.2 Collection and Preparation of Waste Plastics

LDPE and HDPE post-consumer waste plastics were collected from designated waste bins and disposal locations. The collected plastics were sorted manually to separate LDPE from HDPE contaminants and other foreign materials. The sorted plastic materials were thoroughly washed with water and liquid soap to remove dirt, grease, labels, and adhered impurities that could interfere with the blending and thermal analysis processes.

After washing, the plastic materials were not dried under direct sunlight to avoid potential degradation and distortion of the LDPE sachet water films, which are highly sensitive to prolonged solar exposure. Instead, the samples were dried in a well-ventilated room under continuous fan-assisted airflow for approximately 4 days. This approach was adopted to ensure gradual and uniform removal of moisture while preserving the physical integrity and intrinsic properties of the polymers prior to further processing. Complete drying was necessary to prevent moisture-induced defects during melt blending and compression moulding operations. Drying was considered complete when no visible moisture was observed, and the flakes remained free-flowing and non-adherent upon handling.

The dried plastic materials were subjected to size reduction using a locally fabricated shredding machine to obtain relatively uniform polymer particle chips of about 10mm for effective blending.

2.3 Preparation of LDPE/HDPE Blends

Mass measurements of the polymer samples were conducted using a digital weighing balance. The polymer blends were prepared using a two-roll mill compounding machine (Reliable Rubber and Plastic Company, New Jersey, U.S.A., Model 5189), operated at a processing temperature of 180°C for 10 - 15 minutes. The two-roll mill compounding step used a higher temperature (180°C) to ensure adequate melt flow, shear mixing, and homogenization of the LDPE/HDPE blend across the open rollers, where heat loss to the environment is greater. The shredded polymer materials were introduced into the heated rollers and blended thoroughly to ensure proper dispersion and homogenization of the polymer phases.

The blends were prepared using different LDPE/HDPE formulations as follows:

- 200 g/0 g, 180 g/20 g, 160 g/40 g, 140 g/60 g, 120 g/80 g, 100 g/100 g

These formulations were prepared to evaluate the influence of HDPE loading on the dynamic mechanical properties of the polymer blends.

2.4 Compression Moulding of Polymer Blends

Compression moulding of the blended samples was carried out using a Carver compression moulding machine (Carver Inc., Wabash, U.S.A., Model 5019).

The compounded polymer blends obtained from the two-roll mill were processed using the compression moulding technique to produce sheet samples suitable for dynamic mechanical analysis (DMA). The mould platens were electrically heated to a temperature of 150 °C and allowed to stabilise before processing. Compression moulding, by contrast, was carried out on the already-compounded (pre-homogenized) blend in a closed, pressurized system; a moulding temperature of 150°C, above the melting points of both LDPE (~105–115°C) and HDPE (~130–137°C) was sufficient to ensure both polymer phases were fully molten and could consolidate into a uniform sheet, while minimizing additional thermal exposure and reducing the risk of oxidative degradation during the moulding dwell time.

The mould was then preheated to the same temperature, after which the plastic paste was placed into the mould cavity. Compression moulding was carried out at a pressure of 3 MPa for 5 min to produce sheets with dimensions of 240 mm × 220 mm × 4 mm. Before moulding, the mould surfaces were coated with used engine oil to facilitate easy removal of the cured samples. After curing, the moulded samples were removed and allowed to cool to room temperature. The moulded sheets were subsequently cut into smaller specimens with dimensions of 60 mm × 12 mm × 4 mm for DMA characterisation. The prepared samples were then stored under ambient laboratory conditions before testing.

2.5 Dynamic Mechanical Analysis (DMA)

Dynamic mechanical analysis (DMA) of the prepared samples was performed using a DMA 242E NETZSCH Artemis dynamic mechanical analyzer located at the Department of Mechanical Engineering, Ahmadu Bello University, Zaria.

The DMA test was performed under controlled experimental conditions using a heating rate of 6 K/min and an oscillation amplitude of 60 μm. The temperature range employed during the analysis was 30°C to 120°C. Frequency-dependent measurements were conducted at a frequency of 1 Hz.

The key parameters measured by DMA are defined as follows. The storage modulus (E′) represents the energy stored and recovered per cycle of deformation, and is given by:

$$E' = (\sigma_0/\varepsilon_0) \cos \delta \quad (1)$$

where σ_0 is the stress amplitude, ε_0 is the strain amplitude, and δ is the phase angle between stress and strain. The loss modulus (E″) represents the energy dissipated as heat per cycle, and is expressed as:

$$E'' = (\sigma_0/\varepsilon_0) \sin \delta \quad (2)$$

The damping factor, tan δ, is defined as the ratio of the loss modulus to the storage modulus:

$$\tan \delta = E''/E' \quad (3)$$

A high tan δ value indicates a material that dissipates more energy relative to what it stores, reflecting dominant viscous behaviour, while a low tan δ value indicates more elastic, stiffness-dominated behaviour.

Each blend composition was tested once under the specified frequency and heating rate conditions. Formal replicate testing (i.e., triplicate runs with reported means and standard deviations) was not conducted in this study due to material and equipment constraints; this limitation is discussed further in the Results and Discussion section.

3. RESULTS AND DISCUSSION

3.1 Dynamic Mechanical Analysis of LDPE/HDPE Blends

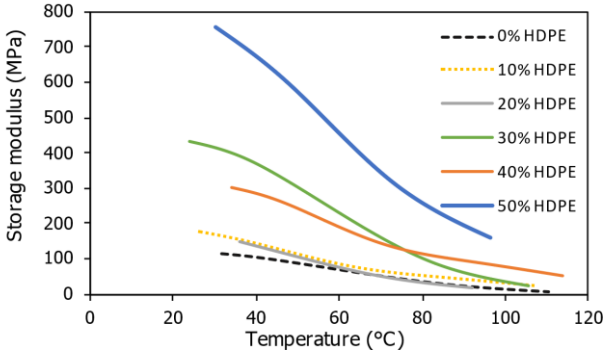

Figure 1.0: Effect of temperature on storage modulus of LDPE/HDPE blend

The variation of storage modulus with temperature for the LDPE/HDPE blends is presented in Figure 1. The results showed that the storage modulus decreased progressively with increasing temperature for all blend compositions due to increased molecular chain mobility within the polymer matrix.

At lower temperatures of approximately 35°C, the incorporation of HDPE significantly improved the stiffness of the blends. The sample containing 50 wt.% HDPE exhibited the highest storage modulus, while the control sample containing 0 wt.% HDPE showed the lowest storage modulus. The 50 wt.% HDPE blend demonstrated an increase of approximately 573% in storage modulus compared to the unfilled control sample.

The increase in storage modulus with HDPE loading can be attributed to the higher crystallinity and rigidity of HDPE compared to LDPE. Consequently, blends containing higher HDPE concentrations exhibited greater resistance to elastic deformation. This behaviour is consistent with findings demonstrating that HDPE forms well-organised spherulitic structures with high crystallinity (81.5%) and rigid amorphous layers between lamellae. In contrast, LDPE forms irregular aggregates with considerably lower crystallinity (27.5%) and mobile amorphous layers, which are structural differences that directly govern the stiffness of their blends (Fu et al., 2022). Furthermore, DMA measurements confirmed that the rigid, confined amorphous phase in HDPE suppresses molecular chain mobility, while the mobile amorphous phase in LDPE introduces greater viscoelastic compliance, explaining the progressive reduction in storage modulus observed as LDPE concentration increases across the measured temperature range of 30°C to 120°C in the present study (Fu et al., 2022).

The storage modulus decreased continuously as the temperature increased from 30°C to approximately 120°C. This reduction is associated with softening of the polymer matrix and decreased resistance to molecular motion at elevated temperatures. Similar observations have been reported for polyethylene-based polymer blends subjected to dynamic mechanical analysis.

It should be noted that due to material and equipment constraints, formal replicate testing with statistical error bars was not conducted in this study. This represents a limitation of the present work, and future studies should incorporate, at a minimum triplicate testing per composition with reported standard deviations to allow full assessment of data reproducibility and statistical significance.

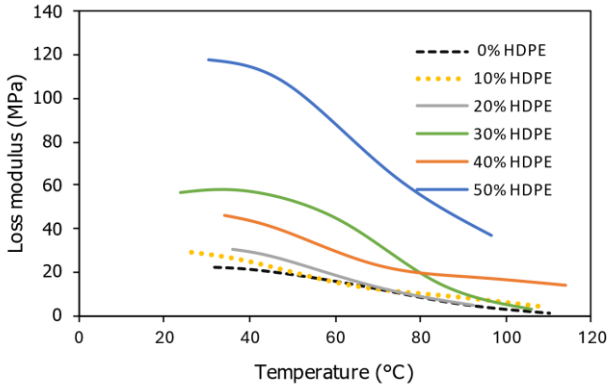

Figure 2.0: Effect of temperature on loss modulus of LDPE/HDPE blend

The loss modulus defines the viscous response of the material, reflecting its capacity to dissipate mechanical energy as heat during deformation, a behaviour governed by internal molecular friction and chain mobility within the polymer network (Satya & Sreekanth, 2020).

The results indicated that the loss modulus decreased with increasing temperature for all blend compositions. At approximately 35°C, the 50 wt.% HDPE sample exhibited the highest loss modulus, whereas the control sample without HDPE loading showed the lowest value. The increase in loss modulus for the 50 wt.% HDPE sample was approximately 426% higher than the control sample, with a modulus difference of about 96.4 MPa.

As the temperature increased, all samples exhibited gradual reductions in loss modulus and eventually converged near 110°C, except for the 50 wt.% HDPE blend, which maintained relatively higher values. This behaviour indicates thermal softening and reduced energy dissipation capability at elevated temperatures due to increased polymer chain mobility. Similar trends have been reported in thermoplastic polymer blends where elevated temperatures reduce viscoelastic resistance (Techawinyutham et al., 2021).

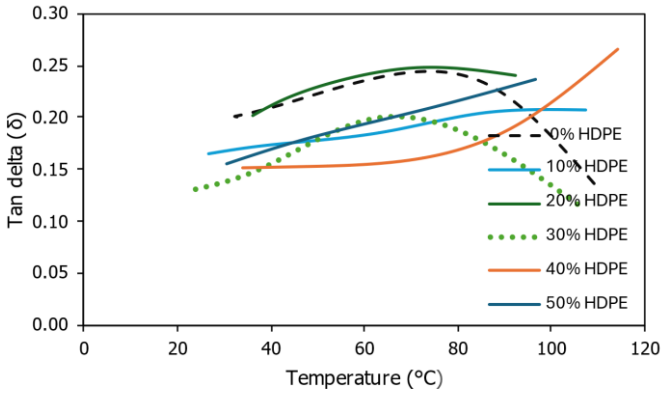

Figure 3.0: Effect of temperature on tan delta (δ) of LDPE/HDPE blend

Tan δ is the ratio of loss modulus (E″) to storage modulus (E′). It represents the damping factor, essentially how much mechanical energy is dissipated as heat versus stored elastically (Poh et al., 2022)

The tan δ curves showed varied behaviour across the HDPE Loadings with an increase in temperature. The polymer matrix for 0 wt.% HDPE blend exhibited a damping value of about 0.20 at room temperature, which constantly declined throughout the entire temperature range, reaching approximately 0.13 at 110 °C. This shows a progressive reduction in energy dissipation capacity with increasing temperature. The 20 wt.% and 30 wt.% HDPE blends displayed a characteristic rise and fall pattern, with their tan δ peak values of about 0.245 and 0.20 at around 70–75°C and 75–80°C, respectively, before declining sharply at higher temperatures. This peak behaviour is associated with the glass-to-rubber transition zone, where maximum molecular mobility and energy dissipation coincide.

In contrast, the 10 wt.% and 50 wt.% HDPE blends exhibited a gradual and continuous increase in damping factor with temperature, plateauing at elevated temperatures without a well-defined peak within the tested range. Most notably, the 40 wt.% HDPE blend demonstrated a distinctly different response, showing a continuous and steep rise in tan δ from approximately 0.15 at room temperature to 0.27 at 120°C, with no observable peak or decline. This behaviour suggests that at this composition, the viscoelastic transition is either significantly broadened or shifted beyond the measurement window, likely due to a unique phase morphology and interactions between the HDPE crystalline domains and the matrix at this specific blend ratio (Sha et al., 1991). These divergent behaviours suggest that higher HDPE content fundamentally alters the damping characteristics of the blends, possibly due to increased crystalline phase constraints and enhanced polymer chain interactions that shift or suppress the peak damping temperature beyond the tested range (Munaro & Akcelrud, 2008).

3.2 Thermal Transition Behaviour

Table 1: Thermal transition temperatures of LDPE/HDPE blends at 1 Hz

LDPE (g)	HDPE (g)	wt.% HDPE	Onset (°C)	Peak (°C)	Offset (°C)
200	0	0	47.9	73.9	92.5
180	20	10	36.8	99.7	108.0
160	40	20	54.1	74.1	92.0
140	60	30	53.5	104.0	114.0
120	80	40	48.4	114.4	116.0
100	100	50	47.7	96.2	Increasing trend

The thermal transition temperatures of the LDPE/HDPE blends obtained from DMA analysis are presented in Table 1. The onset, peak, and offset temperatures varied with blend composition, indicating that HDPE loading influenced the relaxation behaviour and thermal stability of the polymer blends.

The 40 wt.% HDPE blends exhibited a higher peak transition temperature than the 50 wt% blend, which may suggest a non-linear composition-property relationship. One possible explanation is that HDPE crystalline domains may be more favourably dispersed within the LDPE matrix at 40 wt.% loading, which could promote greater interfacial co-crystallisation and chain entanglement (Sha et al., 1991). Beyond this composition, a shift toward a phase-inversion-type morphology may disrupt the crystalline network, potentially reducing the effective thermal transition temperature despite the higher overall HDPE content. However, this interpretation remains speculative, as no direct morphological evidence (e.g., SEM) or complementary thermal analysis (e.g., DSC) was obtained in this study to confirm the proposed dispersion or phase-inversion mechanisms; such characterisation is recommended in future work to validate this hypothesis(Rana, 2002).

Lastly, the 50 wt.% HDPE composition shows an anomalous result in Table 1, where the recorded peak temperature is 96.2°C, and the offset showed an increasing trend. This is physically inconsistent, as the offset temperature should always exceed the peak temperature in a thermal transition. This discrepancy is likely attributable to instrument resolution limitations or data-processing artefacts at the boundary of the transition and should be interpreted with caution. The values for this composition should be revisited with additional testing, if available, or explicitly acknowledged as a measurement uncertainty.

4. CONCLUSION

The dynamic mechanical study of recycled LDPE/HDPE polymer blends indicated that compositional variation has a considerable impact on the material system's viscoelastic and

thermomechanical performance. The storage modulus gradually increased from 112.0 MPa at 0 wt.% HDPE to 754.2 MPa at 50 wt.% HDPE, indicating a significant improvement in stiffness brought about by the addition of HDPE to the LDPE matrix. This improvement suggests that because HDPE has a stronger crystallinity and less molecular chain mobility than LDPE, it encourages greater elastic energy storage capacity.

The loss modulus increased with higher HDPE loading, rising from 22.6 MPa to 119.0 MPa at approximately 31°C. This increase indicates an enhanced ability of the blends to dissipate mechanical energy through viscous deformation. As the temperature increased, all samples transitioned toward rubbery behaviour, which confirms the thermally activated relaxation of polymer chains and the gradual reduction in mechanical integrity at elevated temperatures.

The damping factor (tan δ) showed peak behaviour depending on the composition, with well-defined peaks observed for the 20 wt.% and 30 wt.% HDPE blends (tan $\delta \approx 0.245$ at 70–75°C and $\approx$ 0.20 at 75–80°C, respectively), while the 0, 10, 40, and 50 wt.% HDPE blends did not exhibit a clearly defined peak within the tested temperature range. The presence of separate tan delta peaks demonstrates the viscoelastic nature of the blends and indicates the effect of the interfacial interactions between the LDPE and HDPE phases on the energy dissipation characteristics. The results overall show that LDPE blending with HDPE is a feasible way to achieve mechanical stiffness and damping performance through controlled compositions.

This study contributes to the existing knowledge by establishing a quantitative correlation between the content of HDPE and the dynamic mechanical performance in recycled polyethylene systems. It further demonstrates that waste polyethylene streams can be engineered into value-added materials with tunable mechanical and damping properties instead of being limited to disposal or low-grade recycling applications. The effect of compatibilizers on phase interaction and interfacial adhesion in LDPE/HDPE blends should be studied in future work. Furthermore, morphological studies using SEM and thermal analysis techniques like DSC and TGA are suggested to correlate microstructural changes with the observed viscoelastic behaviour. Tests of long-term fatigue and cyclic loading would also give more insight into the durability and real-world applicability of these recycled polymer systems.

ACKNOWLEDGEMENTS

The authors gratefully acknowledge the Department of Mechanical Engineering, Ahmadu Bello University, Zaria, for granting inter-departmental access to their Dynamic Mechanical Analysis (DMA) facility used in this study. Special thanks go to Mr. Aminu Lawal Yahaya, Laboratory Technologist, for his technical assistance during the DMA testing.

ABSTRACT

Concrete is widely recognized for its high compressive strength, yet it suffers from low tensile capacity, brittleness and susceptibility to cracking under cyclic loading. Coir fibre offers a renewable and low-cost means of improving toughness; however, its high water absorption and vulnerability to alkaline and microbial attack limit long-term durability. This study examined the influence of NaOH pre-treatment on the workability, mechanical properties and biodegradation resistance of coir fibre reinforced concrete (CFRC). Fibres treated with 0, 5 and 10 % NaOH were incorporated at 0.5, 1.0 and 1.5 % by cement weight. Slump, compressive, flexural and split tensile strengths were determined, while fibre biodegradation was evaluated through soil-burial testing for up to 56 days. Workability decreased with increasing fibre content and alkali concentration. The combination of 1 % fibre and 5 % NaOH produced the highest mechanical strengths (22 N/mm² compressive, 4.25 N/mm² flexural and 2.89 N/mm² splitting tensile) together with the lowest mass loss (2.24 % after 56 days), compared with nearly 29 % for untreated fibre. Moderate alkaline treatment at 5 % NaOH with 1 % fibre therefore offers a practical balance of strength and durability for sustainable coir-fibre concrete.

1. INTRODUCTION

Sustainability was defined by the World Commission on Environment and Development (WCED) as meeting the needs of the present without compromising the ability of future generations to meet their own needs (WCED, 1987). One of the major challenges of the modern society is the impact of increasing world population on limited resources especially in the built industry. Demands for built infrastructure have caused significant waste generation, energy and material consumption by the construction industry. The building construction industry is not only a major consumer of energy, raw materials and land; it also contributes immensely to environmental pollution, especially greenhouse gas emission (Melchert, 2007). To improve sustainability in construction materials usage, the construction industry must embrace the reuse of industrial by-products and renewable materials in construction.

Presently, because of their proven performance, the use of synthetic fibres in cement composites is becoming increasingly popular. Cement research literature is replete with studies showing that the ductility, tensile strength, toughness, fatigue strength, impact resistance and absorbed energy of cement-based materials could be enhanced significantly through the addition of steel and polymer fibres. (Cui et al., 2023; Banthia et. al., 1994).

There are three types of natural fibres available for concrete reinforcement: animal-based, mineral-derived and plant-based. Animal fibers, comprising specific proteins, include silk, wool, and hair fibre. Mineral derived fibres include asbestos, wollastonite and palygorskite. Finally, plant-based fibres include cotton, hemp, jute, flax, ramie, sisal, bagasse, specialty fibres processed from wood and etc.

Major improvement in the properties of cementitious material is achievable through the incorporation of plant-based fibres described above. Fortunately, such fibres are gotten from renewable sources and are readily available at relatively low cost compared to synthetic fibres. There are huge benefits in terms of environmental, energy and resource conservation from large scale acceptance and

utilization of plant-based fibres as raw materials for cement-based composites. (Onuaguluchi & Banthia, 2016).

Although several studies have investigated the incorporation of coir fibre in cementitious composites, limited research has focused on the combined influence of fibre dosage and controlled NaOH pre-treatment on both the mechanical performance and long-term biodegradation resistance of coir fibre reinforced concrete. Most existing works have either examined untreated fibres or applied alkali treatment without systematically evaluating its effect on durability under soil burial conditions. Therefore, this study aims to address this gap by investigating the effect of different NaOH concentrations (0%, 5% and 10%) and fibre contents (0.5%, 1.0% and 1.5% by cement weight) on the workability, compressive strength, flexural strength and split tensile strength of coir fibre reinforced concrete. In addition, the biodegradation behaviour of the treated and untreated fibres was assessed through soil burial testing over a period of 56 days.

2. METHODOLOGY

2.1 Materials

Coir Fibre: Raw coconut husks were sourced from Lagos, South West Nigeria, and the fibre extraction was carried out at the National Institute for Chemical Technology (NARICT), Basawa, Zaria.

Sodium Hydroxide Pellets: The NaOH pellets used for the treatment were purchased in Zaria, Kaduna State.

Distilled Water: The distilled water used in the treatment process was obtained from the Chemistry Department, Ahmadu Bello University, Zaria.

Cement: The cement used in this research work was 42.5N Dangote brand of Ordinary Portland Cement and was obtained from open market in Samaru, Zaria, Nigeria.

Fine and Coarse Aggregate: Obtained from a local supplier in Zaria, Kaduna State, the aggregates were subjected to appropriate preliminary test to ensure they meet with standards for making concrete.

Water: Potable water was used for both mixing and curing.

2.2 Methods

2.2.1 Fibre Treatment

The coir fibres were fully immersed in separate containers containing 5% and 10% NaOH solutions at a fibre-to-solution ratio of 1:20 (w/v) and maintained at room temperature (approximately 28 ± 2 °C). Immersion was maintained for 2 hours as recommended by Widodo & Widodo (2024). The alkali treatment procedure adopted in this study follows the method proposed by Yan et al. (2016). Following the 2-hour immersion period, the fibres were removed and thoroughly washed several times with distilled water until a neutral pH was achieved. This step was necessary to eliminate residual alkali from the fibre surfaces and confirm the complete removal of excess alkalinity. Surplus water was carefully expelled by gently pressing the fibres in a sieve to minimise any mechanical damage. The treated fibres were subsequently oven-dried at approximately 70°C for 24 hours to achieve effective moisture removal while preserving their structural integrity.

2.2.2 Mixture Proportion

Table 1: Mix Proportion for Alkali Treated Coir Fibre Reinforced Concrete

Mix ID	Cement (Kg/m^3)	Water (kg/m^3)	Fine Aggregate (kg/m^3)	Coarse Aggregate (kg/m^3)	Fibre Content (%)	NaOH Content (%)
M0	320	160	480	960	0	0
M1	320	160	480	960	0.5	0
M2	320	160	480	960	1	0
M3	320	160	480	960	1.5	0
M4	320	160	480	960	0.5	5
M5	320	160	480	960	1	5
M6	320	160	480	960	1.5	5
M7	320	160	480	960	0.5	10
M8	320	160	480	960	1	10
M9	320	160	480	960	1.5	10

2.2.3 Testing of Alkali Pretreated Coir Fibre Reinforced Concrete

All the concrete batches cast underwent the following tests described below. Three trials are conducted, and the average is taken for each test performed for a specific fibre content and treatment concentration.

Slump test.

This is used to assess the workability of the concrete mixtures. The test was conducted in accordance to BS EN 12350-2:2019. The slump was measured from a mould height of 300mm.

Figure 1: Slump Test

Compressive strength test.

This is used to determine the compressive strengths of the composites used. The test was conducted in accordance to BS EN 12390-3:2019. The specimens used are 150mm concrete cubes, three sample were cast and the average taken.

Figure 2: Compressive Strength Test

Flexural strength test.

The flexural strength test is used to determine the bending capacity of the composite. It was conducted using the four-point load test in accordance to BS EN 12390-5:2019. A block size of 100mm width, 100mm depth, and a span of 500mm were used for the concrete specimens, and three sample were cast and the average taken.

Split tensile strength test.

This is used to determine the tensile strengths of the composites used. The test was conducted in accordance to BS EN 12390-6:2009. The specimens are 150×300mm concrete cylinders, and three sample were cast and the average taken.

Soil Burial Test

Biodegradation tests on treated and untreated coir fibre samples were carried out by a simple soil burial test, ASTM D570-98 (1998), to simulate the natural biodegradation of the fibre. Dog-bone-shaped samples were prepared according to ASTM 638-14 (2014); ASTM D5988-18 (2018) and were buried in natural soil in a plastic bag without any enzyme activity or any composting materials. The soil burial site was kept outdoors under an average ambient temperature of approximately 30°C, in a natural garden soil with pH value of 7.1 and average moisture content of 25% and natural organic matter and buried at a depth of 150mm. Test specimens were removed after exposure periods of 14, 28, and 56 days for further evaluation. At each retrieval stage, the samples were gently washed with water to remove any attached soil particles and subsequently air-dried at room temperature until a constant mass was obtained. Biodegradability was assessed by determining the percentage weight loss of the specimens, based on a comparison of their masses before and after the respective burial durations.

Figure 3: Soil Burial Test

2.2.4 Statistical Analysis (ANOVA)

The statistical analysis tool used for this research is the one-way ANOVA with 95% confidence level and probability value set at less than 5% are considered statistically significant while values more than 5% were considered not statistically significant.

3. RESULTS AND DISCUSSION

3.1 Slump Test Result

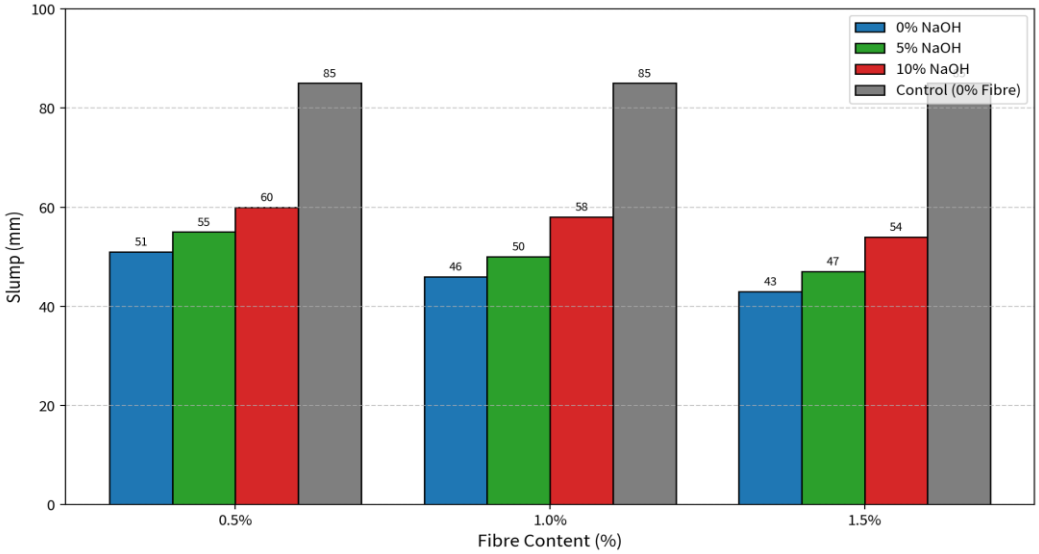

Figure 4: Comparison of Slump Test of Treated and Untreated Coir Fibre Reinforced Concrete

From the result in Figure 4, Slump decreased systematically with increasing fibre content and with higher NaOH treatment. All mixes were in the low–medium workability range (mainly S2 per EN 206), with the highest fibre (1.5%) at 10% NaOH approaching the S1/S2 boundary. The reduction is attributed to fibre water absorption and increased internal friction due to surface roughening from alkaline treatment, which improves fibre–matrix compatibility but lowers flow. For typical reinforced elements placed with vibration, S2 is acceptable; however, for congested reinforcement or pumping, admixture-based water reduction is recommended rather than increasing the water–cement ratio.

3.2 Compressive Strength

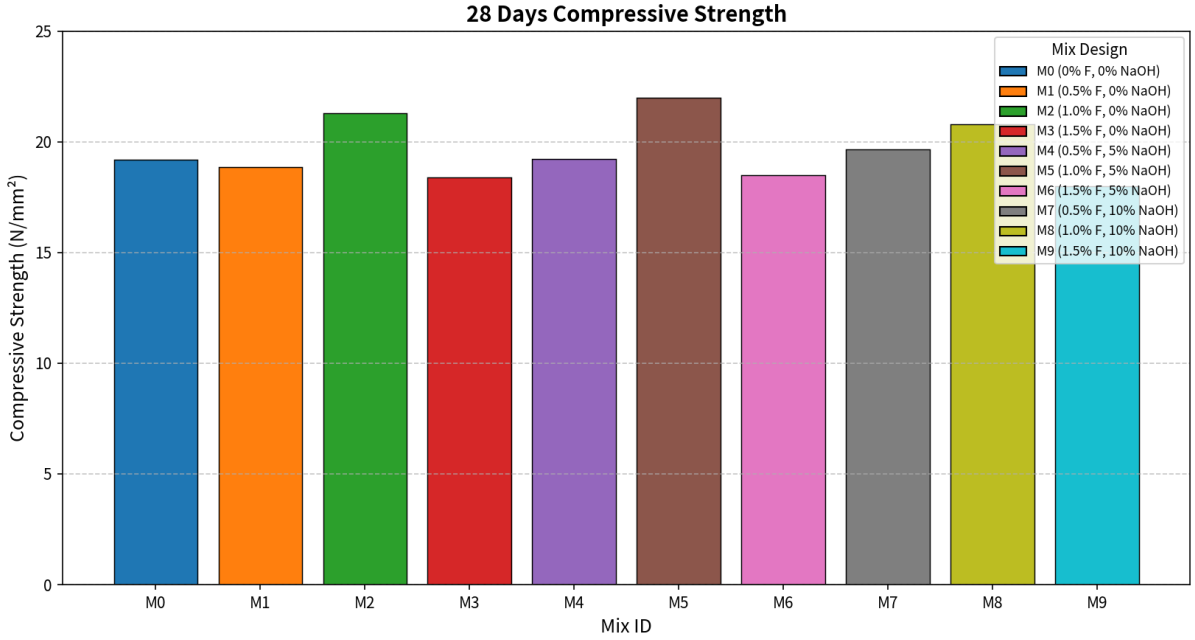

Figure 5: Compressive Strength Test of Treated and Untreated Coir Fibre Reinforced Concrete

The 28-day compressive strength results as shown in Figure 5 indicate that both fibre dosage and alkaline surface treatment significantly modulate concrete performance. At a fixed NaOH dosage, increasing coir fibre content from 0.5% to 1.0% enhanced strength, while further increase to 1.5% led

to a decline suggesting that moderate fibre addition improves reinforcement via crack-bridging and stress transfer, whereas excessive fibre induces agglomeration, impairs workability, and creates microstructural weaknesses. This trend aligns with observations in waste tyre steel fibre-reinforced concrete, where strength improved up to around 1.5% fiber content before declining due to bonding issues and poor dispersion (Augustino et. al., 2023).

The optimum mix (M5) achieved a mean compressive strength of 22 N/mm² at 28 days. According to BS EN 206, Grade C20/25 concrete requires a characteristic cylinder strength of 20 N/mm² (or characteristic cube strength of 25 N/mm²). The obtained mean strength of 22 N/mm² is therefore slightly below the typical target mean strength required for C20/25 concrete under normal production conditions. However, it satisfies the strength requirement for lower-grade applications

3.3 Flexural Strength Test

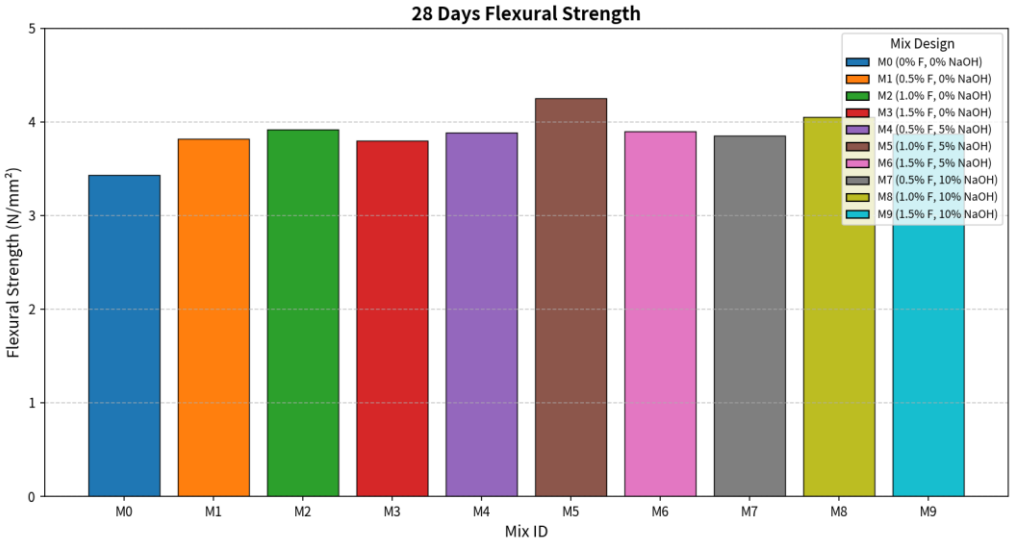

Figure 6: Flexural Strength Test of Treated and Untreated Coir Fibre Reinforced Concrete

The 28-day flexural strength results from Figure 6 demonstrate that both fibre content and NaOH treatment play significant roles in enhancing the mechanical performance of coir fibre reinforced concrete. At 0.5% fibre content, untreated fibre recorded 3.82 N/mm², while NaOH treatment increased strength to 3.88 N/mm² (5% NaOH) and 3.85 N/mm² (10% NaOH). This trend indicates that alkali treatment improved fibre-matrix adhesion by removing surface impurities such as lignin, hemicellulose, and waxes, thereby promoting better stress transfer between fibre and concrete matrix. The improvement aligns with recent findings that alkali treatment enhances the interfacial bonding of natural fibres in cementitious composites, leading to improved flexural performance (Gupta et al., 2023).

At 1.0% fibre content, flexural strength increased further, with untreated fibre yielding 3.92 N/mm² and 5% NaOH-treated fibre reaching the maximum strength of 4.25 N/mm². This demonstrates that an optimal fibre dosage combined with moderate alkali treatment provides the best reinforcement effect. However, at higher treatment levels (10% NaOH), the flexural strength slightly declined to 4.05 N/mm², suggesting that excessive alkali concentration could damage fibre structure, reducing its reinforcing efficiency. These observations are consistent with recent studies that reported diminishing mechanical properties when fibres are over-treated due to cellulose degradation (Luqman et al., 2023).

Beyond 1.0% fibre content, a further increase to 1.5% resulted in a reduction in flexural strength (ranging between 3.80 and 3.90 N/mm²), indicating that excessive fibre dosage may lead to poor dispersion and increased voids within the matrix. Overall, the results confirm that the synergy of fibre content and controlled alkali treatment enhances flexural strength, with the best performance achieved at 1.0% fibre content treated with 5% NaOH, Mix ID M5 (1% F, 5% NaOH).

3.4 Split Tensile Strength

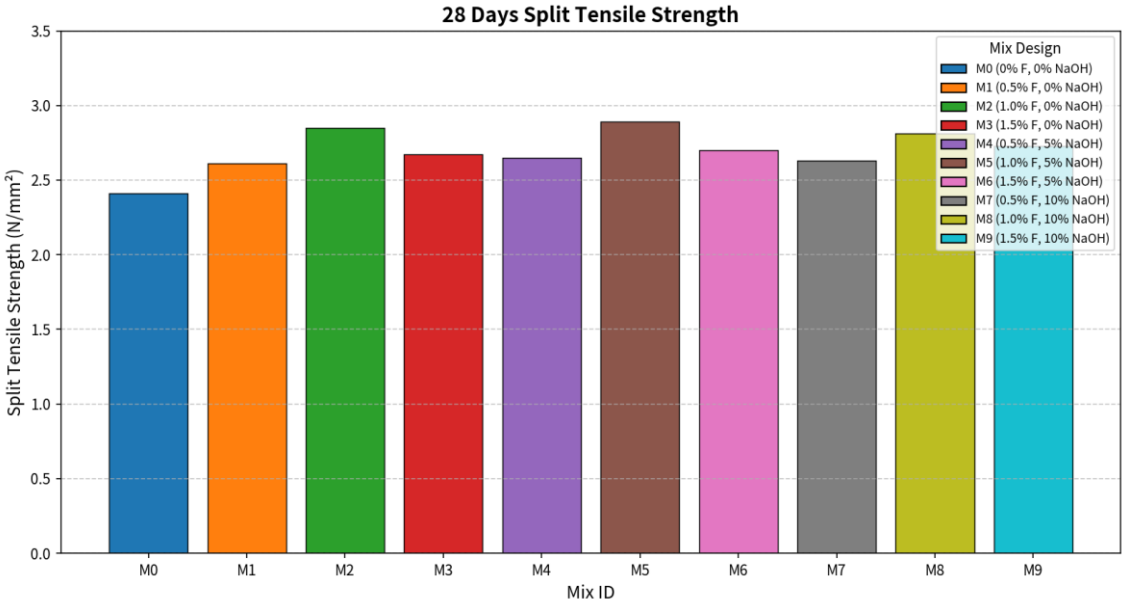

Figure 7: Split Tensile Strength Test of Treated and Untreated Coir Fibre Reinforced Concrete

The 28-day split tensile strength results from Figure 7 for NaOH-treated coir fibre-reinforced concrete reveal significant influences of fibre content (0.5%, 1%, 1.5%) and NaOH treatment (0%, 5%, 10%) on tensile performance. The highest tensile strength of 2.89 N/mm² was achieved with 1% fibre content and 5% NaOH, surpassing the untreated sample at the same fibre dosage (2.85 N/mm²) and the 10% NaOH-treated sample (2.81 N/mm²). This suggests an optimal fibre content of 1%, where coir fibres effectively bridge micro-cracks, enhancing tensile capacity without causing fibre agglomeration (Sanjay et al., 2018).

At 0.5% fibre content, NaOH treatment produced a modest improvement in strength, increasing from 2.61 N/mm² (0% NaOH) to 2.65 N/mm² (5% NaOH) and 2.63 N/mm² (10% NaOH). This indicates improved fibre-matrix bonding due to NaOH's removal of lignin and increased fibre surface roughness (Yan et al., 2016). However, at 1.5% fibre content, strengths remained relatively lower (2.67 N/mm², 2.70 N/mm² and 2.73 N/mm² for 0%, 5% and 10% NaOH respectively), suggesting that higher fibre volumes may lead to uneven distribution or reduced matrix cohesion, limiting reinforcement benefits. Overall, the results confirm that Mix ID M5 (1% F, 5% NaOH) a combination of 1% fibre content with moderate (5%) NaOH treatment provides the most effective enhancement of split tensile strength.

3.5 Soil Burial Degradation

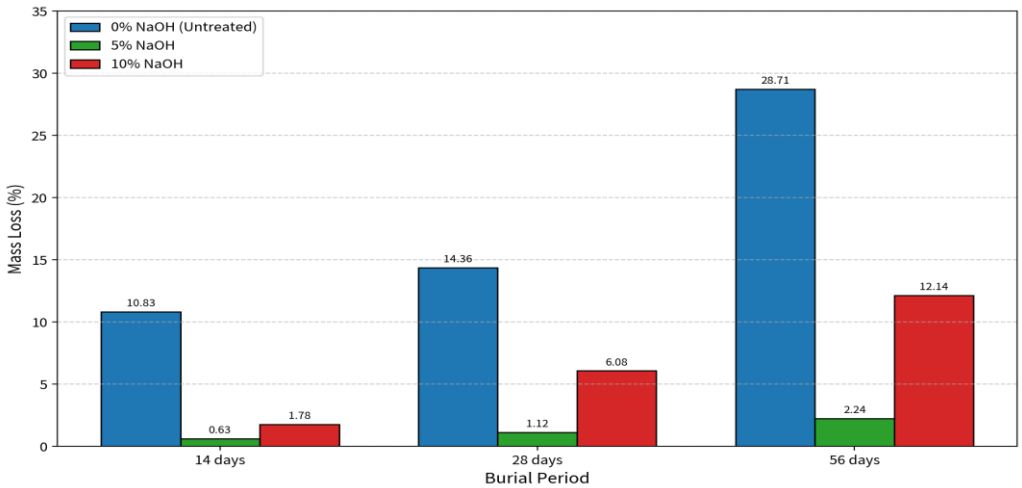

Figure 8: Soil Burial Degradation Test of Treated and Untreated Coir Fibre

The soil burial degradation test results as shown in Figure 8 demonstrate the impact of NaOH treatment on coir fiber durability, critical for their application in alkaline pretreated fiber-reinforced concrete. Untreated coir fibers (0% NaOH) exhibited significant mass loss, with 10.83% after 14 days, 14.36% after 28 days, and 28.71% after 56 days, reflecting high biodegradability due to microbial degradation of hemicellulose and cellulose in lignocellulosic fibres. This rapid degradation limits their suitability for concrete reinforcement, where moisture and alkalinity accelerate fiber breakdown (Ali et al., 2012). Conversely, 5% NaOH-treated fibers showed minimal mass loss (0.63% at 14 days, 1.12% at 28 days, 2.24% at 56 days), indicating enhanced resistance to biodegradation. Alkaline treatment removes hemicellulose and lignin, increasing cellulose crystallinity and reducing microbial attack sites (Mwaikambo & Ansell, 2002). The 10% NaOH-treated fibers had higher mass loss (1.78% at 14 days, 6.08% at 28 days, 12.14% at 56 days), suggesting structural damage from excessive alkali (Sawpan et al., 2011). It is important to note that the soil burial test in this study was conducted on free fibre specimens rather than fibres embedded within hardened concrete. Consequently, the measured mass loss represents the biodegradation behaviour of the fibres under direct soil exposure and should not be interpreted as a direct measure of fibre degradation within the concrete matrix

3.6 Analysis of Variance (ANOVA)

One-way analysis of variance (ANOVA) was conducted to evaluate the statistical significance of differences in mechanical properties among the various mixes. The results indicated statistically significant differences in compressive strength ($F = 13.45$, $p < 0.001$), flexural strength ($F = 4.65$, $p = 0.002$) and split tensile strength ($F = 2.61$, $p = 0.035$). Post-hoc Tukey's Honest Significant Difference (HSD) test further revealed that the mix containing 1% coir fibre treated with 5% NaOH (M5) generally exhibited significantly higher strengths compared to the control mix (M0) and several other combinations. These findings confirm that the observed improvements in mechanical performance, particularly for the optimal mix (M5), are statistically significant and not attributable to random variation.

Acknowledgements - The first author gratefully acknowledges the Petroleum Technology Development Fund (PTDF) for the scholarship that made this research possible.

4. CONCLUSION

From the research, the following are the conclusions:

i. Workability of the concrete decreased progressively with increasing coir fibre content and higher NaOH treatment concentrations, primarily due to increased water absorption by the fibres and greater internal friction resulting from surface roughening.

ii. ii. The optimum mechanical performance was achieved with 1.0 % fibre content treated with 5 % NaOH. This mix recorded the highest compressive strength (22 N/mm²), flexural strength (4.25 N/mm²) and splitting tensile strength (2.89 N/mm²), satisfying the requirements for Grade 20 concrete.

iii. The adoption of 5 % NaOH-treated coir fibre at 1 % dosage offers a cost-effective and environmentally sustainable alternative for improving the tensile and flexural performance of plain concrete, particularly in low- to medium-strength applications such as non-structural elements, rural infrastructure and secondary members.

iv. It should be noted that this study was limited to laboratory-scale testing using coir fibres obtained from a single source. No field application or long-term structural performance evaluation was conducted. Future studies are recommended to investigate the performance of NaOH-treated coir fibre reinforced concrete under real environmental conditions and with fibres from different geographical sources.

ABSTRACT

Polycaprolactone (PCL) is widely recognised as a promising biomaterial owing to its ease of processing, biocompatibility, and biodegradability. Despite these advantages, its slow degradation rate and insufficient mechanical strength and stiffness hinder its application where enhanced structural performance is required. This study investigates the influence of PLA, strontium-doped hydroxyapatite (HAp/Sr), and keratin fibre reinforcement on the chemical structure and mechanical performance of polycaprolactone (PCL)-based biocomposites. FTIR spectroscopy was employed to examine molecular interactions between the polymer matrix and reinforcing phases. The tensile strength, Young's modulus, hardness and fracture toughness tests were conducted to evaluate mechanical integrity. The spectra show the presence of PCL through characteristic absorption bands at 2947 and 2865 cm^{-1}, attributed to the C-H asymmetric stretching vibration. A slight shift is observed in some peaks toward either a lower or a higher wavenumber, with no new peaks observed in the reinforced biocomposites. This indicates possible weak intermolecular interaction rather than new covalent bond formation. Pure PCL (BC1) exhibited the lowest mechanical performance, with an ultimate tensile strength of 4.55, Young's modulus of 2 MPa, hardness of 22.3, and fracture toughness of 0.5659. Incorporation of reinforcing agents (i.e., PLA, strontium-doped hydroxyapatite (HAp/Sr), and keratin fibre) resulted in a significant increase in hardness and fracture toughness, demonstrating the reinforcing effect of bioactive fillers. The sample BC4 showed the highest overall mechanical performance, with ultimate tensile strength (38.5), Young's modulus (4.05), hardness (56.33), and fracture toughness (1.0534), indicating enhanced stiffness and resistance to crack propagation. These findings suggest that the synergistic combination of PLA, keratin fibre, and bioactive ceramic additives significantly enhances the mechanical behaviour of PCL-based materials, making them more suitable for applications requiring improved strength, stiffness, and durability, such as biomedical scaffolds and load-bearing structures.

1.0 INTRODUCTION

Bone tissue serves a number of vital functions in daily life, including safeguarding internal organs, giving the body structural support, facilitating mobility, and controlling the storage and release of minerals (Gharibshahian et al., 2023). Many people suffer from bone diseases brought on by trauma, tumour excision, infection, congenital anomalies, and injuries sustained in accidents (Li et al., 2020). However, defective bone tissue possesses the ability to self-repair or self-regenerate, which occurs in four stages: hematoma, soft callus, hard callus formation and bone remodelling (Monfared et al., 2022). Self-repair and self-regeneration weaken with age or in critical bone defects (i.e., cracks above 2.5 cm). Tissue engineering deploys an innovative approach to repair bone defects (Jung et al., 2022;Yudoh et al., 2023). The approach adopts engineered bone grafting techniques, which aid the healing of the defective bone, while also providing the needed strength that supports the healing process (Menotti et al., 2023). Archunan & Petronis (2021) highlighted that approximately 2.2 million bone grafting techniques are used in orthopaedic surgical processes worldwide, and the number is expected to increase yearly by 13%. However, the current bone grafting techniques (i.e., allograft and autograft) face

different challenges such as risk of disease transmission, limited availability and immune rejection (Gharibshahian et al., 2023).

To overcome the shortfalls from the current bone grafting techniques, bone tissue engineering offers a solution, involving the use of a three-dimensional scaffold made from biomaterials that creates an environment for cell proliferation and regeneration (Biscaia et al., 2022). Biomaterial scaffolds for repairing defective bone are often developed from standalone materials (i.e., ceramics, biodegradable polymers, and metallic materials) or composites (Hernandez et al., 2017). A suitable biomaterial needs to possess good mechanical properties so that it can provide structural support during the healing process (Obada et al., 2021; You et al., 2022). The materials and production methods (i.e., melt extrusion/hot pressing, solvent casting, electrospinning and many others) used in producing the scaffolds influence the mechanical properties.

Biomaterial scaffolds could be produced from biodegradable polymers (either synthesised or sourced naturally) since they have excellent mechanical properties and porous architecture that creates a bioactive environment for cell proliferation and adhesion (Saurav et al., 2024). PCL is known for its great flexibility (Loyo et al., 2024), while PLA is a cost-effective polymer, with good biocompatibility and a low melting point (Zarei et al., 2023). Several attempts have been made to develop a polymer composite by blending PLA and PCL (Aliotta et al., 2023; Min et al., 2024). Vonbrunn et al. (2020) reported that incorporating PCL into the PLA matrix results in a broad surface area for tissue regeneration and host cell structural support. However, PCL/PLA scaffolds have poor hydrophilicity, low cell migration and adhesion. The poor hydrophilicity could result in prolonged degradation (Mohandesnezhad et al., 2020). Also, they lack the optimal combination of mechanical strength, bioactivity and degradation properties necessary for successful bone regeneration.

In this study, scaffolds for tissue engineering rely on the interplay of biodegradable polymers (PLA and PCL), bioactive filler (HAp/Sr), and reinforcement material (keratin fibre). HAp is known for its biocompatibility, osteointegration, osteoconductivity and non-toxicity (Bee & Hamid, 2020). The addition of hydroxyapatite (HAp), enhanced with strontium (Sr), introduces osteoconductive properties that promote bone formation and integration (Obada et al., 2021). Combining these components with biodegradable polymers like polycaprolactone (PCL) and polylactic acid (PLA) creates a scaffold that closely mimics the structure and function of natural bone. Keratin fibres, derived from chicken feathers, are a durable, abundant, and underutilised natural protein with exceptional bioactive and biocompatibility properties, making them a potential reinforcement material. Cheng et al. (2009) reported that keratin fibre obtained from chicken feathers has a special cross-linked and semi-crystalline structure which helps improve the mechanical stress resistance and elastic modulus of polymer-based composites. However, the study utilised PLA rather than PCL; the findings provide the provide for reinforcing capability of keratin fibre derived from chicken feathers. The utilisation of locally sourced materials (i.e., sheep bone and chicken feathers) offers potential cost and sustainability benefits by converting waste into valuable biomaterials. These materials could lower reliance on imported materials while supporting local production; consequently, this supports Nigeria's objectives for industrial growth, creation of sustainable materials and waste management.

Therefore, this study examined the effect of incorporating PLA, HAp/Sr and keratin fibre on the mechanical properties of PCL biopolymer composites. The hardness, fracture toughness, tensile strength and Young's modulus of the developed biopolymer composite were examined. The functional groups in the samples were identified using the Fourier Transform Infrared Spectroscopy technique.

2.0 MATERIALS AND METHODS

2.1 Materials

The polycaprolactone and the polylactic acid powder were purchased from Sino Convoy New Material Co., Ltd. (China) and Guangzhou Bio Plus Materials Technology Co., Ltd, respectively. The hydroxyapatite was obtained from sheep bone, which was sourced from a local abattoir. The collected sheep bones were washed, dried, and carbonised in a charcoal-fired oven. The carbonised bones were calcined in a Muffle furnace at 900 ^{o}C for 2 hours. A mortar and pestle were used to grind the calcined bone into a fine powder. A 100 µm mesh was used to sieve the resulting fine powder to get a uniform particle size (Obada et al., 2024). Strontium was incorporated into the HAp powder using the solution

gelation (sol-gel) technique in a proportion suggested by Obada et al. (2021). The keratin fibres were extracted from chicken feathers using the hydrolysis technique.

2.2 Production of the Pure PCL and PCL Biocomposite Polymers

The polymer samples were produced using a solvent-casting technique guided by the process presented by Adamu et al. (2023) and Rinaldi et al. (2024). The PCL and PLA powders were dissolved in chloroform, then stirred till the powder dissolved completely in the solution. Keratin fibres and HAp/Sr powder were added to the solution, followed by stirring to ensure even distribution. The mixture was then poured into a mould and allowed to dry under controlled conditions. The dried samples were subjected to characterisation and testing. The samples were developed using the composition in Table 1, which was selected after optimising the process using Box-Behnken DOE. The functional groups in the developed samples were identified by FT-IR.

Table 1: Composition of the samples

Sample Code	PCL (wt.%)	PLA (wt.%)	HAp/Sr (wt.%)	Keratin fibre (wt.%)
BC1	100	--	--	--
BC2	78	22	--	--
BC3	68	22	10	--
BC4	61	22	10	7

2.3 Hardness and Fracture Toughness

The hardness of the developed sample was measured using a Vickers hardness tester. An indent load of 300 grams was used, and the indent diagonal was measured, which was then used to calculate the hardness. The fracture toughness was calculated using Equation 1 as adopted by Obada et al. (2023), the parameters included the hardness value, diagonal length and the crack length.

$$K_{ic} = 0.016 \times \left(\frac{c}{a}\right)^{-1.5} \times H_v \times a^{0.5} \quad 1$$

Where Hv: Vickers hardness, c is the sum of half of the diagonal length (l), and a is the crack length: $0.5(a + l)$

2.4 Tensile Strength Measurement

The tensile strength measurement was conducted using a universal testing machine. The standard dimensions used for the test are a gauge length of 50 mm and a diameter of 12.5 mm. The maximum load (tensile strength) and elongation at break were recorded as the test proceeded until the specimen breaks. The tensile strength and Young's modulus of the samples were obtained from the data generated by the machine. For each composition, three independent specimens (n = 3) were tested under the same experimental conditions.

3.0 RESULT AND DISCUSSION

3.1 FTIR Analysis of the Pure PCL and PCL Biocomposite Scaffolds

The FTIR spectra of the PCL and PCL biocomposite are shown in Figure 1. The spectra show the presence of PCL through characteristic absorption bands at 2947 and 2865 cm^{-1}, attributed to the C-H asymmetric stretching vibration. In the BC2 spectrum, no new peaks were observed, indicating that no chemical decomposition or interaction occurred between PCL and PLA during the development process. Maleki et al. (2021) developed a PCL/PLA composite, and the FTIR spectra of PLA, PCL, and the PCL/PLA blend were reported to be similar, indicating that no chemical reaction occurred. The authors then concluded that this illustrates a proper mixture. However, a slight shift is seen in some peaks to either a lower or a higher wavenumber. For instance, the C=O symmetric vibration was seen at 1716 cm^{-1}, but shifted to 1728 cm^{-1} in the BC2 spectrum. The peak shift is attributed to the weak interaction between the PCL and PLA (Lu & Kazarian, 2020). A similar shift is observed in the BC3 and BC4 sample spectra, with no new peak observed, suggesting that the principal functional groups of the individual constituents were retained following the development of the composite. This aligns with the study conducted by Shojaei et al. (2019).

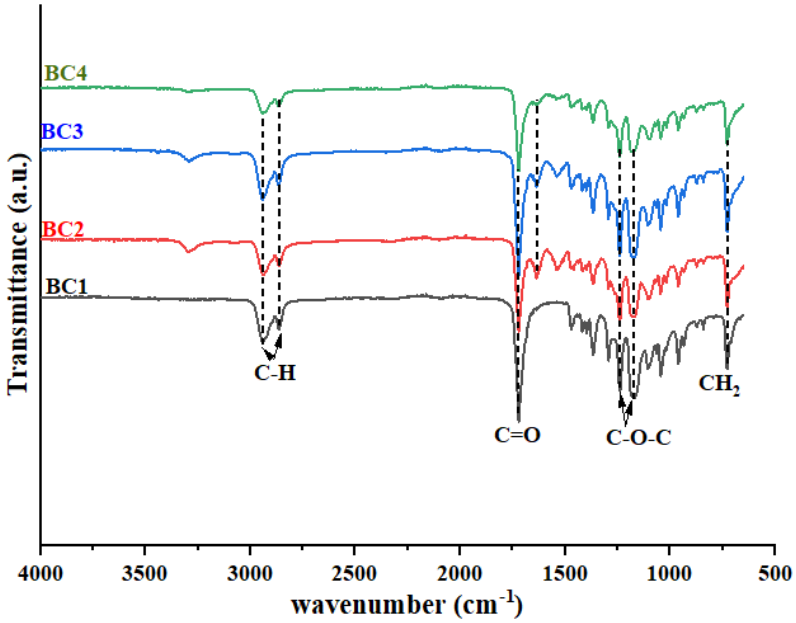

Figure 1: FTIR spectra of the pure PCL and PCL biocomposite

3.2 Mechanical Properties of the Pure PCL and PCL Biocomposite Scaffolds

3.2.1 Hardness Value and Fracture Toughness

The hardness value and fracture toughness of the unreinforced PCL and reinforced PCL are illustrated in Figure 2. The differences observed in samples' hardness and fracture toughness show the effect of both ceramic reinforcement and polymer blending on resistance to crack propagation and deformation. The BC1 had the lowest hardness (22.3 Hv) and fracture toughness (0.566 $MPam^{1/2}$), confirming its relatively soft structure (Chen et al., 2018). A slight improvement was observed when PCL was blended with PLA, as seen in BC2, with hardness and fracture toughness increasing to 24.27 Hv and 0.646 $MPam^{1/2}$, respectively. This indicates that PLA increases the PCL rigidity and its energy absorption capacity during fracture. Homkhiew et al. (2024) noted that increasing the PLA concentration made the composite less flexible, resulting in increased hardness. A more significant improvement was recorded in BC3, where the hardness increased to 33.33 Hv and fracture toughness to 0.664 $MPam^{1/2}$. This enhancement is attributed to the presence of reinforcing agents (i.e., PLA polymer and hydroxyapatite-strontium particles).

These reinforcing agents could have promoted better stress distribution and energy-absorbing capacity that delays fracture propagation. The sample BC4 had the highest value, with hardness and fracture toughness reaching 56.33 Hv and 1.053 $MPam^{1/2}$, respectively. When compared with BC1, BC4 gave a substantial increase, increasing approximately by 60.4% for hardness and 46.3% for fracture toughness. This suggests that there is a strong synergistic interaction between the reinforcing agents and the polymer matrix. The improved homogeneous dispersion of the fillers and enhanced interfacial bonding between the matrix and the filler contributed to improved crack formation and resistance against indentation. The hardness value obtained for BC4 (56.33 Hv) falls within the hardness range of trabecular bone (41.8 – 90.8 Hv) (Wang et al., 2006), making the developed composite suitable for cancellous-bone application, since cortical bone requires higher hardness and strength.

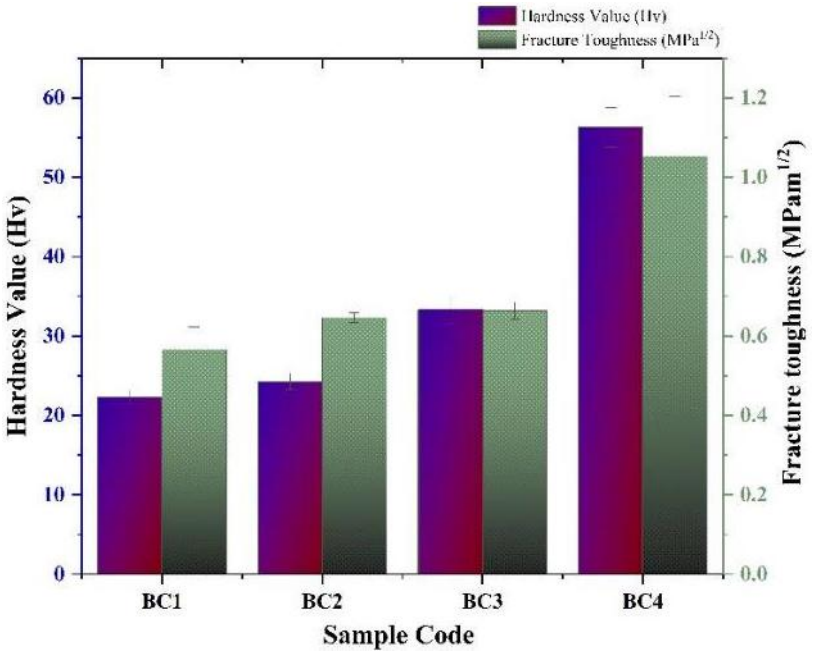

Figure 2: Hardness value and fracture toughness of the samples

3.2.2 Tensile Strength and Young Modulus

Figure 3 presents the ultimate tensile strength and Young's modulus of the pure PCL and the BC4 from section 3.2.1. A low ultimate tensile strength of 4.55 MPa and a Young's modulus of 2 MPa indicate the PCL's ductile, soft and low-stiffness nature. Hashim et al. (2022) noted that the PCL polymer had low modulus and tensile strength. These low values indicate that the BC1 had low resistance to applied stress and possessed a significant tendency for elastic deformation under load, which limits its applicability in structurally challenging situations. A significant increase was observed for BC4, resulting in an ultimate tensile strength of 38.5 MPa and a Young's modulus of 4.05 MPa. This shows that the tensile strength and Young's modulus increase by 88.1% and 50.6%, respectively. This shows a remarkable improvement in the load-bearing capacity and stiffness compared to BC1. The measured values in the study are relatively low, attributed to the production technique used (solvent casting), which can introduce porosity and residual solvent within the composite, thereby lowering the overall mechanical performance.

The improvement suggests that the addition of the reinforcing agents could have fewer structural defects and promote effective load distribution across the matrix. In general, sample BC4 exhibits superior resistance to failure, making it more suitable where structural integrity and mechanical reliability are required.

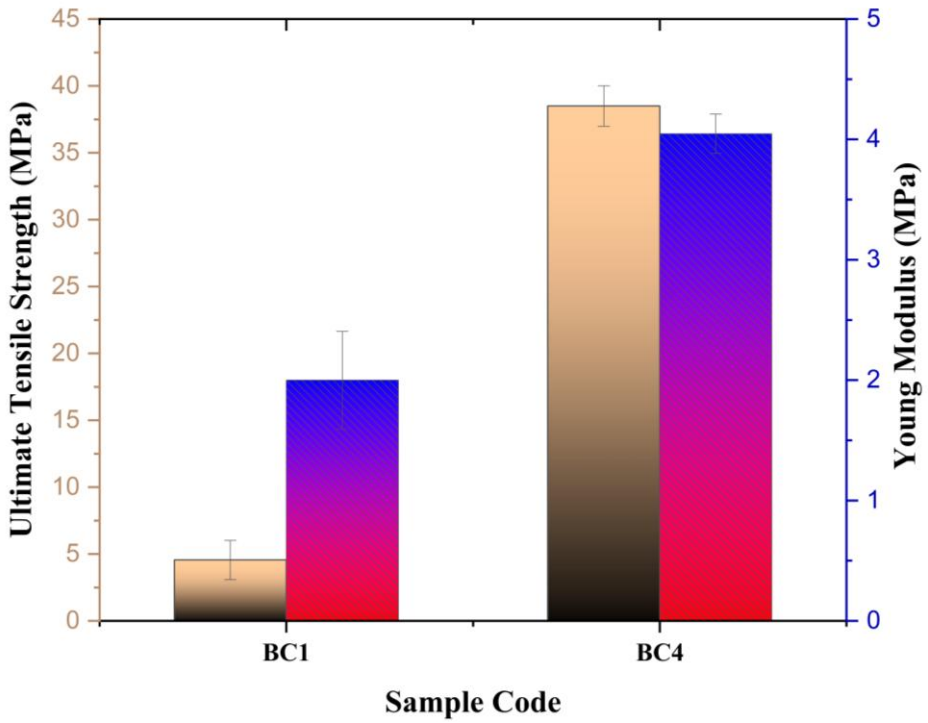

Figure 3: Ultimate tensile strength and Young's modulus of the samples

3.3 Morphological Analysis of the Pure PCL and PCL Biocomposite Scaffolds

The SEM images of the pure PCL and PCL biocomposite scaffolds are illustrated in Figure 4. No surface fractures and a uniform surface morphology were observed in the BC1 scaffold. Additionally, small pores formed as a result of chloroform evaporating during drying were observed. The results are consistent with the research of Adamu et al. (2024), which claimed that the evaporation of chloroform during drying leaves tiny pores in the unreinforced PCL scaffold. The surface of sample BC4 was smoother and more compact, suggesting that the reinforcing agents were evenly distributed throughout the PCL matrix. This could have strengthened the polymer chain, improving the mechanical characteristics, as observed in Figures 3 and 4. According to Matsumoto (2024), the polymer chain is influenced by the surface characteristics and behaviour of the polymer. The physical and mechanical qualities might be impacted by a smooth, compacted surface that limits the mobility of the polymer chains. Additionally, there was a white, bright granule on the surface, indicating that HAp/Sr particles were present in the polymer matrix.

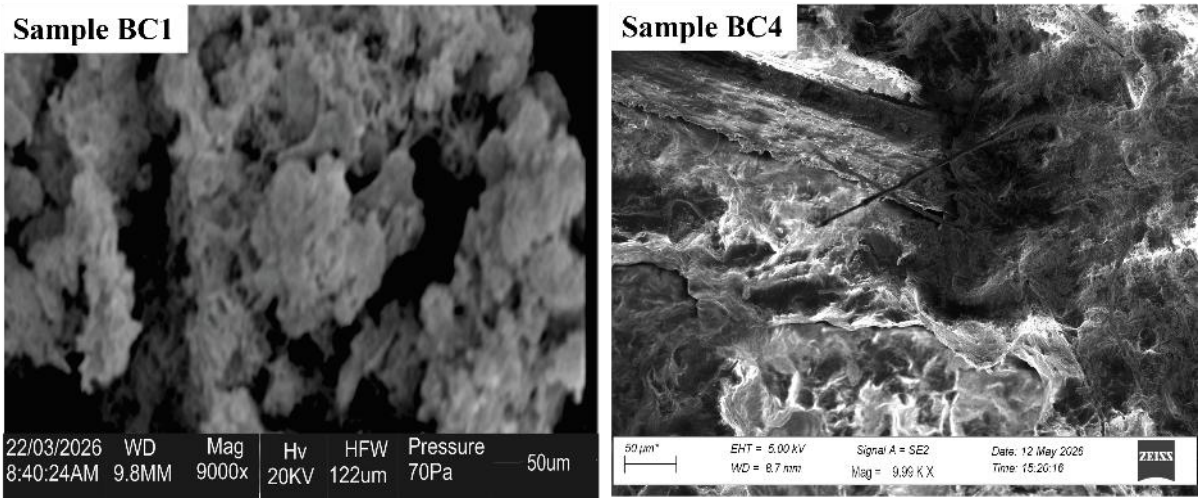

Figure 4: SEM images of the samples

3.0 CONCLUSION

The study demonstrated the successful improvement of the mechanical properties of PCL biopolymer-based composites through material modification. The FTIR spectra show C-H asymmetric stretching vibrations at 2947 and 2865 cm^{-1}, characteristic of polycaprolactone. The addition of reinforcing agents (PLA, HAp/Sr and keratin fibre) resulted in no new peaks, suggesting the materials were properly integrated into the PCL. There is a significant improvement in the mechanical performance resulting from the incorporation of PLA, keratin fibres, and bioactive fillers such as hydroxyapatite and strontium. Sample BC4, which comprises the three reinforcements, exhibited a significant increase in the mechanical properties when compared to BC1. For instance, the addition of the reinforcing agents increases the hardness and fracture toughness by 60.4% and 46.3%, respectively. Also, the tensile strength increased by 88.1%, while the Young's modulus increased by 50.6%. This enhancement is attributed to efficient stress transfer and improved interfacial bonding between the polymer matrix and reinforcing phases. Also, the improvement in both tensile strength and fracture resistance indicates that the developed biocomposites overcome the main limitation of pure PCL, achieving a more balanced combination of durability, toughness and stiffness. In conclusion, the sample BC4 had strong potential as a suitable material in bone repair and regeneration. The findings contribute to the ongoing development of high-performance biodegradable composites, while providing a foundation for further research on structural optimisation.

ABSTRACT

Nigeria's transition toward a sustainable, low-carbon energy system necessitates decentralized engineering solutions capable of converting abundant agricultural residues into clean, high-performance solid biofuels. This study presents a comparative experimental evaluation of solid biofuels engineered from maize straw, rice straw, wheat straw, and selected binary blends, characterized across 18 distinct formulations using cassava starch, Gum Arabic, and coal tar as binders under compaction pressures of 5 and 10 MPa. Characterization included higher heating value (HHV), ash content, moisture content, compressive strength, ignition time, burning rate, and water resistance index (WRI). Two-way Analysis of Variance (ANOVA) and Pearson correlation analyses demonstrated that biomass composition is the primary determinant of thermal behavior and ash characteristics. The 50:50 maize–wheat straw blend bonded with coal tar at 5 MPa (5M5Wc5) recorded the highest HHV (20.5 MJ kg^{-1}), the shortest ignition time (10 s), and a relatively low ash content (7.0%). The highest compressive strength was recorded by the Gum Arabic-bonded wheat straw formulation Wg5 (206.9 kN m^{-2}). Across the full dataset, ash content was negatively associated with HHV ($r = -0.696$), whereas the correlation between compressive strength and WRI is also negative at $r = -0.29$. In Phase II, exploratory two-way ANOVA without replication indicated a statistically significant main effect of compaction pressure on moisture content ($p = 0.0017$), but not on compressive strength ($p = 0.6175$); interaction effects could not be independently estimated. The results demonstrate application-specific trade-offs among thermal performance, mechanical integrity, moisture resistance, and environmental considerations. By converting agricultural residues into value-added solid fuels, the study supports resource recovery and circular-bioeconomy pathways while providing an engineering basis for decentralized biomass-energy systems in Nigeria.

1. INTRODUCTION

The global transition towards low-carbon energy systems has accelerated efforts to diversify renewable energy portfolios, improve energy security, and reduce greenhouse gas emissions in line with the Paris Agreement and the United Nations Sustainable Development Goals (SDGs). Sustainable bioenergy remains a critical component of the global energy transition because it provides dispatchable renewable energy, supports waste valorization, and contributes to decarbonizing sectors that are difficult to electrify, such as hard-to-electrify thermal applications. Modern bioenergy applications are increasingly viewed as complementary to solar and wind power within integrated renewable energy systems (IPCC, 2022).

Nigeria's growing population, rapid industrialization, and increasing demand for reliable, affordable, and sustainable energy have intensified the need for engineering solutions that address energy security, economic development, and climate change mitigation. Despite abundant renewable energy resources, energy poverty remains a major national challenge, motivating the development of innovative technologies that support both universal energy access and long-term decarbonization (International Energy Agency [IEA], 2025; Nigeria Energy Transition Plan [NETP], 2022). The Nigeria Energy Transition Plan establishes a national pathway towards net-zero emissions by 2060

while prioritizing energy access, clean cooking, industrial development, and renewable energy diversification (Nigeria Energy Transition Plan [NETP], 2022).

Within the cooking sector, the ETP identifies the transition away from traditional firewood and charcoal towards cleaner fuels—including modern biofuels, biogas, electricity, and other low-carbon cooking technologies—as a critical strategy for achieving Sustainable Development Goal 7 while reducing emissions and improving public health. The plan also recognizes the importance of developing local biofuel markets and supporting research and innovation for biomass conversion technologies, particularly in rural communities where biomass resources are abundant. Consequently, engineering innovations that convert agricultural residues into high-quality solid biofuels are increasingly recognized as essential components of sustainable energy systems, promoting resource efficiency, waste valorization, and circular bioeconomy strategies (Mujtaba et al. (2023); Sadh, et al., (2023)).

1.1 Engineering Variables Governing Biomass Briquette Performance

Among the various biomass conversion technologies, densification through briquetting has emerged as one of the most practical engineering solutions for upgrading low-density loose agricultural residues into high-quality uniform solid biofuels suitable for domestic, commercial, and industrial thermal applications. Briquetting substantially reduces volume, increases bulk density, and improves storage stability, handling characteristics, and transportation efficiency. It also improves fuel uniformity, enhances combustion characteristics, and produces fuels with improved mechanical integrity and more consistent energy performance (Grover & Mishra, 1996; Kaliyan & Morey, 2009; Tumuluru et al., 2011), with a potential for partially replacing traditional fuels such as firewood, charcoal, and coal in decentralized energy systems.

The quality of briquettes is governed by several interacting variables, including feedstock characteristics, particle size, moisture content, binder type and concentration, compaction pressure, and post-production drying conditions. These parameters influence important fuel quality indices such as calorific value, ash content, compressive strength, ignition behaviour, burning characteristics, and resistance to moisture (Tumuluru et al., 2011; Zhang et al., 2018). Agricultural residues differ considerably in their composition, ash-forming minerals, and natural binding characteristics; consequently, combining different feedstocks offers opportunities to exploit complementary material properties while minimizing the limitations associated with individual biomass resources. Likewise, binder selection determines the strength and durability of briquettes, whereas compaction pressure governs particle rearrangement, contact area, mechanical interlocking, and final briquette density (Sikarwar et al., 2016; Tumuluru et al., 2011).

1.2 Current Knowledge Gaps and Objectives

Although considerable progress has been made in biomass briquetting technology, existing studies have predominantly focused on individual agricultural residues, single binder systems, or isolated processing variables. Many investigations evaluate only one aspect of briquette production, such as calorific value, mechanical strength, or combustion performance, making direct comparison among studies difficult (Obi et al, 2022). Furthermore, relatively few studies (Walozi, et al, 2026) that systematically evaluated multi-variable interactions across multiple distinct processing phases within a single, harmonized experimental framework remains highly limited (Grover & Mishra, 1996; Kaliyan & Morey, 2009; Obi et al., 2022).

This study addresses these gaps by evaluating multiple biomass residues (maize straw, rice straw, wheat straw), several binder systems (cassava starch, Gum Arabic, coal tar), and different compaction pressures (5 and 10 MPa) within a harmonized experimental framework. By integrating these physical, thermal, mechanical, and combustion performance indicators within a single comparative framework, the study identifies the influence of biomass composition, binder characteristics, and densification conditions on briquette quality, providing practical recommendations for sustainable thermal energy production from agro-residues in Nigeria.

2. MATERIALS AND METHODS

The agro-residues investigated as feedstocks in this study comprised maize straw, rice straw, and wheat straw, selected because of their abundance as agricultural residues and their significant potential for renewable solid biofuel production. The residues were collected from agricultural farms around Samaru Zaria, and were cleaned manually to remove soil particles, stones, and other foreign materials. The cleaned residues were air-dried under ambient conditions to reduce their moisture content. The dried residues were chopped into smaller pieces and milled to obtain a relatively uniform particle size suitable for densification. The pulverized materials were sieved using a 2 mm mesh to ensure particle size uniformity and to minimize variability during compaction. The processed biomass materials were stored in airtight containers before briquette production to minimize moisture uptake from the environment. The overall process flow of feedstock preparation, briquetting, and characterization is shown in Figure 1.

2.1 Binder Preparation

Three binder materials with different binding characteristics were investigated, namely cassava starch, Gum Arabic, and coal tar. Cassava starch and Gum Arabic were selected as natural binders because of their availability and established adhesive properties (Ezechiel, 2022), whereas coal tar was included as a conventional binder for comparison of mechanical and combustion performance. The binders were prepared as follows (Plate 1):

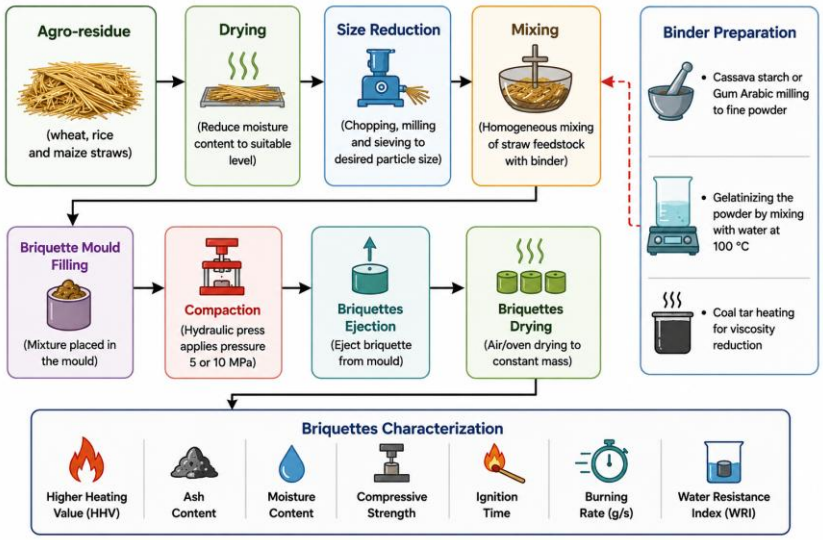

Figure 1: Block Flow Diagram of the Study

1. Cassava Starch Binder: Prepared by dispersing starch powder in water followed by heating with continuous stirring until gelatinization occurred at a temperature of 100 °C, producing a homogeneous adhesive paste. This temperature disrupts the intermolecular bonds, creating hydrogen-bonding networks. After cooking, the binder was allowed to cool for 45 minutes before use.
2. Gum Arabic Binder: Prepared by dissolving small quantities at a time in water that was boiled to 100 °C and allowed to cool to approximately 90 °C to obtain a uniform adhesive solution.
3. Coal Tar Binder: Heated to reduce its viscosity and then allowed to cool to ambient conditions before mixing directly as a binder.

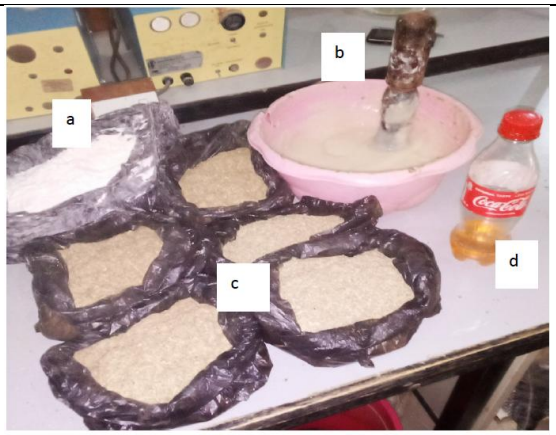

Plate 1: (a) Cassava Starch (b) Starch binder (c) Prepared agro-residues (d) lubricant (oil)

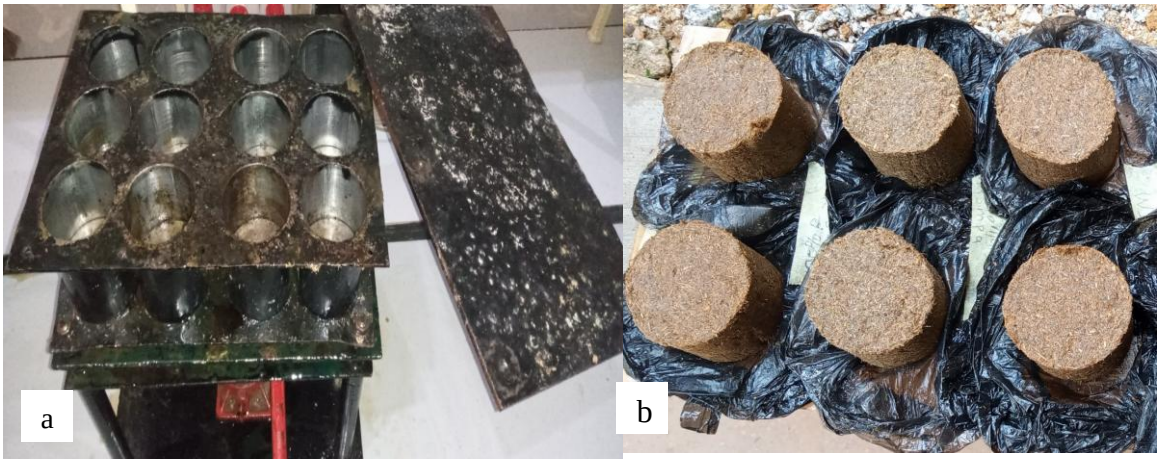

Plate 2: (a) Cylindrical Steel Mould (b) Briquettes (Densified biomass)

2.2 Experimental Design Matrix

A comparative experimental approach was adopted to evaluate the effects of biomass composition, binder characteristics, and compaction pressure on briquette fuel quality. The investigation consisted of two complementary experimental phases as detailed in Table 1.

Table 1: Experimental Design Matrix

S/N	Phase	Sample Code	Feedstock Composition	Blend Ratio (% w/w)	Binder Type	Compaction Pressure (MPa)
1	I	Mg5	Maize straw	100:0	Gum Arabic	5
2	I	Mc5	Maize straw	100:0	Coal tar	5
3	I	Ms5	Maize straw	100:0	Starch	5
4	I	Wg5	Wheat straw	100:0	Gum Arabic	5
5	I	Wc5	Wheat straw	100:0	Coal tar	5
6	I	Ws5	Wheat straw	100:0	Starch	5
7	I	5M5Wg5	Maize straw + Wheat straw	50:50	Gum Arabic	5
8	I	5M5Wc5	Maize straw + Wheat straw	50:50	Coal tar	5
9	I	5M5Ws5	Maize straw + Wheat straw	50:50	Starch	5
10	II	Rs5	Rice straw	100:0	Starch	5
11	II	5R5Ms5	Rice straw + Maize straw	50:50	Starch	5
12	II	7R3Ms5	Rice straw + Maize straw	70:30	Starch	5
13	II	3R7Ms5	Rice straw + Maize straw	30:70	Starch	5
14	II	Rs10	Rice straw	100:0	Starch	10
15	II	Ms10	Maize straw	100:0	Starch	10
16	II	5R5Ms10	Rice straw + Maize straw	50:50	Starch	10
17	II	7R3Ms10	Rice straw + Maize straw	70:30	Starch	10
18	II	3R7Ms10	Rice straw + Maize straw	30:70	Starch	10

In the first phase (I), briquettes were produced from maize straw (M), wheat straw (W), and a 50:50 maize–wheat (5M5W) blend using three binder materials (Gum Arabic, coal tar, and cassava starch) under a compaction pressure of 5 MPa.

In the second phase (II), the influence of biomass composition and compaction pressure was investigated using rice straw, maize straw, and their binary blends (50:50, 70:30, and 30:70 ratios) bonded with cassava starch under compaction pressures of 5 MPa and 10 MPa, resulting in 18 distinct formulations (S/N 1-18).

2.3 Characterization Methods

Measured quantities of the prepared biomass feedstocks were thoroughly mixed with the appropriate binder to obtain homogeneous mixtures (Figure 1). The mixtures were fed into a lubricated cylindrical steel mould and compacted using a hydraulic briquetting press operating at the designated pressure (5 or 10 MPa). The compacted briquettes were ejected and air-dried under ambient laboratory conditions until constant mass was attained. Properties of interest were determined in accordance with standard ASTM protocols where applicable (Table 2).

Table 2: Standard Methods Adopted for Characterization

Property	Adopted Procedure/ Method	Description	References
HHV	ASTM D5865/ D5865M -19	Gross calorific value determination using an adiabatic bomb calorimeter.	ASTM International (2019)
Ash Content	ASTM E1755 -24	Ash determination by complete combustion of oven-dried biomass at 575 ± 25 °C.	ASTM International (2024b)
Moisture Content	ASTM E871 -24	Moisture content determination of particulate biomass by oven drying to constant mass.	ASTM International (2024a)
Compressive Strength	Adapted compression test (UTM)	Maximum compressive load sustained before physical failure using a Universal Testing Machine.	Obi et al. (2022)
Ignition Time	Experimental combustion method	Elapsed time from application of flame until sustained ignition is established.	Obi et al. (2022)
Burning Rate	Experimental combustion method	Measured mass loss per unit time (g/s) during active combustion.	Olugbade et al. (2019); Obi et al. (2022)
WRI	Water immersion method	Time elapsed to complete structural dissolution upon immersion in water.	Obi et al. (2022)

2.4 Statistical Methodology

The experimental data were analysed using two-way ANOVA without replication to provide an exploratory assessment of main-factor effects. Because only one observation was available for each factor combination, interaction effects could not be independently estimated and may be confounded with the residual term. Consequently, the resulting p-values should be interpreted as exploratory evidence of main effects under an additive-model assumption. For Phase I, the additive model evaluated Biomass Feedstock (Maize, Wheat, 50:50 blend) and Binder Type (Gum Arabic, coal tar, cassava starch) under a constant pressure of 5 MPa. For Phase II, an unbalanced Two-Way ANOVA was applied using Type II Sum of Squares to rigorously evaluate Rice-Maize blend ratios and compaction pressures (5 MPa vs 10 MPa) without factor-ordering bias

Pearson correlation analysis was executed on the complete 18-sample dataset to determine linear relationship coefficients (r) between all physical, thermal, and mechanical properties. The statistical significance threshold was set at alpha = 0.05.

3. RESULTS AND DISCUSSION

3.1 General Briquette Performance

The physical, thermal, and mechanical properties of the 18 formulations are summarized in Table 3. The results show that the Higher Heating Value (HHV) varied substantially, ranging from 14.1 to 20.5 MJ/kg, but is comparable to standard solid biofuels. The moisture contents however, ranged from 21.4% to 34.4%, which significantly exceed the commercial solid biofuel standard of <15%. This indicates that the passive post-production ambient air-drying alone is insufficient. According to the international standard ISO 17225-7:2021 (ISO, 2021), the maximum moisture content of ≤ 15% is necessary for commercial graded non-woody briquettes, to prevent physical

degradation, mold growth, and ignition delay during storage (ISO, 2021; Obi et al., 2022). Under the high relative humidity (RH) conditions typical of the study location, Zaria (RH from 36%–46% in dry season, to 82%–88% during the wet season (Yusuf & Shuaib, 2012)), the rate of air-drying limits water removal from the briquettes produced, thus requiring active thermal interventions.

Engineering Drying Process Recommendations: To bring the engineered briquettes to the standard non-woody biofuels moisture content within the ISO-compliant threshold (<15%), a controlled thermal drying stage – like a convective kiln-drying system operating at 60 °C to 80 °C for 12 to 18 hours is proposed (Obi et al., 2022). Maintaining the drying temperature below 100 °C is critical, to avoid damaging the cassava starch binder, as higher temperatures initiate the thermal decomposition and depolymerization of the starch adhesive, which collapses the solid-bridge molecular networks and severely weakens dry compressive strength (Tumuluru et al., 2011; Obi et al., 2022). From an engineering perspective, this active thermal drying carries a substantial energy penalty, as convective air dryers typically consume between 2.4 and 4.5 MJ of thermal energy per kg of water evaporated (Đurdević et al., 2021; Tumuluru et al., 2011).

Table 3: General Characterization Results of Densified Biofuels

S/N	Sample ID	Binder	HHV (MJ/kg)	Ash Content (%)	Moisture Content (%)	Ignition Time (s)	Burning rate (g/s)	Compressive Strength (kN/m²)	WRI (min)
1	Mg5	Gum Arabic	17.3	6.1	28.87	14.0	0.22	195.4	15.0
2	Mc5	Coal tar	19.3	5.2	29.99	12.0	0.17	146.6	2.0
3	Ms5	Starch	18.0	5.8	26.83	15.0	0.24	181.0	2.7
4	Wg5	Gum Arabic	15.7	10.3	31.99	15.0	0.20	206.9	10.0
5	Wc5	Coal tar	16.2	9.2	32.51	17.0	0.23	172.4	7.5
6	Ws5	Starch	15.9	9.7	30.57	20.0	0.27	192.5	5.0
7	5M5Wg5	Gum Arabic	18.2	7.9	29.30	13.0	0.21	201.1	6.0
8	5M5Wc5	Coal tar	20.5	7.0	28.07	10.0	0.15	189.7	6.0
9	5M5Ws5	Starch	19.5	7.6	26.17	15.0	0.25	169.5	3.3

11	5R5Ms5	Starch	14.7	9.5	31.70	17.0	0.20	192.3	5.0
12	7R3Ms5	Starch	14.7	13.9	33.60	15.0	0.23	176.7	6.0
13	3R7Ms5	Starch	14.4	9.1	34.40	11.0	0.17	184.5	3.8
14	Rs10	Starch	14.1	8.6	21.40	14.0	0.27	153.3	15.0
15	Ms10	Starch	17.7	8.2	25.70	10.0	0.20	122.5	2.0
16	5R5Ms10	Starch	14.2	12.8	25.10	18.0	0.23	197.5	7.5
17	7R3Ms10	Starch	15.8	10.7	25.10	14.0	0.23	148.5	6.0
18	3R7Ms10	Starch	14.9	9.1	24.40	12.0	0.17	187.1	3.3

To preserve a positive net energy ratio for the process, waste heat recovered from industrial boiler exhausts or waste heat recovery from the hydraulic briquetting machinery. Alternatively, incorporating solar-assisted convective tunnel dryers operating at 36.5–65 °C for 24 to 36 hours offers a highly viable, low-cost, decentralized engineering solution (Đurdević et al., 2021; Guibunda et al., 2026; Tumuluru et al., 2011).

3.2 Influence of Biomass Composition on Fuel Properties

The primary feedstock composition exerted a dominant role across both experimental phases. The agro-residues have distinct ash profiles and cellular arrangements, dictating their energy density and mechanical interlocking limits. ANOVA tests were completed for all seven response variables, and their exact results are tabulated below in Table 4 and Table 5.

Table 4: Phase I ANOVA Table (Biomass Feedstock & Binder Type under 5 MPa)

Property	Factor Source	Sum of Sq. (SS)	Degrees of freedom (df)	F-Statistic	p-value	Significance
HHV (MJ/kg)	Feedstock	18.5960	2	37.2740	0.0026	Highly Significant ($p < 0.01$)
	Binder	3.8490	2	7.7150	0.0424	Significant ($p < 0.05$)
	Residual	0.9980	4	-	-	-
Ash Content (%)	Feedstock	24.4960	2	1574.714	< 0.0001	Extremely Significant ($p < 0.001$)
	Binder	1.4160	2	91.0000	0.0005	Extremely Significant ($p < 0.001$)
	Residual	0.0310	4	-	-	-
Moisture Content (%)	Feedstock	25.0610	2	27.3070	0.0047	Highly Significant ($p < 0.01$)
	Binder	10.2880	2	11.2110	0.0229	Significant ($p < 0.05$)
	Residual	1.8350	4	-	-	-
Ignition time (s)	Feedstock	36.2222	2	8.5790	0.0357	Significant ($p < 0.05$)
	Binder	21.5556	2	5.1053	0.0792	Marginally Significant
	Residual	-	-	-	-	
Burning rate	Feedstock	0.0015	2	1.1261	0.4093	Not Significant
	Binder	0.0075	2	5.6639	0.0681	Marginally Significant
	Residual	-	-	-	-	
Compressive Strength (kN/m^2)	Feedstock	433.8870	2	1.0360	0.4340	Not Significant
	Binder	1532.5270	2	3.6590	0.1249	Not Significant
	Residual	837.5870	4	-	-	-
WRI	Feedstock	8.7822	2	0.3451	0.7273	Not Significant
	Binder	73.3889	2	2.8838	0.1677	Not Significant
	Residual	-	-	-	-	

Note: residual df = 4 for each property; residual terms are omitted for compactness. Interaction effects are not separately estimable in this unreplicated design

3.2.1 Thermal and Fuel Properties (Phase I ANOVA Evaluation)

The Phase I Two-Way ANOVA established that biomass feedstock selection is a statistically significant driver of HHV ($p = 0.0026$), Ash Content ($p < 0.0001$), and Moisture Content ($p = 0.0047$). Pure maize straw briquettes achieved lower ash contents (5.2%–6.1%) and higher heating values (17.3–19.3 MJ/kg) compared to pure wheat straw, which was penalized by elevated ash (9.2%–10.3%) and lower HHV (15.7–15.9 MJ/kg). Blending these residues in a 50:50 ratio (5M5W series) successfully moderated the high ash penalty of wheat straw (reducing ash to 7.0%–7.9%) while

preserving an attractive HHV (18.2–20.5 MJ/kg). This highlights biomass blending as a primary fuel optimization strategy.

3.2.2 Combustion characteristics (Phase I)

Feedstock selection exerted a significant effect on ignition time ($p = 0.0357$). Pure maize straw briquettes ignited more rapidly (avg. 13.7 s) than pure wheat straw briquettes (avg. 17.3 s). This difference is attributed to ash composition: the higher inorganic mineral fractions (such as silica) in wheat straw act as a thermal barrier during heating, absorbing heat without decomposing, which delays the temperature rise necessary for volatilization and ignition.

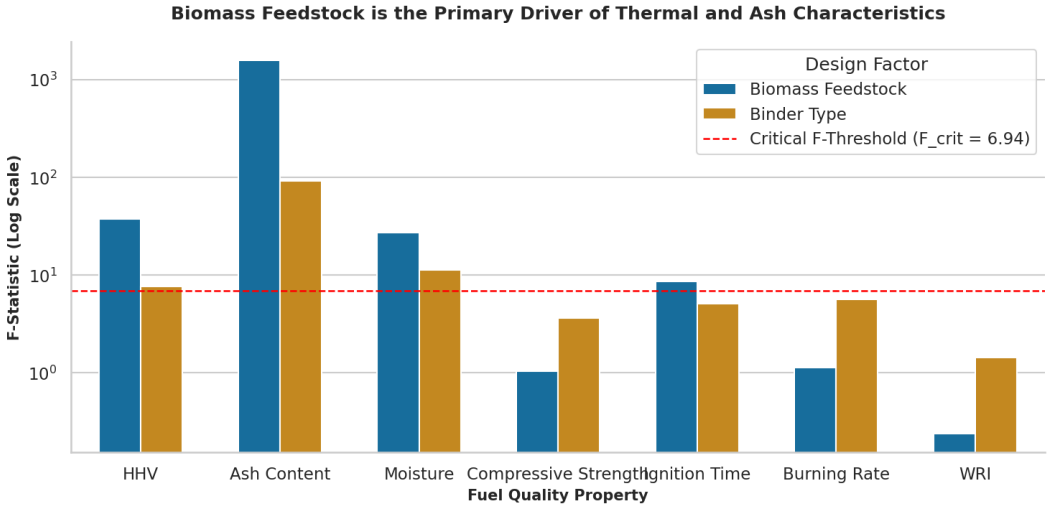

Figure 2: Phase I ANOVA F-statistics showing feedstock and binder type significance across properties relative to critical F-threshold (6.94).

3.3 Influence of Binder Characteristics on Biofuel Quality

Binder type significantly influenced HHV ($p = 0.0424$) and Ash Content ($p = 0.0005$). Natural binders (cassava starch and Gum Arabic) produced intermediate heating values ranging from 15.7 to 19.5 MJ/kg, demonstrating respectable thermal properties and structural interlocking. Gum Arabic produced the highest structural and moisture resistance, achieving a peak compressive strength of 206.9 kN/m² in sample Wg5 (wheat straw, Gum Arabic binder). Cassava starch still provided solid structural integrity, reaching up to 192.5 kN/m² for Ws5 (wheat straw, cassava starch binder). Coal tar binders consistently achieved the highest calorific values—peaking at 20.5 MJ/kg in 5M5Wc5—and the fastest ignition times (10.0 s) due to their high carbon and volatile density. However, the coal tar's origin related to fossil fuels, is a cause for environmental concerns.

3.3.1 Environmental and Sustainability Trade-off of Coal Tar Binder

Although coal tar binder maximizes calorific performance (reaching a peak of 20.5 MJ/kg in 5M5Wc5) and ignition rates, its petroleum/coal origin represents a non-renewable application barrier, because it directly conflicts with clean cooking and environmental goals highlighted in Nigeria's Energy Transition Plan (NETP, 2022). Coal tar is a carbonization byproduct most likely containing carcinogenic polycyclic aromatic hydrocarbons, PAHs (such as Benzo[a]pyrene) in high concentrations (IARC, 2012), which are released upon combustion, along with heavy particulate smoke (Liu et al., 2008; WHO, 2010).

In contrast, cassava starch and Gum Arabic are renewable, non-toxic, and locally available, representing environmentally safe binders for domestic cookstove markets despite slightly lower heating values. This makes cassava starch and Gum Arabic the only sustainable, socially responsible choices of binders for briquetting especially for household combustion applications, where toxic emission control measures are difficult to implement.

3.3.3 Mechanical and Storage Properties

Binder selection governed briquette physical stability. Gum Arabic produced the highest structural and moisture resistance. The binder type was also found to govern physical storability. Gum Arabic generated superior resistance to moisture degradation and produced briquettes with the greatest resistance to water, maintaining structural integrity for 15 min while coal tar-bonded briquettes yielded the lowest. Gum Arabic produced high compressive strength in selected formulations, whereas resistance to water-induced degradation varied among individual briquette formulations. Consequently, dry mechanical strength and water resistance should be evaluated as distinct aspects of briquette storage performance

3.4 Influence of Compaction Pressure and the "Springback" Effect

3.4.1 Compaction Pressure Effect on Moisture

Phase II of the study indicated a statistically significant (Table 5) exploratory main effect of compaction pressure on moisture content ($p = 0.0017$), with the 10 MPa formulations generally exhibiting lower moisture values than the 5 MPa formulations (Figure 3).

Table 5: Phase II ANOVA Table (Feedstock Blend & Compaction Pressure)

Property	Factor Source	Sum of Sq. (SS)	Degrees of freedom (df)	F-Statistic	p-value	Significance
HHV (MJ/kg)	Feedstock Blend	8.0060	4	6.8720	0.0726	Marginally Significant ($p < 0.10$)
	Pressure	0.0610	1	0.2100	0.6777	Not Significant
	Residual	0.8740	3	-	-	-
Ash Content (%)	Feedstock Blend	20.3420	4	1.4350	0.3993	Not Significant
	Pressure	0.0110	1	0.0030	0.9586	Not Significant
	Residual	10.6340	3	-	-	-
Moisture Content (%)	Feedstock Blend	14.1160	4	2.7120	0.2193	Not Significant
	Pressure	154.0010	1	118.3490	0.0017	Extremely Significant
	Residual	3.9040	3	-	-	-
Ignition Time	Feedstock Blend	61.5750	4	2.8203	0.2104	Not Significant
	Pressure	3.1250	1	0.5725	0.5043	Not Significant
	Residual	-	-	-	-	
Burning rate	Feedstock Blend	0.0074	4	8.7500	0.0528	Marginally Significant
	Pressure	0.0006	1	2.8824	0.1881	Not Significant
	Residual	-	-	-	-	
Compressive Strength (kN/m^2)	Feedstock Blend	8250.8620	4	2.8970	0.2043	Not Significant
	Pressure	219.4510	1	0.3080	0.6175	Not Significant
	Residual	2135.7140	3	-	-	
WRI	Feedstock Blend	115.7070	4	9.0161	0.0508	Marginally Significant
	Pressure	6.1250	1	1.9091	0.2610	Not Significant
	Residual	-	-	-	-	

Note: Residual df = 3 for each property. The unbalanced Phase II design and absence of replication require cautious interpretation.

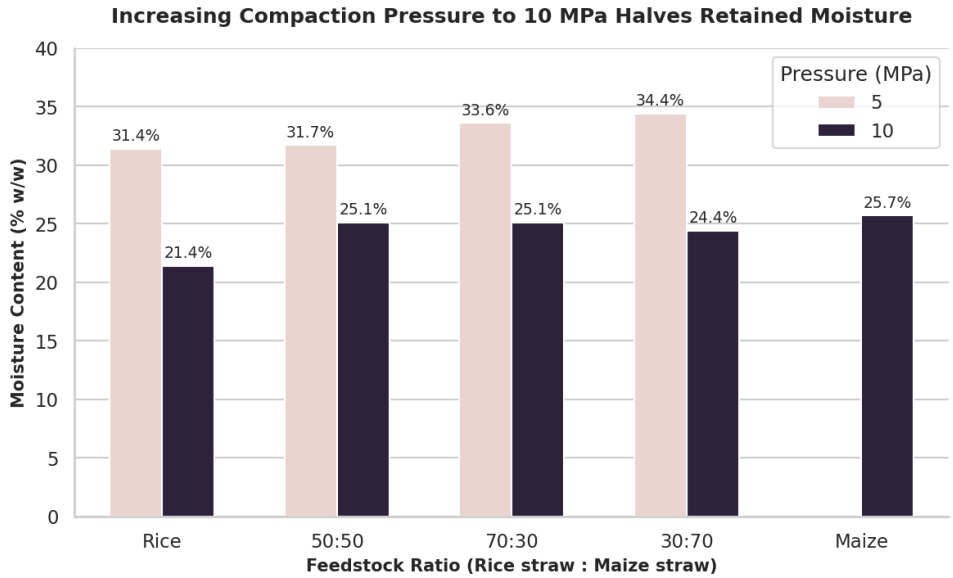

Figure 3: Effect of compaction pressure on moisture content reduction across rice-maize feedstock blend ratios in Phase II

Compaction pressure did not show a statistically significant main effect on compressive strength ($p = 0.6175$) within the limitations of the unreplicated and unbalanced design. This absence of statistical evidence should not be interpreted as proof of a specific physical mechanism. Elastic recovery or springback after ejection is a plausible explanation discussed in biomass-densification literature, but dimensional recovery, internal cracking, and post-ejection expansion were not measured in this study. Springback is therefore treated as a literature-supported hypothesis rather than an experimentally demonstrated mechanism. Doubling compaction pressure from 5 to 10 MPa compacted the particles, forcing out moisture and lowering retained moisture levels from 31.4%–34.4% down to 21.4%–25.7%. However, these values remain above the ideal bioenergy range (<15%), reinforcing the need for active drying protocols as discussed in section 3.1.

3.4.2 Compressive Strength "Springback" Anomaly

Compaction pressure had no statistically significant effect on dry Compressive Strength ($p = 0.6175$, $F = 0.31$). Standard biomass densification theory dictates that higher pressure improves consolidation and strength. However, the data shows highly inconsistent changes; for example, pure maize straw (Ms10) and the 70:30 rice-maize blend (7R3Ms10) actually showed decreased compressive strength at 10 MPa compared to their 5 MPa counterparts.

This statistical insignificance ($p = 0.6175$) does not mathematically establish but is highly consistent with the hypothesis of an elastic recovery or 'springback' phenomenon typical of unheated agricultural crop residues. Because briquetting in the present study was conducted without external heating, thermal softening and flow of natural lignin were likely limited relative to heated densification processes (Kaliyan & Morey, 2009; Tumuluru et al., 2011). Highly elastic straw fibers compress under mechanical pressure but store substantial internal elastic strain energy. Upon ejection from the mould, this stored energy is released, causing immediate physical expansion. Elastic recovery or springback after briquette ejection is a plausible mechanism that may contribute to the absence of a detectable pressure effect on compressive strength. However, dimensional recovery, internal cracking and microstructural changes were not measured in the present study.

Pearson correlations (Table 6) calculated across the authoritative 18-formulation dataset showed a strong negative association between ash content and HHV ($r = -0.7$). This pattern is consistent with the observed tendency for formulations with higher inorganic residue to have lower gross energy content. HHV was also negatively associated with ignition time ($r = -0.45$), while ignition time and burning rate were positively associated ($r = 0.67$). In contrast, compressive strength and WRI showed a negligible pooled association ($r = -0.29$).

3.5 Multivariate Trade-offs and Pearson Correlation Insights

To guide solid biofuel design, the physical trade-offs must be analyzed among thermal performance, mechanical strength, and storability. For example, Gum Arabic produced high compressive strength in selected formulations, while water resistance varied substantially among formulations. Pearson correlation coefficients calculated from the verified 18-sample dataset reveal several key thermodynamic and mechanical relationships (Table 6):

1. Ash Content vs. HHV (r = -0.70): A strong negative correlation that mathematically validates the thermodynamic penalty of inorganic residues. Inorganic minerals (silica, etc.) do not burn, physically diluting the carbon-rich organic fraction per unit mass.
2. Compressive Strength vs. WRI (r = -0.29): Indicates a mechanical design conflict. High dry compressive strength (interlocking film bonds) tends to show lower wet water resistance (WRI), proving that dry mechanical integrity and wet moisture stability operate through different chemical mechanisms.

Table 6: Pearson Correlation Matrix of Briquette Properties

Property	HHV	Ash Content	Moisture Content	Ignition Time	Burning Rate	Compressive Strength	WRI
HHV	1.00	**-0.70**	-0.10	-0.45	-0.28	0.04	-0.15
Ash Content	**-0.70**	1.00	0.16	0.38	0.24	0.12	0.01
Moisture Content	-0.10	0.16	1.00	0.22	-0.24	0.15	-0.05

4. CONCLUSION

This study presented a comparative experimental evaluation of solid biofuels produced from maize, wheat, and rice straws and their binary blends, characterized across 18 distinct formulations under compaction pressures of 5 and 10 MPa. The experimental and statistical results establish that:

- **Feedstock Blending Synergy:** Biomass composition is the primary determinant of combustion characteristics and ash behavior. While pure wheat and rice straw are penalized by high ash contents of up to 10.3% and 13.9% respectively, a 50:50 maize–wheat blend successfully buffers this ash penalty (reducing it to 7.0%–7.9%) while maintaining a high heating value between 18.2 and 20.5 MJ/kg.
- **Optimal Thermal Performance:** The 50:50 maize–wheat straw blend bonded with coal tar at 5 MPa (5M5Wc5) is the optimal thermal formulation, yielding the highest Higher Heating Value (20.5 MJ/kg), the shortest ignition time (10 s), and low ash content (7.0%).
- **Binder Governance and Sustainability:** Binders dictate mechanical durability and water resistance during storage. Gum Arabic produced high compressive strength in selected formulations, while water-resistance behaviour varied among formulations, whereas cassava starch serves as a vital green, renewable, and biodegradable alternative. Coal tar maximizes combustion characteristics but introduces severe environmental and toxicological trade-offs.
- **Pressure Limitations and Springback:** Doubling compaction pressure from 5 to 10 MPa systematically consolidates particles—reducing retained moisture from 31.4%–34.4% to 21.4%–25.7% across all formulations. The limited improvement in compressive strength at higher pressure may reflect elastic recovery effects, although this mechanism requires direct dimensional and microstructural measurements for confirmation.

In summary, high-performance solid biofuel design requires balancing thermal efficiency, mechanical durability, and storage stability rather than optimizing for a single metric. Managing these trade-offs through targeted biomass blending and binder selection offers a practical pathway for decentralized waste valorization to support Nigeria's clean energy transition.

ABSTRACT
Asphalt pavements absorb substantial amounts of solar heat, much of which remains unutilized despite its potential for renewable electricity generation through thermoelectric generators (TEGs), making the enhancement of asphalt thermal properties essential for improving temperature gradients and energy harvesting efficiency. This study evaluates the use of steel slag, an industrial by-product, as a partial replacement for natural coarse aggregates to enhance the thermal performance of asphalt concrete, with mixtures designed using the Marshall Mix method at steel slag replacement levels ranging from 0% to 25%. Laboratory tests measuring thermal conductivity, specific heat capacity, and thermal diffusivity were performed and evaluated using a three-dimensional transient heat transfer model in Abaqus, and the Marshall properties were evaluated against the applicable ASTM D6927 criteria, resulting in an optimum binder content of 6.0%. The results show that the incorporation of steel slag influenced the thermal properties of the asphalt concrete. Among the mixtures investigated, the 5% steel slag replacement produced the highest thermal conductivity of 3.0421 W/m·K and the lowest specific heat capacity of 794.5 J/kg·K. It also recorded the highest thermal diffusivity of 1.58 × 10⁻⁶ m²/s. These findings suggest that a limited proportion of steel slag, particularly at 5% replacement, can improve the thermal response of asphalt concrete. The enhanced thermal properties may provide favourable conditions for future application in pavement-integrated thermoelectric energy harvesting systems. However, the present study focused on the thermal characteristics of the asphalt mixtures, and direct integration of thermoelectric generators (TEGs) and measurement of electrical power output were not undertaken.

Keywords: *Asphalt concrete; thermoelectric generators; energy harvesting; thermal properties; steel slag; 3D finite element*

1. INTRODUCTION

Nigeria continues to face challenges in providing reliable and affordable electricity, with significant dependence on fossil fuels for buildings, industries, and infrastructure. Rising energy costs and inadequate power supply have increased the need for sustainable renewable energy alternatives. Asphalt pavements, which dominate urban road networks, absorb substantial solar radiation due to their dark surfaces and can reach temperatures of up to 70 °C Chen et al., (2009). Although this heat contributes to the Urban Heat Island (UHI**)** effect and can accelerate pavement deterioration, it also represents a potential source of renewable thermal energy.

The rapid growth of urbanization and Information and Communication Technology (ICT) has encouraged the development of smart cities, integrating intelligent infrastructure to improve efficiency, safety, and sustainability (Marsal-Llacuna et al., 2015). One emerging technology is the integration of thermoelectric generators (TEGs**)** into pavement structures to convert temperature gradients into electrical energy through the Seebeck effect (Jiang et al., 2017). Such energy can potentially support low-power applications, including street lighting, traffic signals, and infrastructure monitoring, while requiring relatively low maintenance (Islam & Tarefder, 2014).

The efficiency of pavement-based thermoelectric energy harvesting depends largely on the temperature gradient and heat transfer within the pavement. Therefore, enhancing the thermal conductivity of asphalt concrete is important for improving heat transfer and maximizing TEG performance (J. Chen et al., 2015). Recent studies have investigated industrial and recycled materials,

including steel slag, crumb rubber, and recycled aggregates, as alternatives for improving asphalt pavement performance Hasita et al., 2020; Ding et al., 2019.

Among these materials, steel slag has attracted considerable interest because of its availability and favourable mechanical and thermal properties (Rondón-Quintana et al., 2018; Sabapathy et al., 2017). Its incorporation into asphalt mixtures has been reported to improve mechanical strength, fatigue performance, and thermal characteristics (Hainin et al., 2014; Kavussi et al., 2015; Fang et al., 2013).

Accordingly, this study investigates the use of steel slag as a partial replacement for conventional coarse aggregate in asphalt concrete, with particular emphasis on its effects on thermal conductivity, specific heat capacity, and thermal diffusivity. The thermal response of the modified asphalt mixtures is further evaluated using three-dimensional finite element analysis in Abaqus. The study focuses on characterizing the thermal behavior of the mixtures and assessing their potential for future application in pavement-integrated thermoelectric energy harvesting systems. Direct integration of thermoelectric generators and evaluation of their electrical performance are beyond the scope of the present study.

2. MATERIALS AND METHODS

2.1 Materials

The materials used in this study comprised asphalt binder, natural limestone aggregates, and steel slag. The asphalt binder and natural aggregates were sourced locally within Kano State, Nigeria, while the steel slag was obtained from a rolling steel mill in Katsina State. The binder was characterized using standard consistency tests to determine its suitability for high-performance asphalt pavement applications. The natural aggregate was limestone with a nominal maximum particle size of 20 mm, and its physical and mechanical properties were evaluated in accordance with relevant standard specifications.

The steel slag was obtained from an electric arc furnace and air-aged for a minimum of 12 months prior to use to minimize potential volumetric expansion associated with free lime (CaO) and magnesia (MgO). The steel slag was subjected to the same physical and mechanical characterization tests as the natural aggregate to facilitate direct comparison and assess its suitability as a partial replacement for conventional coarse aggregate in asphalt mixtures.

Table 2.1: Physical properties of natural aggregate and steel slag.

PROPERTY	**UNIT**	**VALUE**	**REQUIREMENT**
Penetration (25^{o}C,100g,5s)	0.1mm	60.19	60-80
Softening Point	^{o}C	47	≥45
Flash Point	^{o}C	273	≥260
Fire point	^{o}C	281	
Density	g/cm^{3}	1.03	___

The results presented in Table 2.1 indicate that steel slag possesses superior mechanical properties compared with natural limestone aggregate, particularly in terms of strength, wear resistance,

and bulk density. These characteristics suggest its potential to improve the structural integrity and deformation resistance of asphalt mixtures when used as a partial coarse aggregate replacement. The bitumen properties presented in Table 2.2 show a penetration value of 60.17, corresponding to a 60/70 penetration grade, with flash and fire points of 273 °C and 281 °C, respectively. These results indicate adequate binder consistency and thermal stability, confirming its suitability for asphalt mixture production.

Table 2.2: Physical properties of bitumen

PROPERTY	Density	Water Absorption %	Crushing Value %	Impact Value %	Abrasion Value %	Flakiness & Elongation %
LIMESTONE	2.69	1.08	15.6	7.7	23	7.5
STEEL SLAG	3.5	1.29	12.1	14.5	13.2	2.2

***2.2** Mix design*

Aggregate gradation was conducted in accordance with the specifications of the Federal Ministry of Works, Nigeria, for a wearing course mixture, with the selected sieve sizes and percentage passing presented in Table 2.3. The aggregates were sieved and proportioned to achieve the specified gradation for asphalt specimen preparation. The Marshall Mix Design method (ASTM D6927) was employed to determine the Optimum Binder Content (OBC)**,** with three specimens prepared at binder contents ranging from 5.0% to 8.0%. The OBC was determined based on the mixture's Marshall Stability, flow, air voids, and volumetric properties**,** as presented in Table 2.4, in accordance with the relevant Marshall design criteria.

Table 2.3: Design gradation adopted in the research

Sieve size (mm)	**% passing**	**% retained**
19	100	0
12.5	92.5	7.5
9.5	83.5	9
6.3	73.5	10
2.36	57.5	16
1.18	43.5	14
600 µ	33	10.5
300 µ	24	9
150 µ	18.5	5.5
75 µ	10.5	8
pan		10.5

Table 2.4: Marshall results for different binder content percentages

BINDER CONTENT	GMM	GMB	VTM %	VMA %	VFA %	STABILITY (KN)	FLOW (MM)
5	2.3	2.43	5.35	19.5	72.56	14.01	12.25
5.5	2.31	2.48	6.9	19.15	63.97	13.61	14.23
6	2.31	2.41	4.14	19.58	78.86	12.09	11.55
6.5	2.36	2.44	3.28	18.27	82.05	10.72	19.54
7	2.31	2.42	4.55	20.43	77.73	10.7	26.25
7.5	2.31	2.43	4.94	21.15	76.64	6.52	30.09
8	2.37	2.39	0.84	6.02	86.05	7.82	31.58

The optimum binder content (OBC) was selected as 6.0% based on the combined Marshall mix design parameters, including stability, flow, voids in total mix (VTM), and voids filled with asphalt (VFA). Although Marshall stability decreased with increasing binder content, the 6.0% binder content provided a suitable balance among strength, deformation, and volumetric properties. At 6.0% binder content, the mixture recorded a stability of 12.09 kN, flow of 11.55 mm, VTM of 4.14%, and VFA of 78.86%. At higher binder contents, the continued reduction in stability accompanied by an increase in flow indicated a progressively softer mixture. Therefore, 6.0% was selected as the OBC for the subsequent mixture preparation.

Following the determination of the OBC, asphalt concrete mixtures were prepared by partially replacing the natural coarse aggregate with steel slag at replacement levels of 5%, 10%, 15%, 20%, and 25%. Three specimens were prepared for each replacement level using the Marshall mix design procedure. The resulting mixtures were evaluated in terms of density, volumetric properties, Marshall stability, and flow to assess their performance and determine the effects of steel slag incorporation.

The thermal properties of the control and steel slag-modified mixtures were also determined at the Physics Laboratory, Ahmadu Bello University, Zaria**.** As shown in Table 2.5, all mixtures satisfied the specified Marshall criteria, indicating that steel slag can be used as a partial replacement for natural coarse aggregate without compromising the overall performance of the asphalt mixtures.

Table 2.5: Marshal results for different steel slag percentages

STEEL SLAG %	GMM	GMB	VTM %	VMA %	VFA %	STABILITY (KN)	FLOW (MM)
5	2.34	2.42	3.3	21.4	84.6	12.37	15.22
10	2.31	2.43	4.9	22.45	78	11.28	9.84
15	2.35	2.44	3.7	21.11	82.5	11.93	9.62
20	2.36	2.45	3.7	20.8	82.2	11.4	10.53
25	2.36	2.46	4.1	20.77	80.26	11.2	9.13

2.3 *Determination of thermal properties*

The thermal conductivity was determined experimentally using Marshall-derived sub-specimens and a steady-state electrical Searle-type apparatus. The method assumes one-dimensional heat conduction, with the apparent thermal conductivity calculated as: k = VIL/(A·ΔT), where (V) and (I) are the applied voltage and current, respectively, (L) is the specimen thickness, (A) is the cross-sectional area, and (ΔT) is the temperature difference across the specimen. Three replicate measurements were conducted for each mixture and their mean values reported. Specific heat capacity was determined using the method of mixtures with a copper calorimeter, also based on three replicate measurements.

The measured conductivity is reported as apparent thermal conductivity (K_{app}), since its determination assumes that the applied electrical power is transferred through the specimen

predominantly by one-dimensional conduction and does not explicitly account for lateral or convective heat losses. These factors may affect the measured conductivity and potentially lead to an overestimation of its absolute value. Therefore, the measured conductivity values are used primarily for comparative assessment of the asphalt mixtures and as material-property inputs for the finite element model. No correction factor was applied to account for the potential experimental bias before the values were incorporated into the Abaqus model. Consequently, the agreement between the experimental and numerical results is interpreted as consistency under the adopted experimental and modelling assumptions rather than as independent validation of the absolute thermal conductivity.

***2.4** Finite element model*

A three-dimensional finite element thermal analysis was conducted using Abaqus to simulate the transient thermal response of the cylindrical asphalt specimens investigated experimentally. The specimen geometry was modelled using the actual laboratory dimensions as a three-dimensional deformable solid. Separate models were developed for the control mixture and the mixtures containing 5%, 10%, 15%, 20%, and 25% steel slag replacement.

The experimentally determined apparent thermal conductivity, specific heat capacity, and density of each mixture were assigned as the thermal material properties in the corresponding Abaqus models. Consistent with the experimental methodology described in Section 2.3, the measured apparent thermal conductivity values were used directly without applying a correction factor for the potential overestimation associated with the laboratory measurement method.

The specimens were discretized using three-dimensional, eight-node linear heat-transfer brick elements (DC3D8). Mesh refinement was applied to obtain an adequately resolved temperature and heat-flux distribution within the specimens. A transient heat-transfer analysis was performed to capture the time-dependent thermal response. The thermal loading and boundary conditions were defined to represent the heat-transfer conditions of the laboratory thermal testing, with heat applied through the heated surface and the resulting thermal response evaluated throughout the specimen.

The numerical analysis was conducted over a simulation period of 3600 s. Temperature, heat flux, and reaction heat flux distributions were extracted from the Abaqus results to assess the thermal response of the asphalt mixtures. Particular attention was given to the 5% steel slag mixture because it exhibited the highest experimentally determined thermal conductivity and thermal diffusivity.

A formal mesh-convergence analysis and complete records of the apparatus-level electrical settings used during the laboratory test were not available from the original experimental programme. Therefore, numerical values for these parameters are not reported retrospectively. This limitation is acknowledged because complete reproduction of the laboratory conditions would require detailed information on the applied electrical input, thermal losses, insulation and contact conditions, together with a formal mesh-independence assessment. These aspects are recommended for consideration in future experimental–numerical studies.

3. RESULTS AND DISCUSSION

***3.1** Thermal Properties of Modified Asphalt Mixtures*

This section presents the experimental thermal properties of asphalt mixtures containing 0%, 5%, 10%, 15%, 20%, and 25% steel slag as partial replacement for natural coarse aggregate. The measured thermal conductivity, specific heat capacity, and calculated thermal diffusivity are summarized in Table 3.1.

Table 3.1: Summary of thermal properties

SN	Concentration of steel slag	Apparent Thermal conductivity (W/mk)	Specific heat capacity (J/KgK)	Thermal diffusivity (m^2/s)
1	0%	2.0598	1207.98	$7.08x10^{-7}$
2	5%	3.0421	794.5	$1.58x10^{-6}$
3	10%	2.689	842.89	$1.31x10^{-6}$
4	15%	2.5072	861.51	$1.19x10^{-6}$
5	20%	2.3615	928.54	$1.04x10^{-6}$
6	25%	2.1683	1010.51	$8.72x10^{-7}$

The incorporation of steel slag influenced the thermal conductivity of the asphalt mixtures. At lower replacement levels, thermal conductivity increased compared with the control mixture. The highest value was recorded at 5% steel slag replacement, with a thermal conductivity of 3.0421 W/m·K, compared with 2.0598 W/m·K for the control mixture. This increase may be associated with the relatively high density and thermal conductivity of steel slag compared with the conventional coarse aggregate. The measured volumetric properties also showed variations in mixture structure with increasing steel slag content. For example, the 5% mixture recorded a VTM of 3.3%, compared with 4.9% for the 10% mixture, while the 15%, 20%, and 25% mixtures recorded VTM values of 3.7%, 3.7%, and 4.1%, respectively. These differences in volumetric characteristics may affect the continuity of solid heat-transfer paths within the asphalt mixture.

Beyond the 5% replacement level, thermal conductivity decreased progressively, with values of 2.6890, 2.5072, 2.3615, and 2.1683 W/m·K recorded at 10%, 15%, 20%, and 25% steel slag replacement, respectively. The reduction may be related to changes in aggregate–binder configuration and the distribution of solid and void phases as the steel slag content increases. Such changes may influence the continuity of heat-transfer pathways within the mixture. However, direct microstructural characterization was not conducted in this study; therefore, this explanation should be regarded as a possible interpretation rather than a confirmed mechanism. Further investigation using microscopic analysis or three-dimensional aggregate-packing analysis would be required to establish the specific microstructural factors responsible for the observed trend.

Overall, the 5% steel slag mixture exhibited the highest measured thermal conductivity among the mixtures investigated, indicating the most favourable thermal conductivity under the conditions of the present experimental programme.

Specific heat capacity also varied with steel slag incorporation. The control mixture recorded the highest value of 1207.98 J/kg·K, whereas the 5% steel slag mixture recorded the lowest value of 794.50 J/kg·K. With further increases in steel slag content, the specific heat capacity increased to 842.89, 861.51, 928.54, and 1010.51 J/kg·K at 10%, 15%, 20%, and 25% replacements respectively.

The distinct reduction at 5% replacement, followed by the gradual increase observed from 10% to 25%, indicates a non-monotonic variation in specific heat capacity. Based on the measurements available in this study, the specific mechanism responsible for the low value at 5% cannot be established conclusively. The variation may be influenced by differences in mixture composition and volumetric characteristics associated with steel slag incorporation, as well as experimental variability in determining the thermal properties of a heterogeneous asphalt mixture. Therefore, the 5% result is considered an observed experimental response rather than evidence of a specific material mechanism. Further studies involving repeated measurements, constituent-level thermal characterization, and microstructural analysis would be useful for explaining this behaviour.

The relatively high thermal conductivity and low specific heat capacity recorded at 5% steel slag replacement contributed to its highest calculated thermal diffusivity. This indicates that the SS-05% mixture had a greater capacity for transmitting thermal energy through the specimen under the conditions investigated.

Thermal diffusivity was calculated from the measured thermal conductivity, density, and specific heat capacity using:

$$\alpha = K / \rho Cp$$

Where **α** is the thermal diffusivity (m²/s), **K** is the thermal conductivity (W/m·K), **ρ** is the density (kg/m³), and **Cp** is the specific heat capacity (J/kg·K). The 5% steel slag mixture recorded the highest thermal diffusivity of 1.58×10^{-6} m²/s, reflecting its combination of relatively high thermal conductivity and low specific heat capacity and, consequently, a greater rate of heat propagation through the mixture.

Overall, the results demonstrate that steel slag content influences the thermal properties of the asphalt mixtures. Among the mixtures investigated, the 5% replacement level produced the highest thermal conductivity and thermal diffusivity, indicating an enhanced thermal response under the conditions of the present study. This improvement may be beneficial for pavement applications where enhanced heat transfer is desirable, including potential future integration with pavement-based thermoelectric energy harvesting systems. However, the present study was limited to the thermal characterization and numerical evaluation of the asphalt mixtures; direct integration of a thermoelectric generator and assessment of its electrical performance were not undertaken.

3.2 Verification of Thermal Results Using 3d Finite Element Simulation In Abaqus

THERMAL RESPONSE OF THE 5% STEEL SLAG MIXTURE

The figures below present the heat flux, temperature, and reaction heat flux distributions of the asphalt specimen containing 5% steel slag (SS-05%) after 3600 s of transient thermal simulation. The heat flux distribution (HFL) was relatively uniform across the SS-05% specimen, with a magnitude of approximately 1242 W/m². The narrow range displayed in the contour legend is consistent with the predominantly conductive and relatively uniform thermal loading adopted in the numerical model, resulting in only small spatial variations in heat flux across the specimen. Therefore, the closely spaced values in the legend do not indicate an absence of heat transfer; rather, they reflect the relatively uniform heat-flux distribution under the applied boundary conditions. The thermal response of the SS-05% mixture was therefore assessed in conjunction with its measured thermal conductivity and thermal diffusivity, as well as the simulated temperature distribution, rather than being inferred from the HFL contour alone.

The temperature distribution ranged from approximately 38.0°C at the edges to 62.5°C at the core, indicating a clear temperature gradient within the simulated specimen. The combination of the observed heat flux and relatively high thermal diffusivity indicates effective heat propagation through the SS-05% mixture under the simulated conditions. Such temperature gradients are relevant to the concept of pavement-integrated thermoelectric energy harvesting because a temperature difference across a thermoelectric generator is required for thermoelectric conversion. However, no TEG device was incorporated into the present finite element model, and electrical voltage, power output, or conversion efficiency was not calculated. Therefore, the simulated thermal response should be regarded as an indication of the potential thermal suitability of the SS-05% mixture for future TEG integration rather than a demonstration of thermoelectric energy generation.

The reaction heat flux distribution (RFL11) shown ranged from $+2.810 \times 10^{-2}$ to -2.810×10^{-2} W/m², compared with approximately $\pm 1.982 \times 10^{-2}$ W/m² for the control mixture. The increased reaction flux magnitude indicates greater thermal exchange at the specimen surfaces. Collectively, the numerical results indicate that the 5% steel slag mixture exhibited favourable thermal behaviour under the simulated conditions, including relatively effective heat propagation and surface heat exchange. These characteristics support further investigation of the mixture for potential application in pavement-integrated thermoelectric energy harvesting. However, the present study did not evaluate the performance of an integrated TEG, including the temperature difference across the device, voltage generation, electrical power output, or thermoelectric conversion efficiency. Therefore, the numerical results should be interpreted as an assessment of the thermal characteristics of the asphalt mixture rather than a direct demonstration of thermoelectric energy generation.

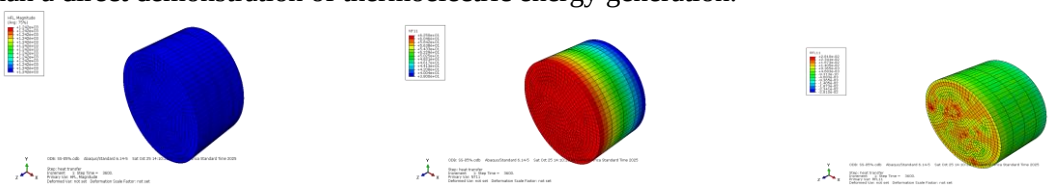

Figure 3.3: Simulated heat flux (HFL, Top left), temperature distribution (NT11, Top right) and reaction heat flux (RFL, bottom) for the optimum % of steel slag (5%)

3.3 Numerical Verification of the Abaqus Model Using Percentage Error Analysis

Table 3.2 presents the percentage differences between the experimental apparent thermal conductivity values and the corresponding Abaqus results. The percentage differences ranged from 4.52% for the control mixture to 5.84% for the mixture containing 25% steel slag. The relatively small differences indicate consistent agreement between the experimental measurements and the numerical results across the investigated replacement levels. However, since the experimental apparent thermal conductivity values were directly assigned as material inputs in the Abaqus models, these differences should be interpreted as a measure of numerical consistency under the adopted modelling assumptions rather than as independent validation of the absolute thermal conductivity.

ABAQUS consistently slightly overestimates the measured thermal conductivity, which may be attributed to idealized modelling assumptions, including homogeneous material properties, perfect aggregate–binder bonding, and the absence of air voids and material imperfections. In contrast, laboratory specimens exhibit inherent heterogeneity and voids that may reduce heat transfer.

The relatively narrow difference between the experimental and Abaqus results, ranging from 4.52% to 5.84%, indicates good numerical consistency across the investigated steel slag replacement levels. The slightly higher Abaqus values may be associated with the idealized representation of the asphalt mixture, including the use of homogeneous material properties and the omission of some physical heterogeneities and heat-loss mechanisms that may be present in the laboratory specimens. Since the experimental apparent thermal conductivity values were directly assigned as material-property inputs without applying a bias correction, the numerical results should be interpreted as verification of the thermal response under the adopted modelling assumptions rather than as independent validation of the absolute thermal conductivity. Nevertheless, the consistent agreement observed across the replacement levels supports the use of the model as a comparative tool for assessing the thermal behaviour of the investigated asphalt mixtures.

Table 3.2: Percentage error analysis

Steel Slag percentages (%)	**Expermental thermal conductivity (W/mk)**	**Abaqus thermal conductivity (W/mk)**	**Percenatge error**
0	2.0598	2.153	4.52%
5	3.0421	3.219	5.82%
10	2.689	2.845	5.80%
15	2.5072	2.653	5.82%
20	2.3615	2.499	5.82%
25	2.1683	2.295	5.84%

4. CONCLUSIONS

The objective of the research is to determine the effect of partially substituting coarse aggregates with steel slag on the thermal properties of asphalt concrete using experiments and to also verify the laboratory results using finite element simulation technique on ABAQUS. The following conclusions are drawn from the study:

1. The physical and mechanical properties of the bitumen, natural aggregate, and steel slag satisfied the relevant specifications for asphalt concrete production. Steel slag exhibited higher density, strength, and abrasion resistance than the natural aggregate, indicating its suitability as a partial replacement material.
2. Partial replacement of conventional coarse aggregate with steel slag altered the thermal properties of the asphalt concrete mixtures. In particular, all steel slag-modified mixtures exhibited higher thermal conductivity and thermal diffusivity than the control mixture, indicating an overall improvement in heat-transfer and thermal-propagation characteristics with steel slag incorporation.
3. The optimum steel slag replacement level for the thermal properties investigated in this study was 5%, which produced the highest thermal conductivity of 3.0421 W/m·K and thermal diffusivity of 1.58×10^{-6} m²/s. These results indicate that the 5% steel slag mixture exhibits favorable thermal characteristics

that may support its potential application in pavement-integrated thermoelectric energy harvesting systems. However, the present study was limited to the thermal characterization of the asphalt mixtures, and direct integration and performance evaluation of a thermoelectric generator, including voltage and power output, were not undertaken.

4. The three-dimensional (3D) transient heat-transfer simulation conducted in Abaqus demonstrated consistent thermal responses across the investigated asphalt mixtures. The differences between the experimental apparent thermal conductivity values and the corresponding Abaqus results ranged from 4.52% to 5.84%, indicating a relatively close numerical agreement across the steel slag replacement levels. However, since the experimentally determined apparent thermal conductivity values were directly assigned as material property inputs in the numerical model, the Abaqus results should be interpreted as demonstrating consistency with the experimental thermal response under the adopted modelling assumptions, rather than as an independent validation of the absolute thermal conductivity values.
5. Further research should investigate the direct integration of thermoelectric generators into steel-slag-modified asphalt pavement systems. Future studies should evaluate the temperature difference across the TEG, electrical voltage and power output, thermoelectric conversion efficiency, and long-term performance under field conditions. In addition, an economic assessment of steel slag sourcing, processing, transportation, and incorporation into asphalt mixtures should be conducted to determine the practical feasibility and scalability of the proposed application.

ABSTRACT
The production of Ordinary Portland Cement (OPC) is associated with high carbon dioxide emissions and energy consumption, creating the need for sustainable supplementary cementitious materials. This study investigated the synergistic effect of Corncob Ash (CCA) and Date Palm Seed Ash (DPSA) as partial cement replacements on the mechanical properties of concrete. CCA and DPSA were produced through controlled calcination at 600°C – 800°C and incorporated as binary (OPC–CCA and OPC–DPSA) and ternary (OPC–CCA–DPSA) blends at replacement levels of 5, 10, 15, and 20% by weight of cement. Cube and cylinder concrete specimens, designed for a target compressive strength of 30 MPa with a water-to-binder ratio of 0.50, were produced and cured for 7, 14, and 28 days and tested for workability, compressive and split tensile strengths in accordance with relevant British Standards. Strength increased with curing age for all mixes, with the binary blends outperforming the ternary blend. At 28 days, OPC–CCA and OPC–DPSA achieved optimum compressive strengths of 32.33 MPa and 32.00 MPa, respectively, at 5% replacement, while the ternary blend attained 28.33 MPa. OPC–DPSA recorded the highest split tensile strength of 3.61 MPa at 10% replacement, whereas the ternary blend reached 3.50 MPa. The study concludes that 5–10% replacement is optimal. Although the expected synergistic enhancement of the ternary blend was not fully realized, longer-term curing may improve its performance. Overall, CCA and DPSA show strong potential as sustainable supplementary cementitious materials that reduce cement consumption while maintaining satisfactory mechanical properties.

Keywords: *Corncob ash; Date palm seed ash; Supplementary cementitious materials; Compressive strength; Split tensile strength; Sustainable concrete*

1. INTRODUCTION

Concrete remains the most widely used construction material worldwide because of its versatility, durability, and the availability of its constituent materials. However, its primary binding material, Ordinary Portland Cement (OPC), is highly energy-intensive to manufacture and is responsible for approximately 7–8% of global anthropogenic carbon dioxide (CO_2) emissions (Chen et al., 2022).

As reported by Tijani et al. (2018) agricultural waste ashes have emerged as promising SCMs because they provide an environmentally friendly means of converting waste materials into value-added construction products. These materials are generally rich in reactive silica and alumina, enabling them to participate in pozzolanic reactions (Papadaki & Tsimas, 2002). Among the various agricultural wastes investigated as SCMs, Corncob Ash (CCA) and Date Palm Seed Ash (DPSA) have attracted increasing research interest because of their availability in many agricultural regions and their favourable chemical compositions. Previous investigations have shown that CCA possesses appreciable amounts of reactive silica capable of improving compressive strength and durability (Adesanya & Raheem, 2009; Apampa et al., 2023). Similarly, DPSA has demonstrated good pozzolanic characteristics, with studies reporting improvements in strength properties (Ahmad et al.,2023; Smith et al., 2020). Recent developments in blended cement technology have shifted attention from binary systems to ternary blended binders, where two or more SCMs are combined to exploit complementary physical and chemical characteristics.

This study therefore investigates the synergistic effect of CCA and DPSA as partial replacements for cement on the mechanical properties of concrete. Binary and ternary blended concretes were produced at varying replacement levels and evaluated through workability, compressive and split tensile strength tests. The findings are expected to provide further insight into the feasibility of utilizing locally available agricultural wastes as sustainable supplementary cementitious materials for low-carbon concrete production.

2. METHODOLOGY

2.1 Materials

Ordinary Portland Cement (OPC) conforming to BS EN 197-1 (2011) was used as the primary binder. Natural river sand conforming to BS EN 12620 (2002) and crushed granite with a nominal maximum size of 20 mm were used as fine and coarse aggregates, respectively. Potable water complying with BS EN 1008 (2002) was used for concrete mixing and curing. Corncob Ash (CCA) was obtained from Zabawa Village, Giwa Local Government Area, Kaduna State, while Date Palm Seed Ash (DPSA) was produced from date palm seeds sourced from Dutsinma Local Government Area, Katsina State, Nigeria. CCA and DPSA were produced through controlled thermal treatment at a temperature of 650^{o}C and 750^{o}C respectively.

2.2 Methods

2.2.1 Materials Characterization

Preliminary characterization of the constituent materials was carried out before concrete production. Tests conducted on cement included specific gravity, standard consistency, setting time, and soundness. Fine and coarse aggregates were evaluated for grading, specific gravity, bulk density, water absorption, Aggregate Impact Value (AIV), and Aggregate Crushing Value (ACV), while the chemical compositions of CCA and DPSA were determined using X-ray fluorescence (XRF). All tests were performed in accordance with the relevant British Standards.

2.2.2 Mix Design and Specimen Preparation

One hundred and seventeen (117), 100 x 100 x 100mm cubes and Seventy eight (78), 100 x 200mm cylinder specimens were prepared. Design of Experiment (DoE) method was used to design a concrete mixtures for a target strength of 30 MPa, with a constant water-to-binder ratio of 0.50. Three binder systems were investigated: binary OPC–CCA, binary OPC–DPSA, and ternary OPC–CCA–DPSA blends. Cement replacement levels of 5%, 10%, 15%, and 20% by weight of cement were adopted alongside a control mix containing 100% OPC.

2.2.3 Fresh and Hardened Properties of Concrete

Fresh concrete workability was evaluated using the slump test in accordance with BS 1881-102 (1983). Hardened concrete was assessed through compressive strength and split tensile strength tests conducted at curing ages of 7, 14, and 28 days in accordance with BS EN 12390-3 (2002) and BS EN 12390-6 (2009), respectively. Compressive strength was determined from 100 × 100 × 100 mm cube specimens, while split tensile strength was measured using 100 × 200 mm cylinders.

2.2.4 Statistical Analysis

The experimental data for the ternary OPC–CCA–DPSA system were analysed using one-way analysis of variance (ANOVA) at a 95% confidence level ($\alpha = 0.05$) to evaluate the effect of replacement level on compressive and split tensile strength at each curing age.

3. RESULTS AND DISCUSSION

3.1 Characterization of Constituent Materials

The physical properties of the Ordinary Portland Cement satisfied the requirements of BS EN 196, confirming its suitability for structural concrete production. Similarly, the fine and coarse

aggregates complied with the relevant British Standards, Fine aggregate; fineness modulus = 2.87827, specific gravity = 2.66, bulk density = 1433.3kg/m3, and Coarse aggregate; grading ≤ 20mm, specific gravity = 2.68, water absorption = 0.7, Aggregate Impact Value (AIV = 24.55), and Aggregate Crushing Value (ACV = 21.61), indicating their suitability for concrete manufacture. The results for chemical composition of CCA and DPSA are presented in Table 1.

Table 1: Chemical composition of CCA and DPSA

Chemical Constituents (%)	**SiO_2**	**Al_2O_3**	**Fe_2O_3**	**CaO**	**MgO**	**Na_20**	**K_2O**	**SO_3**	**LOI**
CCA	62.30	6.25	4.40	10.57	1.86	0.36	3.89	1.02	3.50
DPSA	45.50	20.75	7.25	9.82	0.52	3.00	9.07	0.12	1.72

The XRF analysis revealed that the combined silica (SiO_2), alumina (Al_2O_3), and iron oxide (Fe_2O_3) contents were 72.95% for CCA and 73.50% for DPSA, exceeding the 70% minimum specified by ASTM C618-19 (2019) for natural pozzolans. This confirms the pozzolanic potential of both agricultural ashes and supports their application as supplementary cementitious materials.

3.2 Fresh Properties of Concrete

The results for workability is presented in Figure 1. Workability of all concrete mixtures decreased progressively with increasing cement replacement irrespective of the binder system. The control concrete recorded the highest slump (60 mm), whereas slump values decreased to 23 mm for both binary mixes and 20 mm for the ternary blend at 20% replacement.

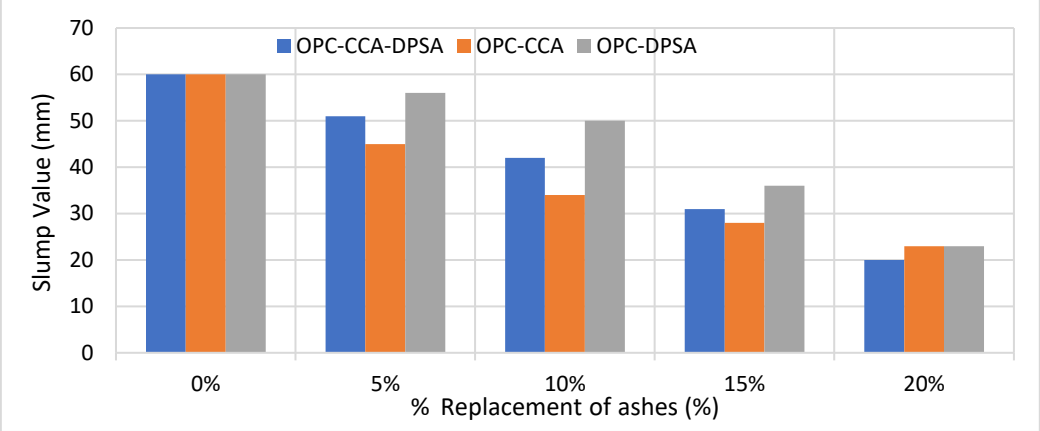

Figure 1: Slump values of control, binary and ternary concrete mixtures.

The reduction in workability is attributed to the higher specific surface area and increased water demand of CCA and DPSA, which reduced the amount of free water available for lubrication within the fresh concrete matrix.

3.3 Mechanical Properties

3.3.1 Compressive strength

The results for compressive strength of all the mixtures are presented in Figures 2, 3, and 4. Generally, increase in compressive strength was observed for all the mixtures, as curing age increases, indicating continued cement hydration and pozzolanic activity. However, strength generally decreased with increasing cement replacement due to the cement dilution effect.

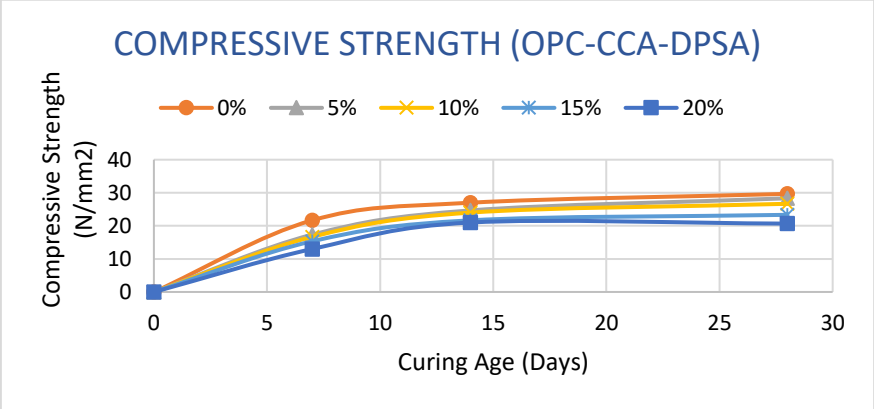

Figure 2: Compressive strength development of ternary concrete.

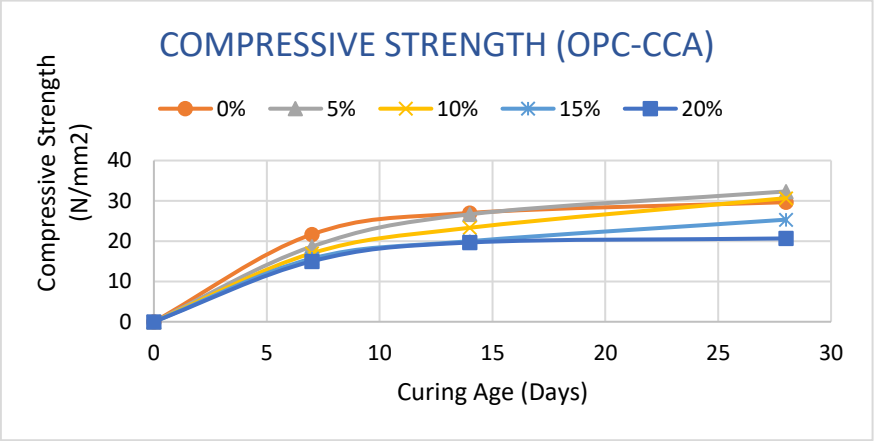

Figure 3: Compressive strength development of OPC–CCA concrete.

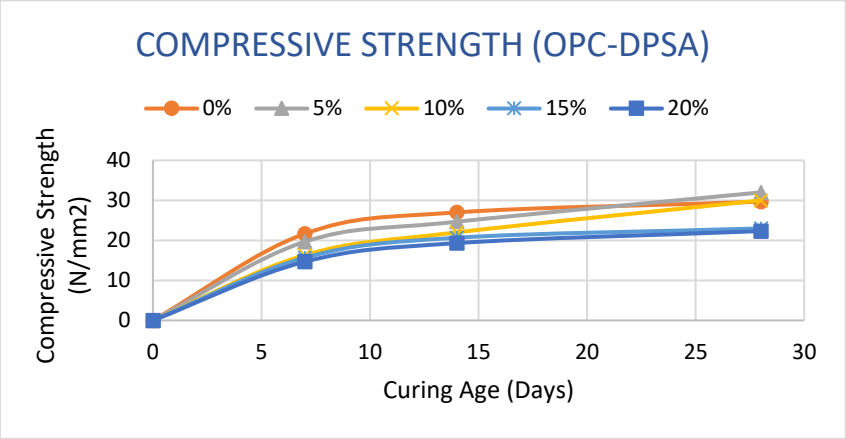

Figure 4: Compressive strength development of OPC–DPSA concrete.

For the ternary OPC–CCA–DPSA concrete, the 28-day compressive strength decreased from 29.67 MPa for the control to 28.33, 26.67, 23.33, and 20.67 MPa at 5%, 10%, 15%, and 20% replacement, respectively. The 5% replacement retained approximately 95.5% of the control strength, suggesting that limited incorporation of both ashes contributed to strength development through secondary pozzolanic reactions.

The binary mixtures exhibited superior performance. At 28 days, OPC–CCA achieved a maximum compressive strength of 32.33 MPa at 5% replacement, while OPC–DPSA attained 32.00 MPa at the same replacement level, both exceeding the control concrete. The ternary blend, however, did not demonstrate the anticipated synergistic improvement. These observations agree with previous studies reporting that agricultural waste ashes produce optimum strength at relatively low replacement levels, beyond which the dilution effect predominates over the benefits of pozzolanic activity (Adesanya & Raheem, 2009; Kavitha et al., 2022; Shakir et al., 2021).

3.3.2 Split Tensile Strength

Split tensile strength increased with curing age for all mixtures as shown in Figures 5, 6, and 7, confirming continued hydration and microstructural refinement. Similar to compressive strength, low replacement levels improved tensile performance, whereas higher replacement levels (15–20%) resulted in strength reduction. The ternary concrete achieved its highest split tensile strength of 3.50 MPa at 10% replacement, slightly exceeding the control value of 3.42 MPa. Among the binary blends, OPC–DPSA produced the highest tensile strength of 3.61 MPa at 10% replacement, followed by OPC–CCA with 3.50 MPa at 5% replacement.

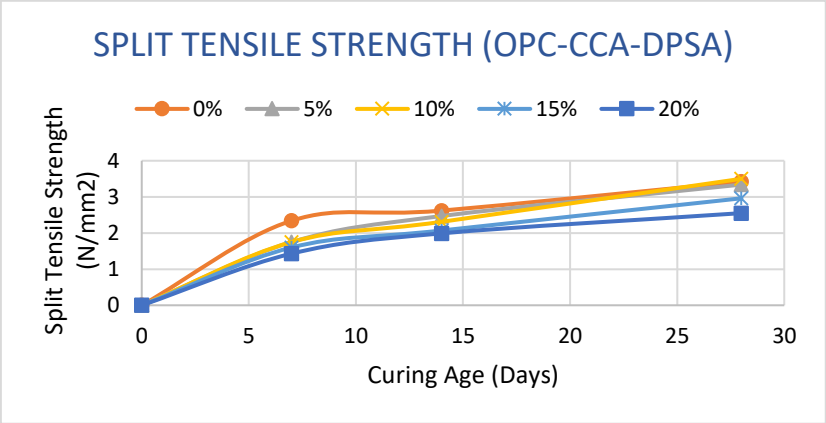

Figure 5: Split tensile strength development of ternary concrete.

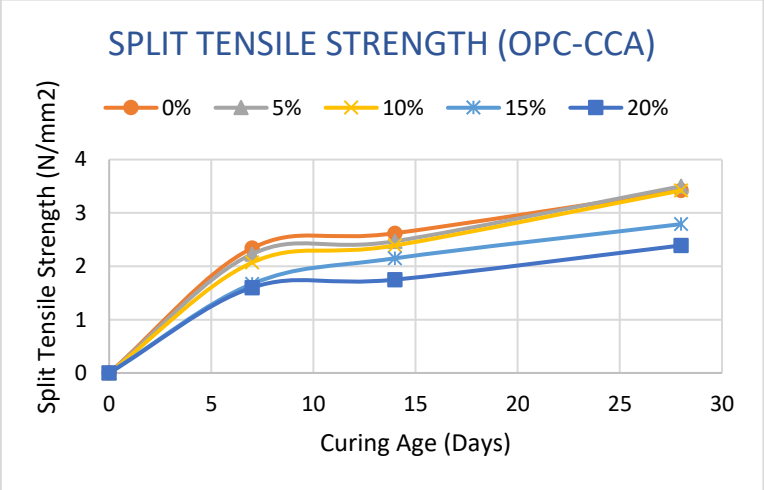

Figure 6: Split tensile strength development of OPC–CCA concrete.

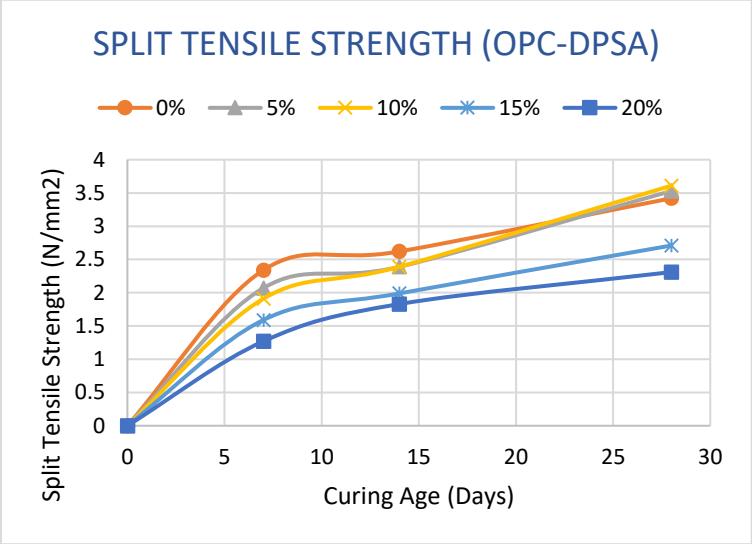

Figure 7: Split tensile strength development of OPC–DPSA concrete.

Although the ternary blend improved the tensile strength relative to the control, it did not outperform the best-performing binary mixture, indicating that the expected synergistic enhancement was not fully realized within the 28-day curing period. The findings are consistent with previous studies which reported that supplementary cementitious materials enhance concrete performance only within an optimum replacement range (Nasir & Al-kutti, 2019; Aswin et al., 2021).

3.4 Statistical Analysis

The one-way ANOVA results as presented in Table 2, showed that replacement level significantly influenced the compressive strength of the ternary OPC–CCA–DPSA concrete at 7, 14, and 28 days, with *p*-values of 0.0256, 0.0334, and <0.001, respectively. Similarly, split tensile strength was significantly affected at 7, 14, and 28 days, with *p*-values of 0.0245, 0.0063, and 0.0314, respectively.

Table 2: ANOVA result for Compressive and Split tensile strength

Test – Curing age	F-statistic	F-critical	P-value	Result (α = 0.05)
Compressive Strength – 7 Days	4.43	3.48	0.0256	Significant
Compressive Strength – 14 Days	4.04	3.48	0.0334	Significant
Compressive Strength – 28 Days	43.82	3.48	2.62e-6	Significant
Split Tensile Strength – 7 Days	7.47	5.19	0.0245	Significant
Split Tensile Strength – 14 Days	14.00	5.19	0.0063	Significant
Split Tensile Strength – 28 Days	6.60	5.19	0.0314	Significant

The results confirm that changes in CCA–DPSA replacement level significantly influenced the mechanical performance of the ternary concrete. The optimum performance occurred at low replacement levels.

4. CONCLUSION

This study evaluated the mechanical performance of binary and ternary concrete. Both ashes showed pozzolanic potential, while increasing replacement reduced workability. Strength generally increased with curing age, with the ternary mixture achieving optimum compressive strength of 28.33

MPa at 5% replacement and split tensile strength of 3.50 MPa at 10% after 28 days. One-way ANOVA confirmed that replacement level significantly affected both properties. However, the ternary blend did not outperform the binary systems at 28 days. Thus, the anticipated synergistic enhancement was not fully realized within the 28-day period. Longer curing periods, varied CCA-DPSA ratios, and microstructural and durability investigations are recommended to determine whether delayed pozzolanic reactions can improve ternary performance and establish an optimum blend.

ABSTRACT

Sustainable construction materials research, including geopolymer concrete, has been ongoing for quite some time. This is because they are environmentally friendly and can be employed as alternatives to ordinary Portland cement (OPC) concrete. The researchers have been pushing for the adoption of geopolymer concrete as an alternative to OPC concrete in structural members' production. However, the applicability of existing reinforced concrete design provisions to reinforced metakaolin-based geopolymer concrete (MBGC) beams was not adequately validated. This study experimentally investigated the flexural and shear capacities of singly reinforced MBGC beams and compared the results with values predicted using Eurocode 2 (EC2). Three beams were produced, each with two 8, 10, and 12 mm tensile reinforcements (RGCB08, RGCB10, and RGCB12 respectively), and were tested to failure under static loading; the experimental ultimate moment and shear capacities were compared with EC2 theoretical values. The results showed that increasing the reinforcement ratio enhanced both flexural and shear performance. Compared with RGCB08, the experimental ultimate moment increased by 10% and 26% for RGCB10 and RGCB12, while the corresponding EC2-predicted moment increased by 28.7% and 41.7%. The EC2 moment capacity predictions were in close agreement with the experimental capacities, with experimental-to-theoretical moment ratios of 1.11, 0.95, and 0.99 (≅ 1.0), respectively, for the three reinforcement ratios. In contrast, the experimental-to-theoretical shear ratios were 2.9, 2.9, and 3.4 for RGCB08, RGCB10, and RGCB12, respectively, indicating that the experimental shear capacities exceeded the EC2 predictions. The conservative shear predictions were attributed to EC2 limitations on the longitudinal reinforcement ratio and effective depth factors for beams without shear reinforcement. The study concludes that despite EC2 underestimating the measured shear capacity, its predictions remain conservative and provide a safe design. EC2 is therefore recommended for the flexural and shear design of reinforced metakaolin-based geopolymer concrete.

1.0 INTRODUCTION

The environmental impacts associated with the production of ordinary Portland cement (OPC), particularly its substantial contribution to global carbon dioxide emissions, have increased the demand for more sustainable construction materials (Jindal et al., 2022). Consequently, geopolymer concrete has emerged as a viable alternative binder through the utilisation of aluminosilicate precursor materials activated by alkaline solutions to produce concrete with comparable mechanical properties and enhanced durability, while significantly reducing greenhouse gas emissions. Among the various aluminosilicate precursor materials, metakaolin has attracted considerable attention because of its high pozzolanic reactivity, uniform chemical composition, and ability to produce geopolymer concrete with superior mechanical performance and long-term durability. This observation is consistent with the findings of Qader et al. (2025). Furthermore, Mo et al. (2016) reported that the application of

geopolymer concrete has gradually progressed beyond material characterisation to structural applications involving reinforced concrete members such as beams, columns, and slabs. Reinforced concrete beams are structural members that support loading primarily by flexure, according to Wasiu and Adedeji (2018). For reinforced concrete (RC) beams, the major failure modes that require focus are the bending moment, shear capacity, and deflection. For a short-span beam as in the case of this research, the critical failure mode is shear according to Chanackya (2009**)** and the ultimate limit state of bending for moderately loaded medium-span beams.

Research conducted on geopolymer beams has focused either on flyash or ground granulated blast slag (GGBS) and sometimes mixed with metakaolin. The research is either on the flexural strength of unreinforced sections or on doubly reinforced beams with shear stirrups. Recent studies have shown that reinforced geopolymer concrete beams exhibit flexural behaviour similar to that of conventional reinforced concrete members, with the reinforcement ratio remaining one of the major parameters influencing the strength, stiffness, cracking behaviour, and failure characteristics of the beams as observed by Ansari et al. (2023). Furthermore, although several experimental studies have reported satisfactory structural performance of reinforced geopolymer concrete beams, the available literature is largely focused on fly ash- and slag-based geopolymer systems. Comparatively limited information is available on metakaolin-based geopolymer concrete beams, particularly with respect to their flexural and shear capacities (Handono et al., 2023), especially within the Nigerian context. This is despite the abundance of kaolin deposits in Nigeria, which can be processed to produce metakaolin for reinforced geopolymer concrete applications.

Furthermore, although the design provisions of Eurocode 2 (EC2) are widely adopted for reinforced concrete structures, their applicability to reinforced metakaolin-based geopolymer concrete beams has not been adequately established through experimental investigations. This means that the application of the code to reinforced metakaolin-based geopolymer concrete beams remains insufficiently validated. Establishing the relationship between the experimentally determined capacities and the theoretical predictions of EC2 is therefore necessary before these design provisions can be confidently applied to geopolymer concrete structures. Accordingly, this study investigates the influence of reinforcement ratio on the flexural and shear capacities of reinforced metakaolin-based geopolymer concrete beams and evaluates the accuracy of the EC2 provisions by comparing the theoretical predictions with the corresponding experimental moment and shear capacities.

2.0 MATERIALS AND METHODS

2.1 Materials: Metakaolin, fine and coarse aggregates, sodium hydroxide (NaOH), sodium silicate (Na_2SiO_3), water, and steel reinforcement were all sourced locally in Zaria except the metakaolin, which was processed from a raw kaolin obtained from Kankara Local Government of Katsina State.

2.2 Methods

2.2.1 Metakaolin and other Materials Processing: The Metakaolin was from the beneficiation of kaolin clay at 800^{o}C for 3 hours based on Keeratikan and Janjit (2018). The metakaolin was found to be a class N pozzolan according to ASTMC618-05. The aggregates were tested for conformity against BS882 (1992) and Nevelli (2011). The steel was tested for yield strength based on BS EN 10002-1 (2001).

2.2.2: Beam Specimen production: The metakaolin (Mc), aggregates were dry mixed and then transferred to an electric mixer. The same batch of concrete mix was used for all specimens. The alkaline liquids and additional water were mixed continuously for an average of 5 minutes and the mix poured in the formworks (Tables 1) in accordance with BS EN 12390-1 (2000) and trimmed based on BS EN 12390-2 (2000). Three (3) 100 mm^3 concrete cubes and 3 short beams each for RGCB08, RGCB10, and RGCB12 (Table 2) were produced and tested for compressive strength based on BS EN 12390-3 (2009) and the average result was presented in Table 1. The beams and cubes were allowed to cure at ambient temperature (13 days) and heat-cured in an oven at 60^{0}C, for 1 day based on Abdul Rahim *et al*. (2014) before testing.

Table 1: Mix Proportions for the Metakaolin-Based Geopolymer Concrete

S/No	Mc (Kg/m^3)	(ALm)	Alr	Fa (Kg/m^3)	Ca (Kg/m^3)	Wc (Kg/m^3)	Acquired Strength (N/mm^2)
1	400	0.9	3	546.7	1093.3	60	31.33

Where ALm is the ratio of metakaolin to alkaline-liquid and Alr is the ratio of Na_2SiO_3 to NaOH.

Table 2: Reinforcement Detail

Beam (No of Beams produced)	Dimension (mm)	Effective depth (mm)	Tensile reinforcement diameter(mm) and Area (mm^2))	Reinforcement ratio (%)
RGCB08 (3 beams)	450×100×100	81	2Y8 (100.53)	1.24
RGCB10 (3 beams)	450×100×100	80	2 Y10 (157.08)	1.96
RGCB12 (3 beams)	450×100×100	79	2Y12 (226.19)	2.86

The tension reinforcements fall within the BS8110 and EC 2 limit of $0.13\% \leq \rho \leq 4\%$. The difference in the effective depths presented in Table 1 is because increasing bar diameter reduces effective depth due to constant overall depth and cover

2.2.3 Beam Test Set-up: The test was conducted per BS EN 12390 -5 (2009) (Plate 1). Three (3) beams each for RGCB08, RGCB10, and RGCB12 were tested. The machine was set to move at an average speed of 20mm/minute (0.33mm/sec). Readings were taken at 2 kN intervals simultaneously with the corresponding deflection reading until failure of the specimen (with a dial gauge at the beams soffit); an average of the three results (for 3 beams) was taken as a representative result. The ultimate (maximum load) and failure (load at failure) loads were all recorded.

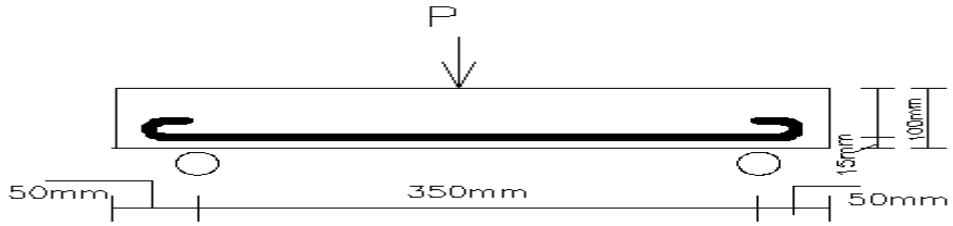

Plate 1: Loading and reinforcement detail of the RGCB (3 Point Loading Test)

It can be deduced that the beam tested is a short beam with a/d (a = 175 mm and d = 100 mm) ≤ 2.5 based on ACI 318 (1992)

2.2.4: Theoretical Beam Moment and Shear Based on Eurocode 2 Formulations

2.2.4.1 Moment Capacity:

The moment capacity of a singly reinforced concrete section based on Eurocode 2, and Mosley *et al.* (2007) expressed it as eqn (1): $for\ x \leq 0.617d$ (steel has yielded)

$$M = 0.567 f_{ck} bsZ = 0.87 A_S f_{yk} Z = 0.87 A_S f_{yk} \left(d - \frac{s}{2}\right) \quad (1)$$

2.2.4.2 Shear capacity:

The Shear capacities are presented in eqn (2 and 3). Where $\rho = \frac{A_S}{bd} \leq 0.02. for\ d\ in\ mm, K = \left(1 + \sqrt{\frac{200}{d}}\right) \leq 2.0$

$$V_{Rdc} = (0.12K(100\rho f_{ck})^{\frac{1}{3}})bd \quad (2)$$

Minimum is $V_{Rdcmin} = (0.035K^{3/2}(f_{ck})^{\frac{1}{2}})bd$ (3)

3.0 RESULTS AND DISCUSSIONS

3.1 Relationship between Theoretical (EC2-based) and Experimental Ultimate Moment

The theoretical moment values computed for RGCB8, RGCB10, and RGCB12 using the EC2 formulations and the corresponding average experimental ultimate moment values obtained from the laboratory are very close to each other (Figure 1). This means that the EC2 flexural design and analysis of reinforced concrete sections could be used for singly reinforced MBGB. From Table 3 and Figure 1, it could be observed that the values of the experimental ultimate moment increased by 10% and 26%, respectively, for RGCB10 and RGCB12 compared with RGCB8; the theoretical ultimate moment increased by 28.7% and 41.7%, respectively, for RGCB10 and RGCB12 when compared with RGCB8. This increase agrees with the conventional concrete behaviour of moment capacity increasing with the reinforcement ratio due to an increase in the tensile capacity of the section.

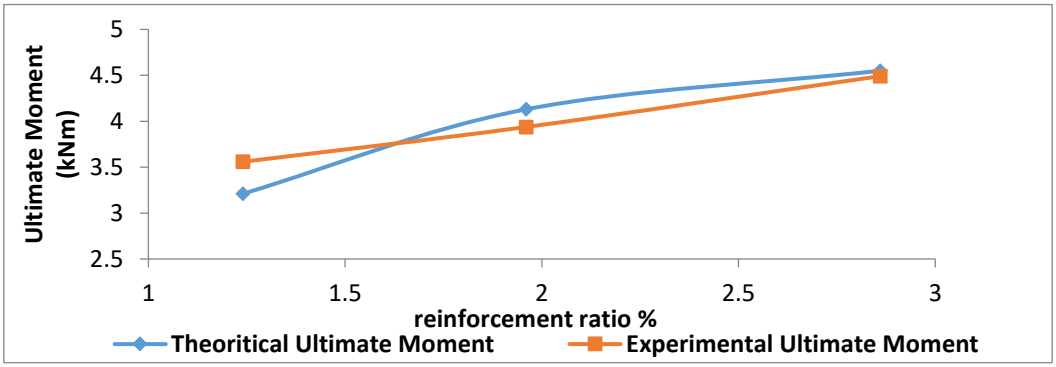

Figure 1: Ultimate moment against the reinforcement ratio

Additionally, from Table 3, it can be deduced that the EC2 formulation for moment capacity of singly reinforced concrete beams agrees with the experimental moment capacity of the reinforced geopolymer concrete beams since the ratios of the experimental to the theoretical ultimate moment at all reinforcement ratios are approximately 1.0. This means the code formulations could be used for the moment capacity of a reinforced geopolymer concrete beam.

Table 3: Comparison between experimental and theoretical moments

Beam	Ultimate Moment (kNm)	Failure Moment (kNm)	Theoretical Moment (kNm)	Experimental/Theoretical Moment ratio
RGCB08	3.5586	3.4326	3.21	1.10861
RGCB10	3.9375	3.8675	4.13	0.95339
RGCB12	4.49138	4.4914	4.55	0.98712

3.2 Relationship between Theoretical (EC2 based) and Experimental Ultimate Shear

The experimental shear capacity of the beam is higher than the theoretical shear; this may be because, as Mosley *et al.* (2007) mentioned, shear analysis of RC beams is complex, and the code expressions are simplifications based on experimental results. Additionally, Chanackya (2009) mentioned that for short-span beams, shear failure is the dominant failure. Based on the results presented in Figure 2, the formulations by the EC2 for beam shear capacity without shear reinforcement provide values that are roughly 29 – 35% of those achieved by experimental values at the ultimate limit state for the RGCB; the higher experimental values as compared with code-based values are generally true even with conventional concrete. Ikponmwosa and Ehikhuenmen (2018) also reported higher

experimental ultimate values when compared with theoretical values in concrete. Also, Jongho *et al.* (2017) submitted that structural working loads are generally less than practical loads. This means that higher actions and reactions will be recorded experimentally.

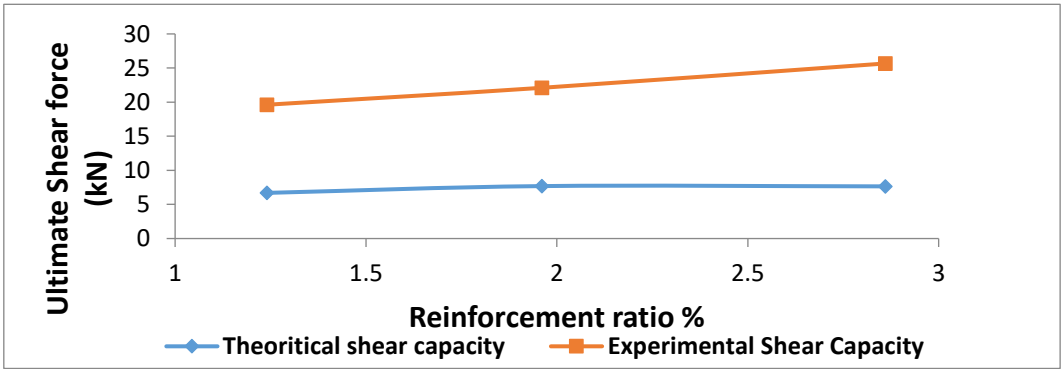

Figure 2: Ultimate shear against the reinforcement ratio

From Figure 2, the experimental shear capacity of the beams increased with the reinforcement ratio increase; this may be a result of the increase in stiffness provided by the increase in reinforcement. Also, the ratio of experimental to theoretical shear capacity for the beams is similar, and is approximately equal to 3.0 on average. From Table 4, shear ratios of 2.9, 2.9 and 3.4 were computed respectively for RGCB08, RGCB10, and RGCB12. The theoretical shear capacities are less than the experimental on account of the fact that EC2 (2004) sets limits of 2 and 0.02 for the depth ratio (K) and reinforcement ratio (ρ), respectively, for the computation of shear capacity of RC beams without shear reinforcements. RGCB12 has the highest failure load and hence highest experimental shear capacity; on the other hand, the same beam relatively has the least theoretical shear capacity due to the EC2 (2004) limit for $\rho \leq 0.02$ despite the beam having a ρ value of 0.0286 coupled with the fact that the beam has the highest bar diameter and hence least effective depth; and the code based formulations for shear capacity increases and reduces with effective depth for uniform beam cross-sections.

Based on the ratios in Table 4, it can be said that the theoretical shear capacities of the beams were all reached before yielding (yield load) of the concrete composite; this showed that the theoretical expression from EC2 (2004) for beam's shear capacity without shear reinforcement underestimates the beams shear capacity, this could be because shear is a complex phenomena (Mosley et al., 2007) but results to a safe design by ensuring the shear capacity of the beam is not reached, as a result, the code can be adopted for geopolymer concrete beams.

Table 4: Comparison between experimental and theoretical (EC2) Shear force

Beam	Ultimate Shear force (kN)	Failure Shear force (kN)	Theoretical Shear force (kN)	Experimental/Theoretical shear ratio
RGCB08	20.335	19.61	6.69	2.9
RGCB10	22.5	22.10	7.69	2.9
RGCB12	25.665	25.67	7.65	3.4

4.0 CONCLUSIONS

Based on the experimental and theoretical moment results and comparisons presented in this study, the following conclusions were drawn;

i. The moment capacity of reinforced metakaolin-based geopolymer concrete beams increased with an increase in the longitudinal reinforcement ratio. This was evidenced by the experimental ultimate moment, which increased by 10% and 26% for RGCB10 and RGCB12, respectively, when compared with RGCB08. Similarly, the corresponding theoretical ultimate moment predicted using EC2 increased by 28.7% and 41.7%, respectively.
ii. The EC2 moment design provisions can be used for the design of singly reinforced metakaolin-based geopolymer concrete beams, since the experimental-to-theoretical moment capacity ratios were 1.11, 0.95, and 0.99 for RGCB08, RGCB10, and RGCB12, respectively.

iii. The experimental-to-theoretical shear capacity ratios were observed to be 2.9, 2.9, and 3.4 for RGCB08, RGCB10, and RGCB12, respectively, indicating that the experimental shear capacities were considerably higher than the theoretical predictions. This indicates that the EC2 shear design provisions provide conservative estimates of the shear capacity of reinforced metakaolin-based geopolymer concrete beams, thereby providing an adequate margin of safety.

iv. It is recommended that the Eurocode 2 can be safely used to design singly reinforced geopolymer concrete short beams, based on the mix batching, production, and testing conditions.

ABSTRACT

The incorporation of plastic waste into lateritic soil provides an opportunity to reduce plastic pollution while modifying the compaction behaviour of earth materials used in road works. This study investigated the influence of the morphology and content of waste sachet-water plastic (SWPW) on the maximum dry density (MDD) and optimum moisture content (OMC) of a marginal lateritic soil. Used sachet-water bags collected in Kano State, Nigeria, were cleaned, air-dried and processed into fiber and powdered forms. The fiber pieces were approximately 5 mm wide and 25 mm long. Powdered SWPW was incorporated at 0-15% of dry soil mass at 2.5% intervals, while fiber SWPW was incorporated at 0-5% at 1% intervals. Compaction testing was carried out in accordance with BS 1377-4:1990. The untreated soil had an MDD of 1.94 g/cm3. With increasing powdered SWPW content, MDD decreased progressively to 1.33 g/cm3 at 15%, while OMC increased from 12.90% to 17.51%. Fiber SWPW similarly reduced MDD to 1.69 g/cm3 at 5% and increased OMC to 18.41%. The results demonstrate that SWPW morphology and dosage significantly influence the compaction response of lateritic soil, with the powdered form producing the larger reduction in dry density over the investigated range. The present study is limited to compaction characteristics; strength, durability and field-performance tests are required before structural suitability for pavement applications can be established.

1. INTRODUCTION

According Plastic waste is a persistent environmental problem because of its high rate of generation and slow degradation. In Nigeria, single-use sachet-water packaging is widely used and discarded sachets frequently enter drains, waterways and open dumps. Reuse of this waste in geotechnical construction materials offers a potential route for diverting plastic from the environment while reducing demand for conventional materials. In soil engineering, waste plastics have been investigated as discrete fibres or inclusions, with reported effects on compaction and strength depending on plastic type, geometry, dosage and soil characteristics (Jalal & Hassan, 2021; Zukri et al., 2017; Munirwan & Jaya, 2019; Akinwumi et al., 2022).

Previous studies show that the response of soil to plastic inclusion is not governed by dosage alone. Jalal and Hassan (2021) reported that discrete plastic fibers altered the compaction characteristics of clayey soil and could also influence its mechanical behaviour. Zukri et al. (2017) investigated polyethylene and polypropylene in clay stabilization, while Munirwan and Jaya (2019) demonstrated that plastic waste content affects the geotechnical response of cement-stabilised soil intended for pavement layers. Akinwumi et al. (2022) similarly showed that recycled plastic inclusions can modify the engineering behaviour of soil. These studies establish the potential of plastic waste in geotechnical applications but also show that the form in which the plastic is introduced is important.

Most published studies have focused on plastic fibers, strips or shredded particles. Comparatively less attention has been given to the direct comparison of different morphologies prepared from the same waste stream, particularly waste sachet-water plastic incorporated into lateritic soils. Powdered plastic and elongated fibers differ markedly in particle geometry, surface area and interaction with the soil skeleton and may therefore produce different compaction responses. Understanding these differences is relevant when considering the reuse of sachet-water waste in earthworks and low-volume road construction.

This study therefore investigates the influence of two morphologies of waste sachet-water plastic - powdered SWPW (P-SWPW) and fiber SWPW (F-SWPW) - on the compaction characteristics of a marginal lateritic soil. The specific objective is to quantify the changes in maximum dry density (MDD) and optimum moisture content (OMC) with increasing plastic content and to compare the responses produced by the two morphologies. The study is intentionally limited to compaction behavior; strength and durability performance are outside the scope of the present investigation.

2. MATERIALS AND METHODS

2.1 Materials

Waste sachet-water plastic (SWPW) was collected from disposal locations in Kano State, Nigeria. The collected material was washed to remove adhering soil and other contaminants and then air-dried. Two morphologies were prepared from the same waste stream. For F-SWPW, the sachets were manually cut into fibres approximately 5 mm wide and 25 mm long. For P-SWPW, the cleaned and dried sachets were mechanically reduced to a powdered form before mixing with the soil. The plastic-specific density, tensile strength and detailed particle-size distribution of the powdered material were not experimentally determined in this study; this is recognised as a limitation and should be addressed in subsequent material-characterisation work

2.2 Methods

The natural lateritic soil was first characterised using index-property tests comprising particle-size distribution, Atterberg limits and specific gravity. Compaction tests were performed in accordance with BS 1377-4:1990 (U et al., 2022) using the light compaction procedure. The soil was compacted in a 1 L mould in three approximately equal layers using a 2.5 kg rammer falling through 300 mm, with 27 blows applied to each layer. For each mixture, the required quantity of SWPW was calculated as a percentage of the dry mass of soil and thoroughly dry-mixed with the soil to obtain a visually uniform distribution before water was added. P-SWPW contents of 0, 2.5, 5, 7.5, 10, 12.5 and 15% were investigated, while F-SWPW contents of 0, 1, 2, 3, 4 and 5% were investigated. For each plastic content, specimens were prepared over a range of moisture contents and the corresponding dry densities were determined. The moisture-density relationship was plotted and the MDD and OMC were obtained from the peak of the compaction curve. No curing period was adopted because the investigation concerned the immediate physical effect of SWPW on compaction rather than chemical stabilization. Strength and durability tests such as CBR and UCS were not included in the present experimental programme.

3. RESULTS

3.1 Material Basic Properties

With a plastic limit within the range of well-graded soil and a liquid limit just above the clayey soil zone, the soil sample exhibits strong structural qualities. In Nigeria, the soil may be used as a suitable fill for rural road bases without further processing or additions.

Table 1: Basic Geotechnical Properties of the soil

Parameter	Value
Liquid Limit	45%
Plastic Limit	30%
Plasticity Index	15%
Linear Shrinkage	8.0%
Specific Gravity	2.57
Max.Dry Density	1.94g/cm^3
Optimum Moisture	13.91%

3.2 Compaction Test Results

According to the findings of the compaction test, the moisture properties of soils improve as the P-SWPW concentration rises, suggesting that the addition of specific waste materials affects these properties (U et al., 2022). According to the research, finely processed SWPW is appropriate for rural roads in Nigeria's tropical environment because it enhances surface area and water retention capacity. However, when the P-SWPW concentration rises, MDD values fall, indicating possible changes in the soil. The results support the development of sustainable infrastructure and highlight the need of giving rural road building applications considerable thought. Compaction test findings for the fiber form of Sachet Water Plastic Waste (F-SWPW) demonstrate different patterns in soil compaction values as the amount of F-SWPW grows, as seen in figures 3 and 4. Perhaps because of its finer texture, the powdered form exhibits a greater decrease in OMC and an increase in MDD when compared to the fiber form. These findings are consistent with research on soils reinforced with fiber (Akinwumi et al., 2022). Nevertheless, the present results establish only the compaction response; the observed changes should not be interpreted as evidence of improved or reduced strength without CBR, UCS or other mechanical testing.

Table 2: Compaction characteristics of lateritic soil containing powdered and fibre SWPW

SWPW morphology	SWPW content (%)	MDD (g/cm3)	OMC (%)
Powdered (P-SWPW)	0	1.94	12.90
Powdered (P-SWPW)	2.5	1.84	13.29
Powdered (P-SWPW)	5	1.75	14.00
Powdered (P-SWPW)	7.5	1.60	14.45
Powdered (P-SWPW)	10	1.50	15.50
Powdered (P-SWPW)	12.5	1.46	16.98
Powdered (P-SWPW)	15	1.33	17.51

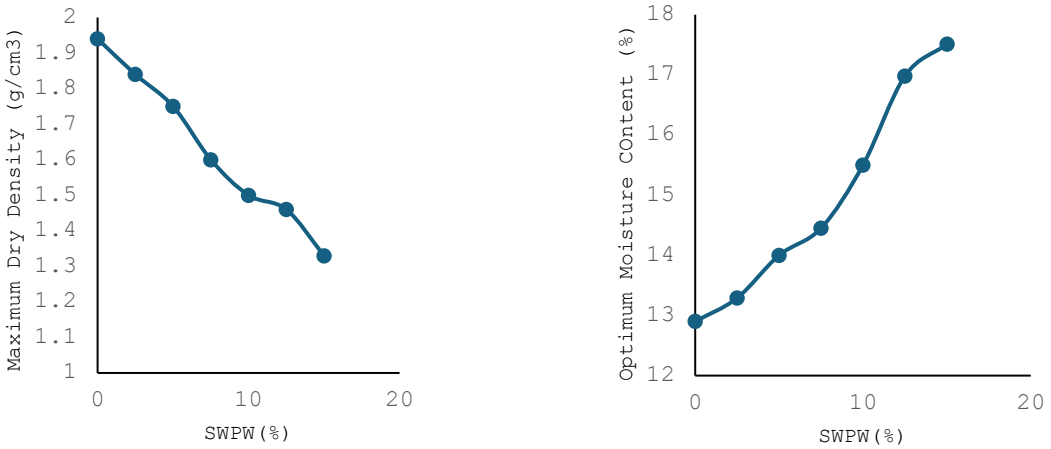

Figure 3: Variation of OMC and MDD with different % of sachet water powder

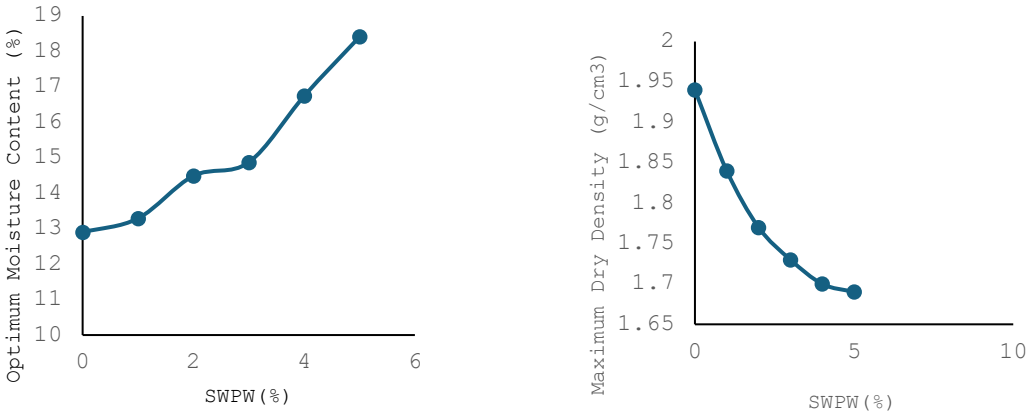

Figure 4: Variation of OMC and MDD with different % of sachet water fiber

4. CONCLUSION

This study demonstrates that the morphology and dosage of waste sachet-water plastic significantly influence the compaction characteristics of the investigated marginal lateritic soil. For P-SWPW, increasing the plastic content from 0 to 15% reduced MDD from 1.94 to 1.33 g/cm3, while OMC increased from 12.90 to 17.51%. For F-SWPW, increasing the fibre content from 0 to 5% reduced MDD from 1.94 to 1.69 g/cm3 and increased OMC to 18.41%. Thus, both morphologies produced lower dry densities and higher optimum moisture requirements, although the magnitude of the response differed with morphology and dosage. The powdered form produced the greater overall reduction in MDD, whereas the fibre form produced the highest measured OMC at 5%. These findings are useful for understanding the compaction behavior of lateritic soil containing recycled sachet-water plastic; however, they are not sufficient to establish structural suitability for road-base or subbase applications. The principal limitation of the present study is the absence of strength and durability testing and detailed physical characterization of the plastic additive. Future work should therefore include CBR, UCS or shear-strength tests, soaked/durability assessment, microstructural evaluation and field compaction trials to identify technically acceptable and environmentally sustainable SWPW contents for road earthworks.

ABSTRACT

Aluminum matrix nanocomposites are gaining prominence in automobile manufacturing due to their competitive properties. The present study explores the effect of T6-aging treatment on the selected mechanical properties of a novel nanocomposite, namely Aluminium A356 reinforced with melon husk ash nanoparticles. Melon husk ash (MHA) nanoparticles, produced from an abundant Nigerian agro-waste—Egusi melon (Citrullus colocynthis L.) husks—were used to reinforce A356 aluminium alloy through a low-frequency vibration-assisted stir casting technique. Samples of the cast nanocomposite and the unreinforced alloy were subjected to T6-aging heat treatment, after which hardness and tensile properties were determined using standard test procedures. X-ray diffraction (XRD) and optical microscopy (OPM) were used to study the microstructure of the samples. XRD patterns of the nanocomposite samples revealed the presence of α-Al, Si, β-Al_5FeSi, Mg_2Si, and SiO_2, while optical micrographs revealed a refined microstructure comprising primary α-Al dendrites, acicular Si, and a relatively even distribution of nanoparticles within the matrix of the heat-treated nanocomposite samples. Results of the mechanical tests showed that the T6-heat-treated nanocomposite exhibited improved properties over both the as-cast nanocomposite and the unreinforced samples. The tensile strength of the heat-treated nanocomposite (180.57 MPa) represented an improvement of 24.87% over the as-cast nanocomposite and 53.42% over the as-cast unreinforced sample. The ductility of the heat-treated nanocomposite (6.63%) represented a 22% improvement over the as-cast nanocomposite and a 32% improvement over the as-cast alloy. Meanwhile, the hardness value of the heat-treated nanocomposite (127.14 HV) represented an improvement of 0.9% over the as-cast nanocomposite and 55% over the as-cast alloy. In summary, the study demonstrates that MHA nanoparticles are a viable and effective reinforcement for aluminium matrix composites, and that T6-aging heat treatment offers a sustainable pathway for enhancing their mechanical properties.

1. INTRODUCTION

Metal matrix composites (MMCs) are an important class of engineering materials with attractive properties and widely used in aerospace and automotive applications (Azimi *et al.*, 2021). Although conventional composites (reinforced micron-sized particulates) may generally exhibit superior performance to their matrix alloys, they have significant drawbacks, including poor ductility and low fracture toughness compared to the bare alloys. To take care of these limitations, research focus has shifted towards developing metal matrix nanocomposites (i.e. metal matrices reinforced with nanoparticles), whereby the strength and ductility composites are improved simultaneously (Malaki *et al.*, 2020; Shayan *et al.*, 2020). This has opened the horizon for developing MMCs incorporating nanoparticles as reinforcing phase and amenable for several advanced applications.

A very common MMC used in automotive and other applications is aluminium matrix composite (AMC) owing to its lightweight and relatively good mechanical properties. The most commonly used aluminium alloys for aluminium matrix nanocomposites are those belonging to the Al-Si system owing to their high fluidity, low solidification shrinkage levels, corrosion resistance, etc. (Callegari *et al.*, 2023). When alloyed with Mg and/or Cu to form alloys like A356 Al-Mg-Si alloy, they become amenable to heat treatment, a thermal procedure used to improve their properties. The

procedure is the same for the alloys and composites developed from the alloys (Alam, 2014). The most common heat treatment procedure for modifying, particularly, the mechanical properties of Al-Si alloys containing Mg and/or Cu and their composites is the T6 age hardening or precipitation hardening (Tiwery *et al.*, 2018). The process, which basically enhances mechanical properties by forming fine precipitates that impede dislocation movement (Usman, 2026). In age-hardenable aluminium-based nanocomposites, the role of reinforcement nanoparticles during heat treatment includes accelerating the aging processes by creating more nucleation sites for precipitation within the α-Al and refining the microstructure by Zenner pinning, i.e., restricting dendritic growth and altering the dendritic grain growth morphology (Guo *et al*., 2018; Nithesh *et al.*, 2021).

Reinforcements used in fabricating the composite are mostly synthetic ceramic particulates of borides, oxides, carbides and nitrides (Samal *et al.*, 2020). However, industrial and agro waste-derived particulates are now becoming popular due to their relatively more economic viability and abundance (Parveez et al, 2021); and to date, several agro-waste materials have been successfully incorporated into metal matrices to develop composites with competitive properties. However, most of the studies have been limited to micron size agro-based reinforcements, with limited studies on nano size agro-based reinforcements (Kelsey *et al.*, 2025).

Although nanoparticles-reinforced metal matrix composites exhibit superior properties, it is very difficult through stir casting (which is the most widely used and cost-effective composite fabrication route) to achieve uniform dispersion of the nanoparticles in the matrix, due to their large surface-to-volume (Shayan *et al.*, 2020), prompting researchers to implement modifications, such as application of ultrasonic vibrations to the molten mixture among several other methods, to improve the viability of the economic and simple casting process (Malaki *et al.*, 2019).

Melon husks (MHs) are agro wastes generated from processing of *Citrullus colocynthis L.* (commonly known in most parts of Nigeria as *Egusi* melon). Nigeria was ranked the highest producer of the crop in 2018 globally (Robert *et al.*, 2021). About a decade ago, a number of materials scientist have made attempts to convert melon husks to reinforcing materials for aluminium matrix composites. The studies have investigated the effect of melon husk ash particulates on mechanical and tribological properties of aluminium-based composites (Abdulwahab *et al.*, 2017; Suleiman *et al.*, 2018; Abolusoro *et al.*, 2025 & Usman *et al.*, 2026). However, most of the studies were limited to micron-sized particulates, and the effect of T6-heat treated was not investigated by the studies. The present study therefore investigates the effect of T6 heat treatment on the hardness and tensile properties of aluminium alloy A356/melon husk ash nanocomposite.

2. METHODOLOGY

2.1 Materials

The matrix is A356 aluminium alloy wheel scraps (AAWS), sourced from an automobile service center located at Zaria, Kaduna State of Nigeria. Chemical composition of the matrix alloy is shown in Table 1. The Si composition is slightly below that of a standard A356, consistent with previous studies on automobile aluminium alloy wheel (Song *et al.*, 2012). Melon husk ash nanoparticles (MHAnp) of average particle size 57.53 nm as reinforcement in this study was synthesized through thermal treatment and mechanical milling. Details of the synthesis route and characterization of the reinforcement (see Figures 1a &b) are reported in another study (Usman, 2026). Chemical composition of the MHAnp determined using X-ray florescence spectroscopy shows it is composed of SiO_2 as the constituent present in the largest amount, as shown in Table 2.

a b

Figure 1: (a) Melon husks and (b) Melon husk ash

Table 1: *Chemical composition of aluminium alloy wheel scraps (AAWS)*

Element	**Weight %**
Al	91.87
Si	6.22
Mg	0.33
Cu	0.02
Fe	0.27
Mn	0.03
Sr	0.01
Others	Balance

Table 2: *Chemical composition of melon husk ash nanoparticles (MHAnp)*

Composition	**Weight %**
SiO_2	39.50
K_2O	8.23
Al_2O_3	8.44
MgO	6.53
CaO	7.66
P_2O_5	15.00
Fe_2O_3	6.09
SO_3	1.70
Na_2O	1.75
SnO_2	1.89
TiO_2	0.92
ZnO	3.90

2.2 Fabrication of A356/MHAnp Samples

Al-Mg-Si alloy matrix composites reinforced with 3.5 vol. % melon husk ash nanoparticles (MHAnp) was produced by stir-casting process. The nanocomposite was fabricated by charging 795g of aluminium alloy wheel scrap (AAWS) pieces into a graphite crucible, heating the charge to a temperature of 800ºC and holding at the same temperature for a length of time sufficient for complete melting of the matrix alloy. The temperature of the melt was then lowered to 600ºC where it was semi-sold and 3.5 vol. % of MHA nanoparticles (preheated at 350ºC for 1 hour) added to it and the mixture stirred continuously at a speed of 400 rpm for 7 minutes. 4 wt. % Mg (with respect to the matrix alloy) wrapped in an Al foil was added to compensate for losses during melting and to improve wettability. The temperature of the melt was then raised to 750ºC and the molten mixture agitated for 2 minutes by dipping a probe resonating at a frequency of 60Hz (power output: 150W; voltage: 220V) to improve

dispersion of the nanoparticles in the matrix before pouring into a prepared sand mold. A control sample of the unreinforced alloy was also produced for comparison of properties.

2.3 Heat Treatment

Cast composite samples were subjected to T6 heat treatment, which involved successive solution treatment and artificial aging. The unreinforced alloy and nanocomposite specimens were subjected to T6 aging treatment which entails solution treatment at 540^{o}C for 6 hours followed by water quenching at room temperature, and a final step of artificial aging at 155^{o}C for 5 hours in accordance with the study by Haskel *et al.* (2018) on A356 wheels. X-ray diffraction (XRD) analysis and optical microscopy were conducted to study phases and morphologies of the heat-treated specimens, respectively.

2.4 Characterization

Microstructural examination: To study the morphological features of the samples, samples of dimensions ø15 x 10 mm were machined and polished using emery clothes meshed 300, 600, 800, 1200 and 2400, successively. Alumina suspension (0.05 lm) was then subsequently used for final polishing. Thereafter, the samples were submerged in Keller's reagent and etched for 30s. Subsequently, the samples were washed and dried for microstructural observation and capturing under an optical metallurgical microscope equipped with an inbuilt camera (Model No.: NJF:-12A). The microstructures were captured at a magnification of x100. The phases present in the samples were also studied using X-ray diffraction (XRD) analysis.

Tensile test: Tensile test was performed in accordance with ASTM E-8 standard on Electronic Universal Testing Machine (Model: WDW-100KN, S/No.: 190536). Three standard tensile test samples were machined from each cast sample and tested for tensile properties on the universal testing machine at a crosshead speed of 10cm/min. Average of three observations was recorded as tensile strength and percent elongation of the sample, as the case may be.

Hardness test: Hardness values of the samples were determined using a Vicker's micro-hardness tester (Model: MV1-PC, machine no: 07/2012-1329) in accordance with ASTM E-384 standard. Samples of dimensions ø15 x 10 mm were prepared for the test. An average of three observations were taken from indentations at different points on a polished surface of each sample with a load of 0.3 Kgf at 15 seconds dwell time.

3. RESULTS AND DISCUSSION

3.1 XRD Patterns of the Samples

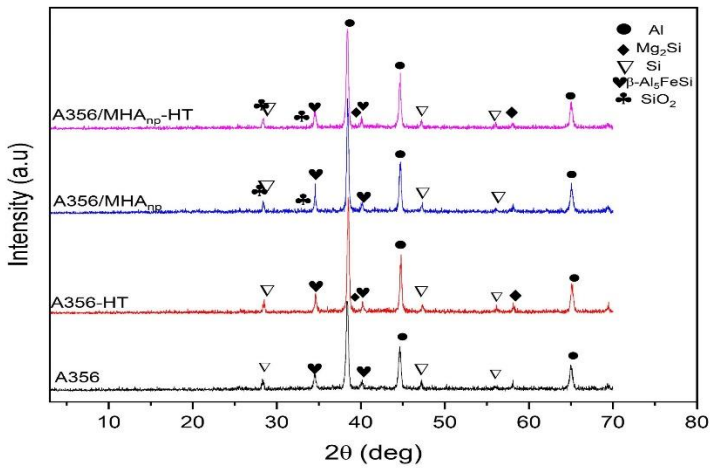

Figure 2: XRD patterns of the samples in as-cast and T6 heat-treated conditions

The XRD patterns of the alloy and nanocomposite samples, in both as-cast and T6-heat treated states, are depicted by Figure 2. The XRD patterns of the samples analysed using MDI Jade 6 software

show the presence of α-Al, Si, Mg, Mg_2Si, β-Al_5FeSi and SiO_2. The XRD spectrum of A356 has the peaks (111) at 2θ= 38.473°, (200) at 2θ = 44.722° and (220) at 2θ = 65.099° corresponding to Al (PDF card no. 99-005); the peaks (111) at 2θ = 28.443°, (220) at 2θ = 47.304° and (311) at 2θ = 56.124° corresponding to Si (PDF card no. 99-0092); and minor peaks (111) at 2θ = 34.594° and (220) at 2θ = 40.165° corresponding to FeSi intermetallic compound , Al5FeSi (PDF card no. 38-1397). Mg is also detected overlapping Si at 2θ = 47.304°. These peaks are common to the other samples, except the peaks (211) at 2θ = 28.794 ° and (212) at 2θ = 33.127° corresponding to SiO_2 (PDF card no. 47-1300) present in A356/MHAnp and T6-heat treated A356/MHAnp, which could be from the agro-waste-derived reinforcement— melon husk ash nanoparticles. There are also other peaks present in the T6-heat treated alloy and nanocomposite samples, i.e., (220) at 2θ = 40.121° and (400) at 2θ = 58.028° corresponding to Mg_2Si precipitates (PDF card no. 35-0773). This finding is in agreement with previous studies on Al-Mg-Si alloys (Lakshmikanthan *et. al*., 2020).

3.2 Tensile Properties of the Samples

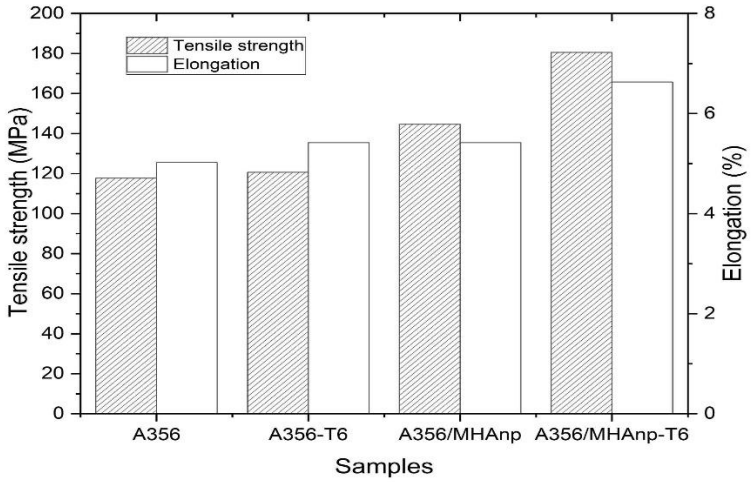

Figure 3: Tensile properties of samples in as-cast and heat-treated conditions

Figure 3 shows the tensile properties of the alloy and the nanocomposite samples, in the as-cast and heat-treated states. The tensile strength values are 117.70, 120.61, 144.60 and 180.57 MPa for A356, A356-T6, A356/MHAnp and A356/MHAnp-T6, respectively, and the percent elongation values are 5.02, 5.42, 5.42 and 6.63 for A356, A356-T6, A356/MHAnp and A356/MHAnp-T6, respectively. The improvement in tensile properties on addition of melon husk nanoparticles can be attributed to the resultant grain refinement and the action of the nanoparticles as barriers to dislocation movement, i.e. Orowan strengthening, thereby overcoming the traditional strength-ductility trade-off and simultaneously improving both properties (Singhal *et al.*, 2025). Similar observations were made by Li *et al.* (2019). Both alloy and nanocomposite samples in the T6-heat treated state also exhibited better tensile properties than the as-cast samples, an observation attributable to the strengthening effect of Mg_2Si precipitates in the heat-treated samples (Alam, 2014). The heat treatment condition may however require optimization as improvements in ductility are marginal.

3.3 Hardness of the Samples

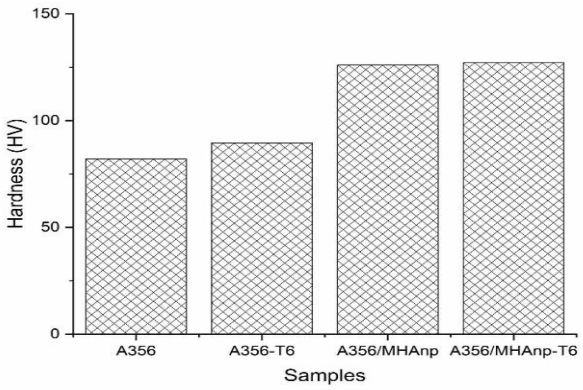

Figure 4: Hardness values of samples in as-cast and heat-treated conditions

Figure 4 shows the hardness values of the alloy and the nanocomposite samples, in the as-cast and heat-treated states. The micro hardness values are 82.00, 89.50, 126.00 and 127.14 HV for A356, A356-T6, A356/MHAnp and A356/MHAnp-T6, respectively. The results show significant enhancement in hardness by addition of melon husk nanoparticles to the alloy, underscoring the effectiveness of the nanoparticles in strengthening the Al alloy matrix. This observation can be attributed to increased dislocation density and grain refinement (Salur *et al.*, 2021). While noticeable improvement in hardness was observed for the alloy after heat treatment due to microstructural modifications and precipitation of the strengthening phase Mg_2Si, the improvement for the composite was negligible. The already high nanoparticle-induced hardness may have limited precipitation strengthening effects for the composites.

3.4 Microstructures of the Samples

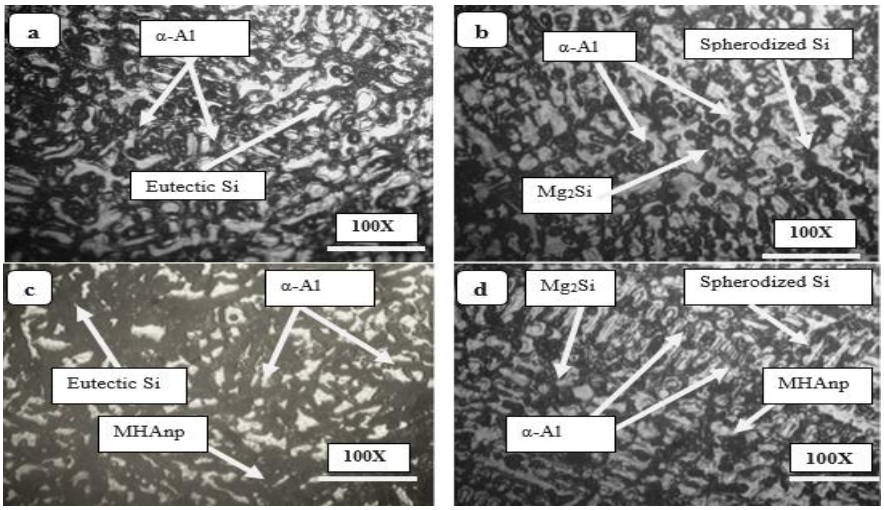

Plate I: Optical micrographs of (a) as-cast A356 alloy, (b) A356-T6 alloy, (c) as-cast A356/MHAnp composite and (d) A356/MHAnp-T6 composite; Etchant: Keller's reagent.

The microstructures of the alloy and nanocomposite samples, in both as-cast and T6-heat treated states, are depicted by the micrographs in Plates I (a-d).

The micrograph of the as-cast A356 sample in Plate I (a) shows dendritic structure of α-Al and acicular eutectic Si. In the micrograph of the T6-heat treated sample, in Plate I (b), spherodized Si and Mg_2Si precipitates are obvious in the matrix, which may have been responsible for the comparatively better mechanical properties of the heat treated sample. The micrograph in Plate I (c) depicts the microstructure of as-cast A356/MHAnp sample. The microstructure is finer than that of the alloy, which may have resulted from nanoparticles locking the grain boundaries and preventing excessive grain growth during cooling (Shayan *et al.*, 2020). The microstructure is made up of primary α-Al dendrites,

acicular Si and a relatively even distribution of nanoparticles. Some agglomeration are also noticeable at some spots, which may have been the cause for the marginal improvements in the tensile strength and ductility (Hoziefa *et al.*, 2016). The micrograph in Plate I (d) depicting the microstructure of the T6-heat treated nanocomposite sample shows the presence of continuous α-Al dendrite, spherodized Si, Mg_2Si precipitates and a relatively uniform distribution of MHAnp.

4. CONCLUSION

This study demonstrates that T6-aging heat treatment significantly enhances the mechanical properties of A356 aluminium alloy reinforced with melon husk ash (MHA) nanoparticles, based on the following key findings:

1. A356/MHAnp nanocomposites were successfully produced via low-frequency vibration-assisted stir casting, utilizing MHA nanoparticles derived from Nigerian Egusi melon husk agro-waste as a sustainable reinforcement.
2. XRD analysis confirmed the presence of α-Al, Si, β-Al_5FeSi, Mg_2Si, and SiO_2 phases, while optical microscopy revealed a refined microstructure with a relatively uniform nanoparticle distribution following heat treatment.
3. T6-aging improved tensile strength to 180.57 MPa, representing gains of 24.87% and 53.42% over the as-cast nanocomposite and unreinforced alloy, respectively.
4. Ductility of the heat-treated nanocomposite improved by 22% and 32% over the as-cast nanocomposite and alloy, respectively, indicating enhanced deformability alongside increased strength.
5. Hardness reached 127.14 HV, an improvement of 0.9% and 55% over the as-cast nanocomposite and unreinforced alloy, respectively.
6. Overall, MHA nanoparticles are an effective and sustainable reinforcement for A356 alloy, and T6-aging offers a practical pathway for optimizing its mechanical performance, positioning A356/MHAnp as a promising lightweight material for automotive applications.

ABSTRACT

High-volume substitution of natural coarse aggregates with Recycled Concrete Aggregate (RCA) typically impairs mechanical strength and increases water absorption due to the porous residual mortar layer. This study investigates the performance improvement of Grade 25 concrete incorporating 100% RCA through the pozzolanic addition of Rice Husk Ash (RHA) as a partial Portland cement replacement. Characterization via X-ray Fluorescence (XRF) confirmed RHA as a reactive pozzolan with a combined oxide composition ($SiO_2 + Fe_2O_3 + Al_2O_3$*) of 89.47%. Concrete mixes were prepared with 0%, 10%, 15%, and 20% RHA substitution levels at a fixed water-cement ratio of 0.57. Experimental results demonstrate that incorporating 15% RHA counteracts RCA-induced strength losses, yielding a 28-day compressive strength of* $25.9\ N/mm^2$ *(an 18.8% enhancement over the unblended RCA control), a splitting tensile strength of* $2.5\ N/mm^2$*, and a reduced water absorption of 1.23%, meeting BS 812-2 durability standards. Combining 15% RHA with 100% RCA effectively remediates microstructural weaknesses inherent in recycled aggregate matrices.*

Keywords: *Rice husk ash; Recycled concrete aggregate; Sustainable concrete; Microstructural improvement; Compressive strength; Water absorption*

1. INTRODUCTION

Sustainable construction practices have become necessary in contemporary civil engineering, driven by the urgent need to reduce negative environmental impacts and promote resource efficiency. In this context, the utilization of alternative materials in concrete production has emerged as a promising avenue to enhance sustainability in construction projects. This study aims to investigate the effects of incorporating rice husk ash (RHA) as partial replacement of cement and recycled concrete aggregate (RCA) as coarse aggregate on the performance and sustainability of concrete mixtures for construction applications.

Sustainable construction embodies principles aimed at minimizing environmental impact, conserving resources, and fostering societal well-being throughout the lifecycle of built infrastructure (Barlow, 2019). By integrating environmental, social, and economic considerations, sustainable construction practices seek to address global challenges such as climate change, resource depletion, and waste generation (Nawaz et al., 2020).

One of the primary challenges is the limited understanding of the performance of concrete mixtures containing RHA and RCA. Without a clear understanding of the mechanical, physical, and durability properties of concrete incorporating RHA and RCA, construction stakeholders may hesitate to adopt these materials in real-world applications. The integration of RHA and RCA into concrete mixtures may pose challenges in terms of compliance with existing standards, specifications, and regulatory requirements. Traditional concrete standards often do not account for the use of alternative materials, leading to ambiguity and confusion among designers, engineers, and regulators. Additionally, the lack of standardized testing protocols for evaluating the performance of concrete containing RHA and RCA further complicates the adoption process. Establishing clear guidelines and standards for

incorporating alternative materials into concrete mixtures is essential to ensure their widespread acceptance and use in construction projects. Finally, the lack of awareness and acceptance among construction stakeholders, including designers, contractors, developers, and policymakers, presents a significant barrier to the widespread adoption of RHA and RCA in construction projects. Many stakeholders may be unfamiliar with the properties, benefits, and limitations of these alternative materials, leading to skepticism and resistance to change. Building awareness, disseminating knowledge, and fostering collaboration among stakeholders are crucial steps towards overcoming this challenge and promoting the adoption of sustainable construction practices.

The significance of this study lies in its potential to advance sustainable construction practices by evaluating the performance of rice husk ash (RHA) as partial replacement of cement and recycled concrete aggregate (RCA) as coarse aggregate in concrete mixtures. The utilization of RHA and RCA offers significant environmental benefits by reducing the demand for virgin raw materials, conserving energy, and mitigating greenhouse gas emissions associated with traditional concrete production methods. The integration of RHA and RCA into concrete mixtures promotes resource conservation by utilizing waste materials that would otherwise be disposed of in landfills. By diverting waste streams from landfills and incorporating recycled materials into new construction projects, the construction industry can minimize its environmental footprint and contribute to resource efficiency.

The aim of this study is to evaluate the Effect of rice husk ash (RHA) as partial replacement of cement and recycled concrete aggregate (RCA) as coarse aggregate in concrete mixtures for sustainable construction applications. The following are the objectives: To investigate the chemical composition of rice husk ash so as to assess its level of pozzolanic content, To determine the properties of constituent materials used in this research to assess their suitability and conformity with standards, To carryout concrete mix design that will be used in this work, To investigate the mechanical properties of concrete mixtures containing varying proportions of rice husk ash as partial replacement for cement and recycled concrete aggregate as coarse aggregate, To determine the percentage replacement of cement with RHA that will produce optimum result.

Un-modified RCA concrete consistently exhibits lower compressive strength and higher permeability due to microcracks and old adhered mortar (Kou et al., 2011; Tam et al., 2012). This study investigates a microstructural remediation approach using 15% RHA to counteract RCA-induced strength degradation and restore Grade 25 concrete capacity[cite: 8, 10].

2. METHODOLOGY

Concrete Mix Design:

The concrete mix design was carried out using the Building Research Establishment (BRE) method. A mix ratio of 1:1.98:3.52 and water cement ratio of 0.57 from the concrete mix design was arrived at for this research. Concrete cubes of dimensions 150mm x 150mm x 150mm and cylinders with dimensions 100mm x 200mm were produced by partially replacing cement (Dangote). Rice husk ash (RHA) variation is at 0%, 10%, 15%, and 20%, the cube samples were cured in water for 7, 14, and 28 days and subjected to compressive and tensile strengths. A mix proportion of 1:1.98:3.52 with water cement ratio w/c 0.57 was achieved for Grade 25 (G25) in accordance with BS EN 197-1 (2005).

Preliminary Preparation of Rice Husk Ash Sample

The Rice Husk was cleaned and dried for 3 weeks so it would lose all its moisture content. It was burnt to ash using an incinerator in the department of Building, A.B.U Zaria. The ash after cooling was ball milled to further reduce the size and later grind. The rice husk was calcined at $700^{\circ}C$ in a controlled incinerator. This temperature transforms amorphous silica into optimal reactive pozzolanic silica without forming crystalline quartz phase silica, which occurs above $800^{\circ}C$ and reduces pozzolanic reactivity (Prasittisopin & Trejo, 2014; Thomas & Gupta, 2016).

METHODS

The tests carried out were physical and chemical for the determination of the physical and chemical properties of the materials used and effect of partial replacement of cement with rice husk ash

and a full replacement of coarse aggregate with recycled concrete aggregate on the properties of this sustainable concrete.

Test Equipment used

The following equipment in the heavy structures and concrete material laboratory are to be used in the course of these experiments:

1. Weighing Scale.
2. B. S. Sieves.
3. Concrete Moulds.
4. Rammer/Tamping rod.
5. Compression Testing Machine.
6. Tensile Testing Machine.
7. Slump cone.
8. Concrete mixer.
9. Vibrating table.

Casting and Curing of Concrete

Before casting the cubes, the 150mm x 150mm x 150mm steel cube moulds used were tightened, cleaned and oiled. The essence of oiling it is to facilitate easy and smooth demoulding of the concrete after hardening. The concrete mix was then poured into the moulds in 3 layers. The concrete was tamped 25 blows before adding another layer of concrete to the mould. This is to ensure that air bubbles are driven out and that the concrete is properly compacted. Excess concrete on the mould or on the floor was removed in time to avoid it from hardening. The surface of the concrete was then leveled and allowed to harden slightly before being marked for identification. The samples were demoulded after 24 hours and immediately immersed in clean water in a tank for curing. Curing is a process of hydrating the concrete samples which leads to increase in strength.

Compressive Strength test

Compressive strength test was carried out on the concrete in accordance to BS EN 196-1 (2005). The compressive strength test was conducted on cubes of 150mm x 150mm x 150mm mixed concrete using the compressive testing machine of 2500kN capacity (Denison) at the heavy structures and concrete laboratory of A.B.U, Zaria. The failure load was observed and recorded and the compressive strength in N/mm^2 was calculated from the equation below.

$Rc = Fc/A$ (N/mm^2)

Where, Rc is the compressive strength, in Newton per millimeters square,

Fc is the maximum load at fracture, in Newton and,

A is the area of the concrete sample in square millimeters.

Tensile Strength test

The tensile strength test was conducted on cylinders of 100mm x 200mm mixed concrete in an indirect form using the compression testing machine at the heavy structures and concrete laboratory of A.B.U, Zaria. The failure load was observed and the tensile strength in N/mm^2 was calculated from the equation below

$MC = 2P/\pi DH$

Where, MC is the tensile strength, in newton per millimeters square,

P is the maximum load at fracture, in newton and,

D and H are diameter and length of the cylindrical concrete sample respectively.

Water Absorption test

Water absorption test was carried out to determine the water absorption value of the mixed concrete, expressed in percentage. This property is particularly important in mortar and concrete used for water-retaining structure or watertight basement, as well as being critical for durability. This test was performed on a 150mm x 150mm x 150mm cube specimens prepared in the laboratory. Water absorption measurements were done by weighing the saturated specimens (Ws) and dried specimens (Wd) which was oven dried at $110^{\circ}C$ for 24 hours at curing time 28 days. The water absorption was calculated using equation below

$$\text{Water absorption (\%)} = \frac{Ws - W}{Wd} \times 100$$

Specimen Replication and Statistical Design

To ensure statistical reliability and reproducible results, three ($n = 3$) replicate 150 mm $\times$ 150 mm $\times$ 150 mm cube specimens were prepared and tested for each mix proportion (0%, 10%, 15%, and 20% RHA) at each curing age (7, 14, and 28 days), yielding a total of 36 compressive strength specimens. Similarly, three ($n = 3$) cylindrical specimens (100 mm $\times$ 200 mm) and three ($n = 3$) durability samples were cast per mix design for splitting tensile strength and 28-day water absorption testing, respectively. Mechanical and physical test values are reported as the arithmetic mean $\pm$ standard deviation (SD).

3. RESULTS AND DISCUSSION

Table 4.1: Result of Standard consistency test of cement

Test	Weight of Cement (g)	Vol. of Water (ml)	Penetration (mm)	Consistency (%)
1	400	122	5.0	30.5
2	400	120	5.5	30.0
3	400	122	6.0	30.0
	Average Consistency (%)		**30.2**	

Source: Laboratory test (2024)

The result of 30% average consistency in Table 4.1 implied a good result as the plunger penetrations were between 5mm-7mm from the base of the mould. It is in line with BS EN 196-3 (2016) which stipulates consistency of cement to be between 26% and 33%. This conforming result is not unconnected with the freshness of the cement used and procedure of BS EN 196-3 (2016) that was followed.

Table 4.2: Result of Setting time test of cement

The results of the tests carried out in the course of this research are presented and discussed with respect to literatures and standard codes of practice.

Test	Weight of Cement (g)	Vol. of Water (ml)	Penetration (mm)	Initial Setting Time(hrs:min)	Final Setting Time(hrs:min)
1	400	122	7.0	1:59	2:34
2	400	120	6.0	2:04	2:47
3	400	122	6.0	1:48	2:38
	Average Initial Setting Time = 1hr. 57mins				
	Average Final Setting Time = 2hrs. 40mins				

Source: Laboratory test (2024)

The average initial setting time and average final setting time as in Table 4.2 are within specifications of greater than 45minutes and less than 10 hours respectively. These results satisfied BS EN 196-3 (2016) and in line with Ejeh (2017). The cement is fit for the production of concrete and other masonry works. Setting time tests were conducted on unblended Portland Limestone Cement (PLC)

paste to establish baseline raw material compliance in accordance with BS EN 196-3 (2016). The binder exhibited an initial setting time of 1 hr 57 mins and a final setting time of 2 hrs 40 mins, satisfying standard requirements (>45 mins and <10 hrs). While RHA blending generally retards hydration slightly due to water absorption, baseline cement tests were prioritized to verify binder quality prior to batching.

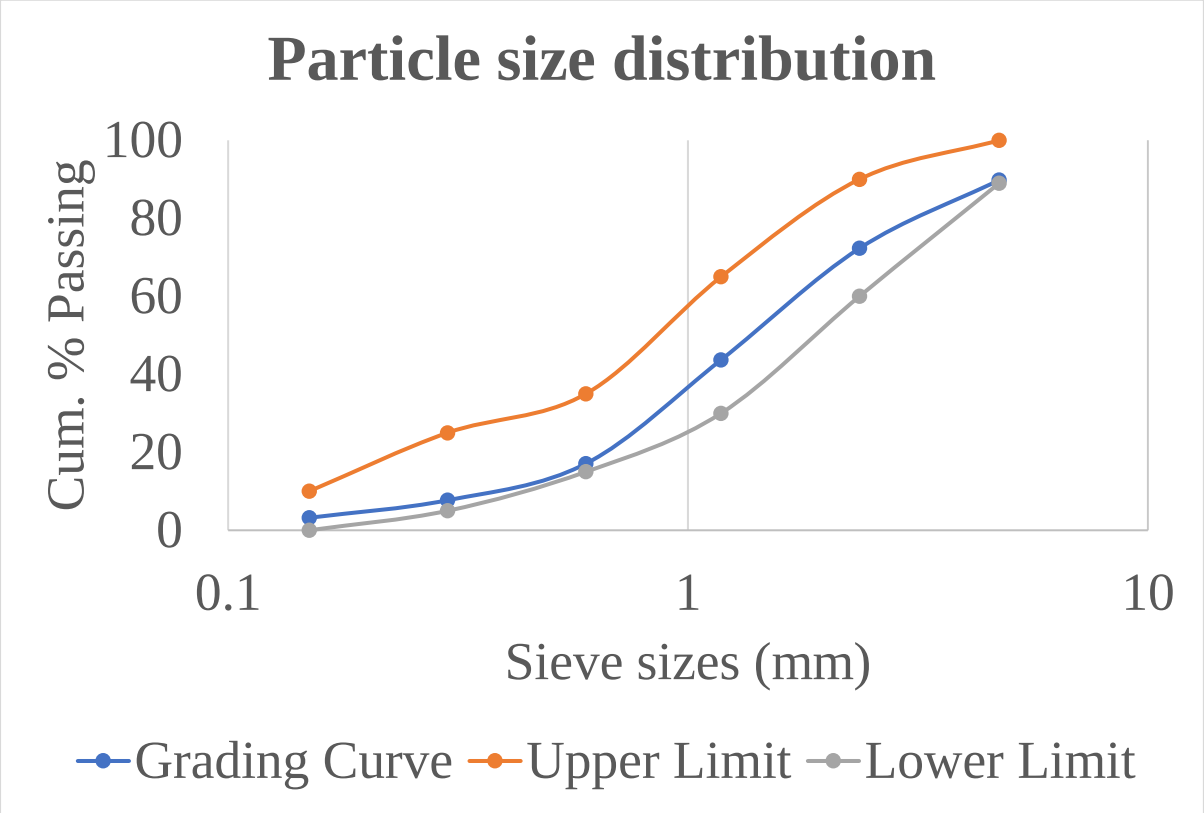

Figure 4.1: Particle Size Distribution Curves for Zone 3 (Fine Aggregate)

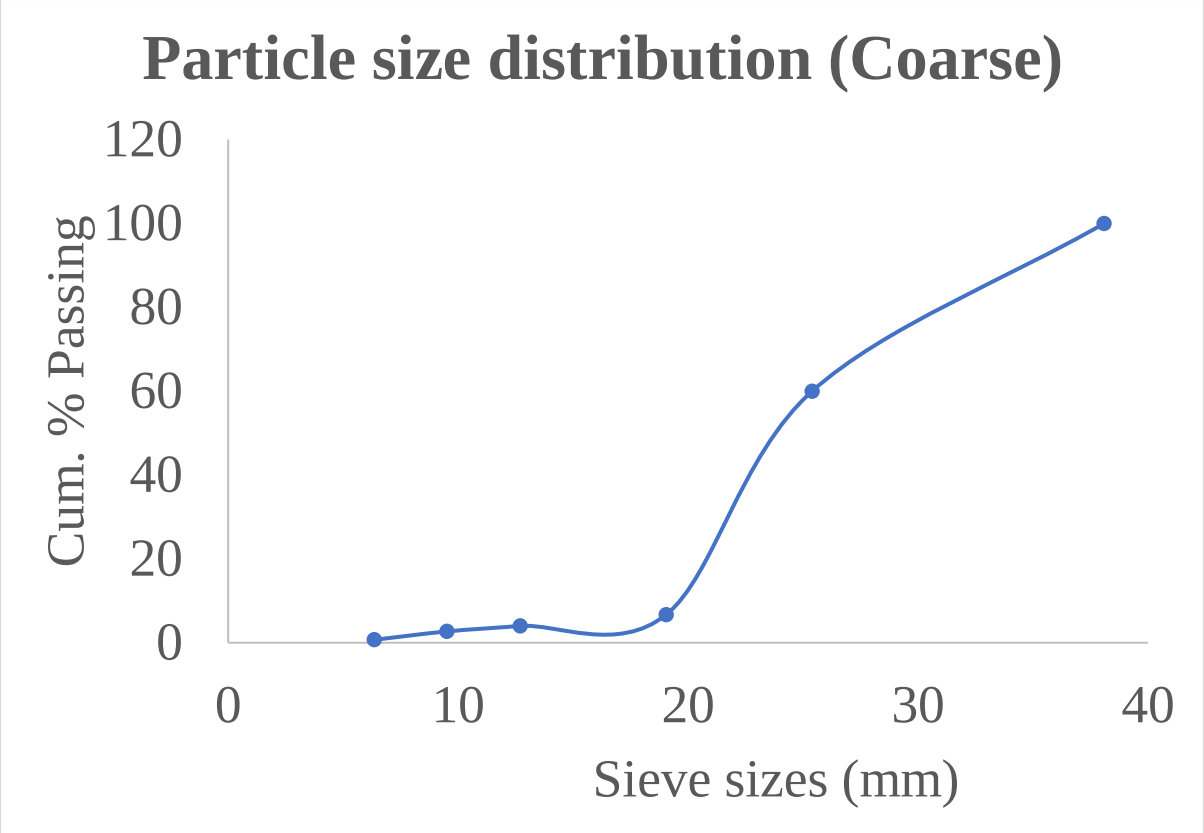

Figure 4: 2 Particle Size Distribution Curve for Coarse Aggregate

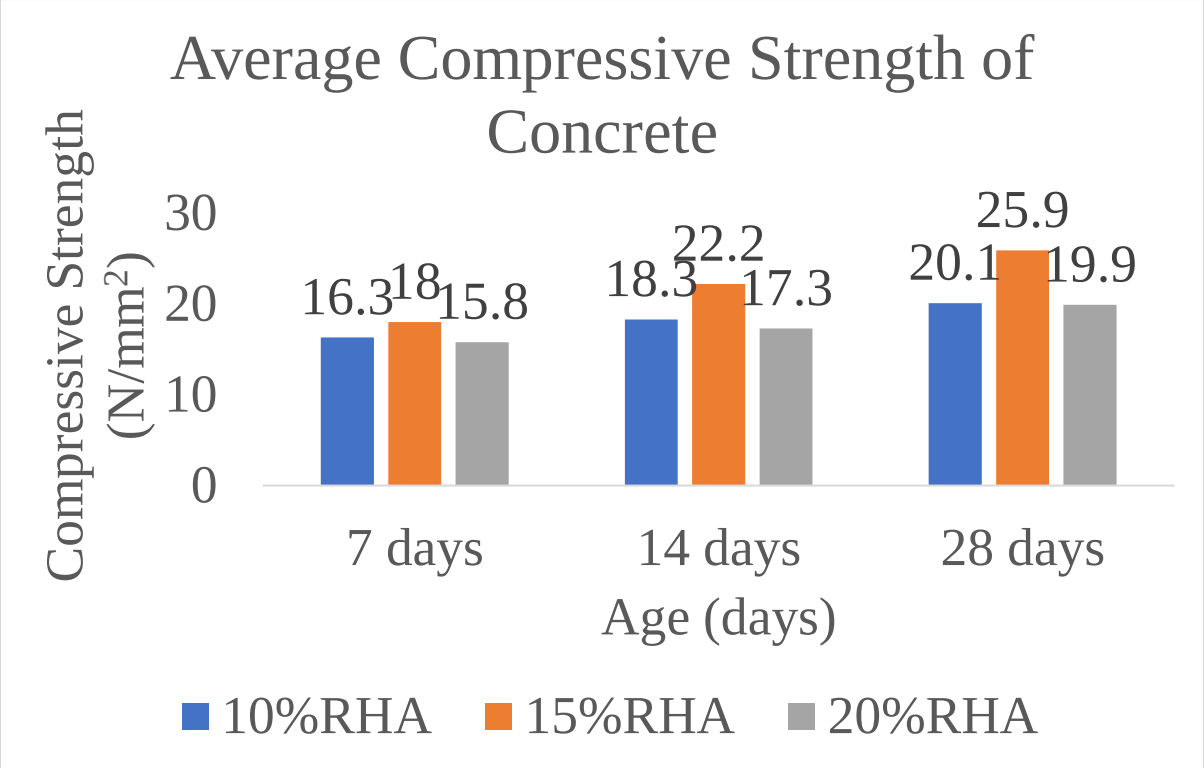
The result in Figure 4.1 conformed to BS EN 933-1 (2012) with a fineness modulus of 3.662. From the result of the sieve analysis, the sample is of zone 3 having a coarse grain size. From Figure 4.1 it can be seen that the sample falls within the standard upper and lower limits therefore good for the production of concrete.



The result in Figure 4.2 with Fineness modulus of 4.259 indicates a coarser aggregate. This is also supported by BS EN 933-1 (2012).

Table 4.3: Result of Chemical composition of Rice Husk Ash

CHEMICAL COMPOSITION	RICE HUSK ASH (%)
SiO_2	87
Fe_2O_3	1.29
Al_2O_3	1.18
C	17.24
CaO	1
K_2O	1.32
$SiO_2 + FeO_3 + Al_2O_3$ = 89.47 %	
Carbon / Loss on Ignition	(LOI)17.24%
Calcium Oxide (CaO)	1.00%
Potassium Oxide	(K_2O)1.32%

Source: Laboratory test (2024)

Table 4.3 presents the sum of pozzolanic oxides (89.47%) exceeds the 70% minimum threshold specified by ASTM C618 for Class F/N pozzolans, confirming high pozzolanic reactivity. The LOI value reflects residual unburnt carbon from controlled incineration.

Source: Laboratory test (2024)

Figure 4.3: Average Compressive Strength of concrete with partial replacement of PLC with RHA

Figure 4.3 showed 15% RHA replacement produced higher compressive strength for both 7 days and 14 days curing ages. It is observed that the 28 days compressive strength of concrete with 15% replacement of RHA produced a strength of 28.85% and 30.15% higher than 10% and 20% RHA replacement respectively. The strength increase can be attributed to the interaction of microstructural mechanisms during which the pores in the mix are filled by the presence of RHA (Pornkasem et al., 2018).

The increase in strength is also supported by Jangral et al., (2022). In their work they found increase in strength as RHA percentage increases but declined beyond 15%. It is also in line with Bapat et al. (2004) who inferred that strength increases with age as evidenced in figure 4:3 even with the addition of a supplementary cementing material. The rice husk ash also served as filler of the pores in the concrete which made the concrete more compact, dense and durable. 100% RCA introduces a double Interfacial Transition Zone (ITZ)—between the original aggregate and old mortar, and between old mortar and new cement paste. This dual ITZ increases overall porosity and reduces compressive strength. However, the inclusion of 15% RHA counteracts this deficit. The micro-silica in RHA reacts with free calcium hydroxide $[Ca(OH)_2]$ released during cement hydration, forming additional secondary Calcium Silicate Hydrate (C-S-H) gel that densifies the ITZ and fills micro-voids.

The drop in 28-day compressive strength at 20% RHA ($19.9\ N/mm^2$) is attributed to the **cement dilution effect**. Excessive cement substitution reduces the primary $Ca(OH)_2$ concentration required to sustain the pozzolanic reaction, leaving unreacted RHA particles that act as structural weak points rather than binding matrices.

Table 4.4: Fresh Workability (Slump) Test Results

Mix Identification	RHA Content (%)	Coarse Aggregate Type	Water/Cement Ratio (w/c)	Measured Slump (mm)	Slump Type
Control (0% RHA)	0%	Natural Aggregate	0.57	65	True Slump
RCA-0% RHA	0%	100% RCA	0.57	48	True Slump
RCA-10% RHA	10%	100% RCA	0.57	38	True Slump
RCA-15% RHA	15%	100% RCA	0.57	30	True Slump
RCA-20% RHA	20%	100% RCA	0.57	22	Shear/Low Slump

Workability decreased progressively with increasing RHA replacement levels and complete substitution of natural aggregate with RCA. RCA exhibits higher initial water absorption due to adhered porous mortar. Concurrently, the high specific surface area and cellular porous structure of RHA particles increase water demand, leading to reduced slump values.

Table 4.5: Baseline Mechanical and Physical Properties of Control vs. Experimental Mixes (28 Days)

Concrete Mix Parameter	**Control (0% RHA + Natural Coarse Agg.)**	**RCA Baseline (0% RHA + 100% RCA)**	**RCA + 10% RHA**	**RCA + 15% RHA (Optimum)**	**RCA + 20% RHA**
28-Day Compressive Strength (N/mm^2)	**27.4**	**21.8**	**20.1**	**25.9**	**19.9**
28-Day Tensile Strength (N/mm^2)	**2.8**	**2.1**	**2.0**	**2.5**	**1.8**
Water Absorption (%)	**0.85%**	**2.10%**	**1.65%**	**1.23%**	**1.80%**

Table 4.6: Splitting Tensile Strength and Water Absorption across All Replacement Levels

Mix Designation	**RHA Replacement (%)**	**Splitting Tensile Strength (N/mm2) [28 Days]**	**Water Absorption (%) [28 Days]**
Control Mix	**0% (Natural Agg)**	$\mathbf{2.8 \pm 0.12}$	**0.85%**
RCA Control	**0% (100% RCA)**	$\mathbf{2.1 \pm 0.10}$	**2.10%**
RCA-10% RHA	**10%**	$\mathbf{2.0 \pm 0.15}$	**1.65%**
RCA-15% RHA	**15%**	$\mathbf{2.5 \pm 0.11}$	**1.23%**
RCA-20% RHA	**20%**	$\mathbf{1.8 \pm 0.14}$	**1.80%**

4. CONCLUSION

From this research, the following conclusions are drawn

- The oxide composition of the RHA used is 89.47% which is above the minimum specified oxide content of 70%. Therefore, it is a good pozzolan.
- The result of the physical properties of the basic constituent materials used in this research indicated satisfaction and in line with standard codes of practice including the British Standard Institution.
- The design of Grade 25 concrete was carried out and the materials mix ratio was 1:1.98:3.52 with water/cement ratio of 0.57 (W/C=0.57)
- The 28 days compressive strength for 10%, 15% and 20% of RHA are 20.1 N/mm^2, 25.9 N/mm^2 and 19.9 N/mm^2 respectively. The 15% cement replacement gave the optimum compressive strength with a corresponding tensile strength of 2.5 N/mm^2. The Water Absorption capacity of the 15% cement replacement concrete was 1.23% which is within the specifications of BS 812: part 2 (1995).

- The optimum mechanical properties like compressive strength, water absorption capacity of the concrete was achieved at 15% cement replacement level.

RECOMMENDATION

From the research, it is found that the optimum mechanical properties like compressive strength, water absorption capacity of the concrete were achieved at 15% cement replacement level. Therefore, it is recommended that in the concrete mix cement should be replaced with Rice Husk Ash by 15%.

ABSTRACT
The growing demand for environmentally sustainable construction materials has stimulated interest in incorporating agricultural waste products into concrete production. This study investigates the mechanical performance and optimization of doum palm fibre (DF)-reinforced concrete containing rice husk ash (RHA) as a partial replacement for Portland limestone cement. A multilevel factorial experimental design based on Response Surface Methodology (RSM) was employed to evaluate the combined influence of RHA replacement (0–25%) and DF content (0–2%) on compressive strength, flexural strength, split tensile strength, and punching shear strength. Predictive regression models were developed using Design-Expert software and assessed through analysis of variance (ANOVA), coefficients of determination (R^2), and residual diagnostics. Quartic polynomial models adequately represented all responses, with predicted, adjusted and coefficients of determination ranging from 0.9529 to 0.9914. Numerical optimization identified an optimum mixture containing 2.0% DF and 10.45% RHA, producing predicted compressive, flexural, split tensile, and punching shear strengths of 18.010 MPa, 5.370 MPa, 4.420 MPa, and 1.053 MPa, respectively, at 56 days. Experimental validation showed prediction errors below 5%, confirming the reliability of the developed models. The findings demonstrate that response surface methodology provides an effective tool for optimizing sustainable fibre-reinforced concrete mixtures while reducing experimental effort. The combined use of rice husk ash and doum palm fibre offers a viable approach for producing environmentally friendly concrete with satisfactory mechanical performance.

1. INTRODUCTION

Concrete remains one of the most widely used construction materials worldwide because of its versatility, durability, structural performance, and ability to withstand diverse environmental conditions (Habert et al., 2020; Olsson *et al*., 2023). Rice husk ash (RHA), an agricultural by-product generated from the controlled combustion of rice husks, has emerged as a promising SCM owing to its high silica content and pozzolanic reactivity. Several recent studies have reported that the appropriate partial replacement of cement with rice husk ash can improve concrete compressive strength (Al-Alwan *et al*., 2024).

Although numerous studies have examined the individual effects of RHA or fibre reinforcement on concrete performance, limited information is available regarding the combined influence of RHA and doum palm fibre on both conventional strength properties and punching shear behaviour of reinforced concrete flat slabs. Furthermore, predictive models capable of optimizing these properties simultaneously remain scarce. Therefore, this study investigates the performance optimization of doum palm fibre-reinforced concrete incorporating rice husk ash as a partial cement replacement. This knowledge gap restricts the practical implementation of sustainable fibre-reinforced concrete mixtures for structural applications.

2. METHODOLOGY

2.1 Material

2.1.1 Cement

Portland Limestone Cement (PLC), conforming to BS EN 197-1**,** was used as the primary binder. Properties of cement were determine in accordance with BS EN 196-3:2016 to verify compliance with the relevant specifications.

2.1.2 *Rice Husk Ash*

Rice husk ash (RHA) was produced by controlled calcination of rice husks in a laboratory muffle furnace at temperatures between 600 and 700 °C for 4 h**.** The resulting ash was ground and sieved through a 75 μm sieve to obtain a fine pozzolanic material suitable for use as a supplementary cementitious material.

2.1.3 Doum Palm Fibre

Doum palm fibres (DF) were collected from naturally growing doum palm trees at Buzai Village near Zaria, Kaduna State, Nigeria. The fibres were cleaned, air-dried, and cut into lengths ranging from 20 to 25 mm**,** corresponding to an aspect ratio of approximately 80 to 120**.**

2.1.4 *Aggregates*

Crushed granite with a nominal maximum size of 20 mm was used as coarse aggregate. The aggregate was obtained from Abdu Kwari Quarry, Zaria, Nigeria. Natural river sand with a maximum particle size of 0.5 mm served as the fine aggregate..

2.1.5 *Mixing Water*

Potable water supplied by the Ahmadu Bello University, Zaria Water Works was used for concrete mixing and curing. The water satisfied the requirements of BS EN 1008:2002.

2.1.6 *Statistical Software*

Design-Expert Version 13 (Stat-Ease Inc., USA) was used for all the statistical analysis conducted**.**

2.2 Methods

2.2.1 *Experimental Design*

Full factorial design was adopted on Response Surface Methodology (RSM). Two independent variables were considered: Rice husk ash (RHA): 0, 5, 10, 15, 20, and 25% by mass replacement of cement. Doum palm fibre (DF): 0, 0.5, 1.0, 1.5, and 2.0% by volume of concrete. 30 different Mix ID were obtained from the design of experiment each Mix ID having 2 replica giving total of 60 runs.

2.2.2 *Concrete Mix Proportion*

Concrete mixtures were proportioned in accordance with BS EN 14889-1:2006 using a constant mix proportion of 1:1.5:3 (cementitious material, fine aggregate, coarse aggregate) and a constant water-to-binder ratio of 0.50. Rice husk ash replaced Portland limestone cement at replacement levels of 0–25%, while doum palm fibre was incorporated at dosages ranging from 0 to 2.0% by concrete volume.

2.2.3 *Specimen Preparation and Curing*

Concrete constituents were mixed until a uniform and homogeneous consistency was achieved. 30 different mix ID were cast, 3 samples for each curing day, as 7,14,21,28 and 56 days. Total of 450 samples for each of cubes, cylinders and beams and total of 90 samples for flat slabs were cast. These implies the averages of the three (3) results for each of the sample were recorded for

analysis of the compressive, split tensile and flexural strength respectively, while the averages of the three (3) results for samples of each of the 30 Mix ID of the flat slabs for only 56 days of curing were considered for punching shear strengths analysis making 90 cast samples.

2.2.4 *Mechanical Property Test*

The compressive strength test was carried out in accordance with BS EN 12390-2: (2009). Three set of each concrete cubes of size 100x100x100mm were used. Split tensile strength of the fibre reinforced concrete was carried out in accordance with BS-EN 12390-6 (2009). Concrete cylinders of 100x200mm size were used. The failure load was determined and the split tensile strength was calculated using the Equation 1.

$$\text{Split tensile strength} = \frac{2P}{\pi LD} \quad (1)$$

Where P is the failure load, L is the length of the cylindrical specimen and D is the diameter of the specimen. The flexural strength test of the fibre reinforced concrete beam was carried out in accordance with BS 12390-5(2019). Beams of 100x100x450mm size were used. The flexural strength of the beam was determined using three-point bending test. The punching shear test was carried out in accordance with BS-8110-1:1997. The curing duration was 7, 14, 21, 28 and 56days for all the test, expect the punching shear, where only 56days was considered. Laboratory test results for the mechanical properties were not reported in this study only the optimized results from the software were reported.

2.3 Response Surface Modelling and Optimization

Regression models were developed to establish relationships between the independent variables (RHA replacement level and DF dosage) and the measured responses. The general polynomial model adopted is expressed as shown in Equation (2):

$$y = b_o + \sum_{i=1}^{k} b_i x_i + \sum_{i=1}^{k} b_{ij} x_i + \sum_{i=1}^{k=1} \sum_{j=i+1}^{k} b_{ij} x_i x_j + ... + \varepsilon \quad (2)$$

Where: y = predicted response variable, b_0 = intercept, b_i = model coefficients, b_{ij} = linear/interaction terms, x_i and x_j = reaction factors, ε = represents errors. The optimization objectives and constraints for the variables and responses are presented in Table 1.

Table 1: Optimization Objectives and Constraints

Variables/Responses	Goal	Lower Limit	Upper Limit
Doum Palm fibre (DF)	Maximize	0.0	2.0
Rice husk ash (RHA)	Maximize	0.0	25.0
Compressive Strength(N/mm^2)	Maximize	13.15	19.73
Flexural Strength(N/mm^2)	Maximize	4.12	5.78
Split Tensile Strength(N/mm^2)	Maximize	3.02	4.78
Punching shear strength(N/mm^2)	Maximize	0.623	1.231

3. RESULTS AND DISCUSSION

3.1 Development of predictive models

Mathematical prediction models for the strength properties of doum palm fibre reinforced concrete incorporating rice husk ash as a partial replacement of cement were developed using Design-Expert software (Version 13). The software was used to generate regression equations for all the investigated responses in both coded and actual forms. Based on model fitting and adequacy checks, quartic polynomial models were identified as the most suitable for describing the compressive, flexural, split tensile, and punching shear strengths. To improve model reliability, statistically insignificant terms were eliminated, and the final refined models were established as presented in equations (3) to (7).

$$F_c = 18.70 - 0.5183D - 2.85R - O.O700DR - 2.09D^2 - 1.59R^2 + 0.7054DR^2 - 0.0167D^3 + 1.49D^4 \quad (3)$$

$$F_f = 5.46 - 0.0381D - 0.2500R - 0.0148DR - 0.0995D^2 - 0.0979R^2 + 0.0043D^2R - 0.1786DR^2 + 0.0389D^3 - 0.3090R^3 + 0.0871D^3R - 0.2500DR^3 - 0.1693R^4 \quad (4)$$

$$F_s = 4.46 - 0.0475D - 0.6796R - 0.0682DR - 0.1000D^2 - 0.5132R^2 - 0.1196D^2R - 0.0982DR^2 + 0.1641R^3 - 0.1020D^2R^2 - 0.2442DR^3 + 0.3011R^4 \quad (5)$$

$$F_p = 1.07 + 0.0086D - 0.2313R + 0.0057DR - 0.1021D^2 - 0.3907R^2 + 0.0178D^2R - 0.0180DR^2 - 0.0099D^3 - 0.0475R^3 + 0.0643D^4 + 0.2549R^4 \quad (6)$$

Where: D and R are coded factors for doum palm fibre and rice husk ash respectively. F_c F_f , F_s and F_p Are compressive, flexural and split tensile strength of the concrete and punching shear strength of the concrete slabs.

The ANOVA results presented in Tables 2 to 5 summarize the relevant statistical parameters evaluated at a 95% confidence level for 60 runs signifying 2 replicate of the 30 Mix ID.

The ANOVA results indicate that rice husk ash replacement was the dominant factor governing the strength properties, contributing approximately 88% of the model sum of squares for compressive strength.

3.2 Optimization

The essence of optimization was to obtain optimal values of factors that yielded optimum responses. Figure 1 illustrates the optimized outcomes corresponding to the most suitable solutions for the selected response variables. From the optimization search, the software identified four (4) possible solutions, of which the most desirable was achieved at a doum palm fibre content of 2.00% and a rice husk ash replacement level of 10.45% at 56 days curing age.

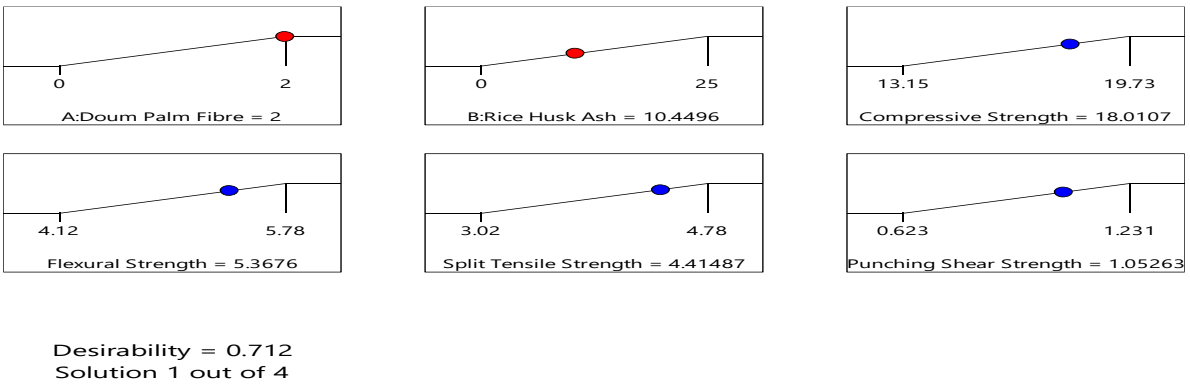

Figure 1: Optimization ramp combination for independent variables and results outcomes for responses

The optimized strengths values of 18.011 N/mm² for compressive strength, 5.368 N/mm² for flexural strength, 4.415 N/mm² for split tensile strength, and 1.053 N/mm² for the punching shear strength of the flat slab were obtained from the optimisation analysis of the Design-Expert software at this mix combination. The overall desirability index for this solution was 0.712, which indicates a satisfactory level of optimization.

Table 6: Optimization Result of doum palm fibre reinforced concrete with rice husk ash as partial replacement of cement

S/N	Doum Palm Fibre(%)	Rice Husk Ash(%)	Compressive Strength (N/mm^2)	Flexural Strength (N/mm^2)	Split Tensile Strength (N/mm^2)	Punching Shear Strength(N/mm^2)	Desirability	
1	**2.000**	**10.450**	**18.011**	**5.368**	**4.415**	**1.053**	**0.712**	**Selected**
2	2.000	10.207	18.061	5.370	4.425	1.054	0.712	
3	2.000	10.000	18.104	5.372	4.432	1.055	0.711	
4	1.467	10.511	18.492	5.444	4.510	1.078	0.708	

3.3 Model Validation

The validation of the developed models were carried out experimentally and the percentage error differences were indicated in Table 7.

Table 7: Experimental Model Validation

Responses	Doum palm fibre(%)	Rice husk ash (%)	Curing Age(days)	Predicted Values	Experimental Values	Error (%)
Compressive strength(N/mm^2)	2.00	10.45	56	18.011	18.51	2.70
Flexural strength(N/mm^2)	2.00	10.45	56	5.368	5.25	-2.25
Split Tensile Strength(N/mm^2)	2.00	10.45	56	4.415	4.30	-2.67
Punching shear strength(N/mm^2)	2.00	10.45	56	1.053	1.10	4.27

The percentage errors were found to be below 5%, this suggested that the predicted values from the developed models are in close agreement with the experimental result.

4. CONCLUSION

This study developed response surface models for predicting the mechanical properties of doum palm fibre-reinforced concrete incorporating rice husk ash as a partial cement replacement. The developed quartic models demonstrated excellent predictive capability, with the predicted, adjusted and coefficients of determination exceeding 95% for all investigated responses and experimental validation errors below 5%. Multi-response optimization identified an optimum mixture containing 2.0% doum palm fibre and 10.45% rice husk ash, providing a balanced improvement in compressive, flexural, split tensile, and punching shear strengths. And row experimental strengths properties were not reported in this study only the responses from software were reported for modelling and optimization.

ABSTRACT

The increasing demand for sustainable materials has intensified research into lignin-based adhesives derived from agricultural biomass. This study presents an integrated approach for optimizing organosolv extraction of lignin from groundnut shell waste for potential adhesive applications. Groundnut shell lignin was extracted via an organosolv process. A three-factor central composite design (CCD) of response surface method (RSM) was applied to optimize extraction variables using design expert 13.0.1 including ethanol concentration, temperature, and reaction time considering % yield and lignin reactivity index (LRI). The model was tested with its adequacy fit statistics, where R^2-value is 0.9941 which has 0.90 % and 4.4 % difference from the adjusted R^2 and predicted R^2 values. The theoretical optimal parameters obtained were 55 % ethanol concentration, 120 ℃ temperature, and 45 minutes reaction time which yielded a lignin recovery of 87.55 % and 5.17 LRI. These were validated having a close value of the responses 86.24 % yield and 5.25 LRI having a 1.45 % and 1.52 % error for yield and LRI respectively, as compared with the theorical values. FTIR and compositional analysis confirmed successful isolation of a lignin-rich fraction from groundnut shell. The extracted lignin retained characteristic hydroxyl, aliphatic C-H, aromatic skeletal and C-O/ether functionalities, with prominent absorptions observed around 3404, 2928, 1508 – 1529, 1410 – 1412 and 1044 – 1119 $^{cm-1}$. The novelty of this work lies in consideration of quantity and quality of lignin in optimization of organosolv extraction method of groundnut shell lignin, an underutilized agricultural waste, to produce a functionally improved adhesive precursor. Conclusively, the optimized extraction conditions produced high lignin yield and enhanced lignin reactivity, demonstrating that groundnut shell is a sustainable and promising source of reactive lignin for the development of bio-based adhesive precursors. These findings provide a reliable foundation for the subsequent modification and functionalization of high-performance and environmentally friendly bio-adhesives synthesis.

1. INTRODUCTION

The increasing global emphasis on environmental sustainability and the depletion of fossil-based resources have intensified research into renewable and eco-friendly alternatives for industrial materials. Conventional adhesives, largely derived from petroleum-based polymers such as epoxy, polyurethane, and phenol–formaldehyde resins, are associated with significant environmental concerns, particularly the emission of volatile organic compounds (VOCs) during their production and application (Paez & Fatehi, 2025). In response, bio-based polymers derived from lignocellulosic biomass have gained increasing attention as sustainable substitutes. Among these, lignin has emerged as a promising renewable resource due to its aromatic structure, high availability, and compatibility with phenolic resin systems (Mateo *et al*., 2025; Ait Benhamou *et al*., 2025).

Lignin is a complex, three-dimensional amorphous polymer composed of phenylpropanoid units, namely p-coumaryl, coniferyl, and sinapyl alcohols, which give rise to hydroxyphenyl (H), guaiacyl (G), and syringyl (S) structural units (Liu *et al*., 2023). It functions as a natural adhesive within

plant cell walls, imparting rigidity, hydrophobicity, and resistance to biological degradation (Zhang *et al*., 2024). Although it is the second most abundant biopolymer after cellulose, lignin remains largely underutilized, with the majority being combusted for energy recovery in pulp and biorefinery industries rather than converted into value-added products (Mateo *et al*., 2025). This presents a significant opportunity for its valorization in the development of sustainable materials, particularly bio-adhesives.

Groundnut (*Arachis hypogaea*) shell (Figure 1) is an abundant agricultural residue generated in large quantities in many developing countries, including Nigeria. Global groundnut processing produces millions of tonnes of shell waste annually, which is often disposed of through open burning or landfilling, thereby contributing to environmental pollution (Ogunkunle *et al*., 2024). However, groundnut shell is rich in lignocellulosic components, typically comprising cellulose, hemicellulose, and lignin, making it a viable raw material for lignin extraction (Adebayo & Adeola, 2023). Its utilization for lignin recovery therefore supports sustainable waste management and the development of renewable bio-based products (Gerber & Roberts, 2024).

Figure 1: Groundnut Shell (*Arachis hypogaea*)

Several extraction techniques have been reported for lignin recovery from biomass, including Kraft pulping, soda pulping, organosolv processes, and deep eutectic solvent (DES) systems. Among these, the organosolv process has attracted considerable interest due to its ability to produce high-purity lignin with relatively low structural degradation compared to conventional alkaline methods (Xu *et al*., 2024). Although emerging fractionation technologies such as DES extraction have demonstrated considerable potential for lignin recovery, organosolv extraction was selected in this study because its established ability to selectively fractionate lignocellulosic biomass and recover sulfur-free lignin with relatively high purity and useful hydroxyl functionalities. These characteristics are particularly relevant to the intended functionalization of lignin for adhesive precursor development (Alam *et al.*, 2024; Tanis *et al.*, 2024). Among organic solvents used in organosolv processing, ethanol is attractive for its lignin-solubilizing capacity, relatively low toxicity, miscibility with water and potential for recovery and reuse (Brienza *et al.*, 2024). However, the efficiency of lignin extraction and the quality of the resulting product are strongly influenced by operational parameters such as solvent composition, reaction temperature, and extraction time (Ruwoldt *et al*., 2024). Consequently, optimisation of these parameters is essential to obtain lignin with desirable physicochemical properties suitable for adhesive applications.

Despite growing interest in lignin valorisation, limited studies have systematically optimised organosolv extraction conditions for lignin recovery from groundnut shell and evaluated its reactivity to suit adhesive synthesis precursor. In particular, the relationship between extraction parameters, and lignin structural characteristics remains insufficiently understood.

Therefore, this study aims to optimise the organosolv extraction of lignin from groundnut shell and evaluate its suitability for adhesive synthesis. Specifically, the study focuses on optimisation of extraction parameters of lignin from groundnut shell using the organosolv method for improved quantity and quality, and characterisation of the extracted lignin for possible adhesive applications.

This work contributes to the sustainable utilisation of agricultural waste and supports the development of environmentally benign bio-based adhesives as alternatives to petroleum derived products.

2. MATERIALS AND METHODS

The details of reagents used are presented in Table 1, and experimental setup is shown in Figure 2, showing all methods used.

Table 1: *Chemicals and reagents used*

S/N	Chemical	Purity/Grade	Supplier
1	Ethanol	≥99.5%	Sigma-Aldrich
2	Sulfuric acid	95%	Sigma-Aldrich
3	Distilled water	Laboratory grade	Laboratory supply

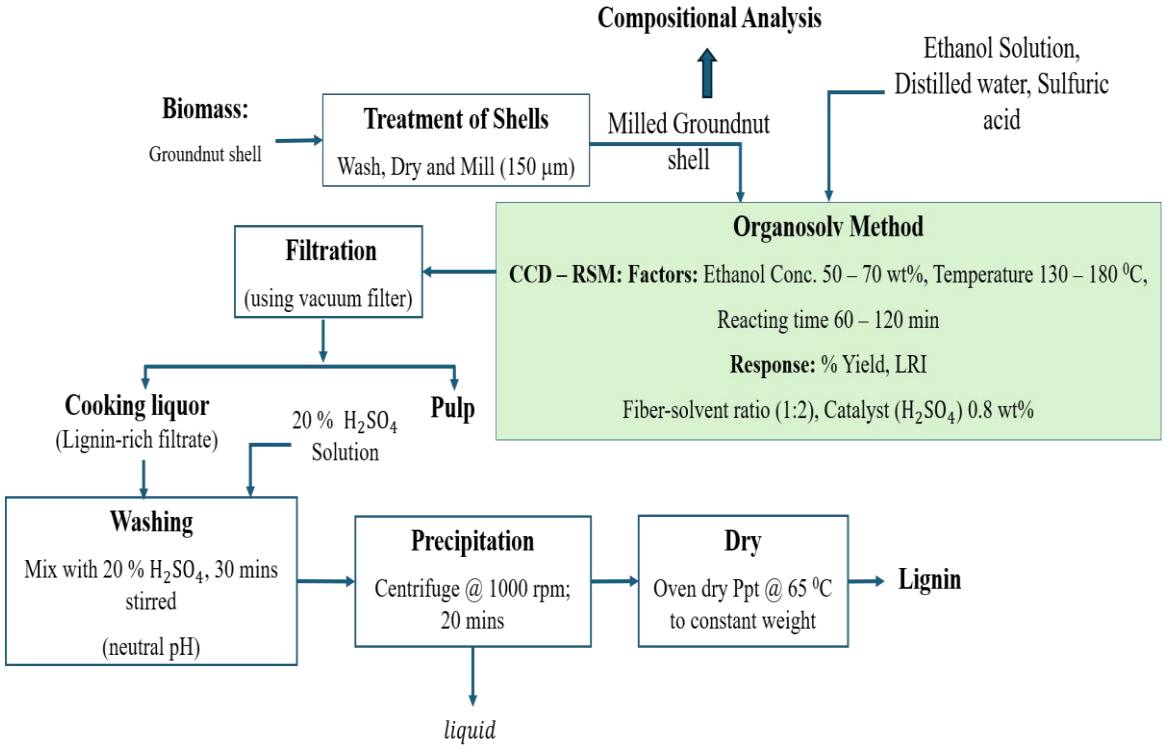

Figure 2: *Experimental Setup of the extraction process*

Groundnut shells (*Arachis hypogaea*) were collected from local oil processing mills in Zaria, Kaduna State, Nigeria. The shells were thoroughly washed with distilled water to remove adhering dirt and impurities, sun dried, and further oven dried at 65 °C (Memmert UN55 Oven, Germany) for 6 h to reduce moisture content. The dried shells were milled using a hammer mill (SIEBTECHNIK GmbH) and sieved to a particle size of 150 µm. All chemicals and reagents as presented in Table 1 were of analytical grade and were used as received without further purification. Ethanol was selected as the extraction solvent based on its reported efficiency in producing high purity organosolv lignin. Sulfuric acid (0.8 wt%) was employed as a mild catalyst in line with previous studies (Farid *et al.*, 2023).

2.1 Experimental Design

The experimental design was developed using Design-Expert software (Version 13.0.1, Stat-Ease Inc., USA) based on three-factor Central Composite Design (CCD). The coded factorial levels (-1 and +1) corresponded to ethanol concentration (50 – 70% v/v), reaction temperature (130 – 180 °C), and reaction time (60 – 120 min). The CCD axial points extended the actual experimental design space to 43 – 77 % ethanol concentration, 113 – 198 °C, and 39 – 141 min reaction time. The response variables were lignin yield (%), and reactivity index. A total of 16 randomized experimental runs were

generated with two-center points, allowing evaluation of linear, interaction, and quadratic effects of the process variables. All experiments were conducted in triplicate, and the average values were reported.

2.2 Extraction of Lignin from Groundnut Shell

Prior to extraction, compositional analysis was carried out on the groundnut shell to ascertain and compare with the existing literature, the percentage of lignin, cellulose, and hemicellulose present in the shell. 100 g of groundnut shell powder of a particle size 150μm was pretreated by washing in hot distilled water at 80 °C to remove soluble extractives and then oven-dried at 65 °C to a constant weight and then transferred into the reactor. Organosolv extraction was carried out using ethanol – water solution (50 – 70% v/v) at a solid-to-liquid ratio of 1:2 (w/v). The solution was added into the batch reactor, and sulfuric acid (0.8 wt%) was then added as a catalyst to enhance cleavage of ether linkages (Farid *et al.*, 2023). The lignin extraction was carried outing a closed-sealed, mechanically stirred and temperature-controlled pressure reactor. The reactor head was mechanically secured to the vessel prior to operation to provide a closed reaction environment, then purged with nitrogen for 3 min to minimize oxidative degradation and heated to the desired temperature range (130 – 180 °C) for 60 – 120 min continuously stirred at 800 rpm, in accordance with the CCD matrix. At the end of the reaction time, heating was automatically stopped and the reactor was cooled to below 45 °C before pressure was released through the release valve. The resulting slurry was recovered for lignin separation, vacuum filtered to separate the solid residue from the black liquor. A photograph of the experimental reactor and control system is presented in Figure 3

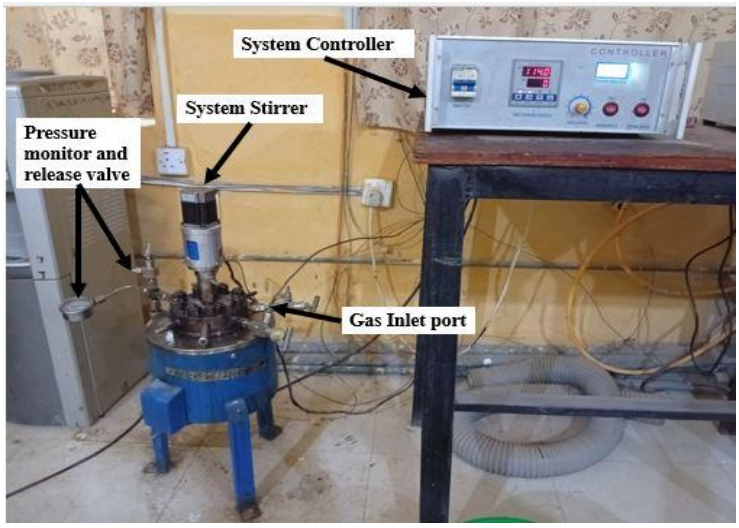

Figure 3: *Reactor and control system setup*

Lignin was recovered from the liquor by dilution with sulfuric acid solution, followed by centrifugation at 1000 rpm to precipitate the lignin fraction. To quench the reaction, the precipitate was washed repeatedly with distilled water until neutral pH (6.5 – 7.5) was achieved and subsequently dried under vacuum at 65 °C to constant mass.

Lignin yield, an important response signifying extraction efficiency which is usually expressed in percentage for the lignin recovered from the biomass (Mao *et al*, 2025; Sandner *et al.*, 2025). This was calculated using equation 1:

$$\text{Yield } (\%) = \frac{W_L}{W_S} \times 100 \qquad (1)$$

where W_L is the dry mass of extracted lignin and W_S is the dry mass of raw groundnut shell.

Lignin reactivity index (LRI) is a measure of chemical reactivity of extracted lignin, revealing the availability of reactive functional groups (Karlsson *et al.*, 2023). LRI was calculated using equation 2.

$$Lignin\ Reactivity\ index\ (LRI) = \frac{A_{\sim 3400}}{A_{\sim 1510}} \quad (2)$$

$$Abundance\ (A) = log\left(\frac{100}{(\%T)}\right) \quad (3)$$

2.3 Functional Group Analysis

The extracted lignin using the optimum extraction parameters was characterized to evaluate the functional groups of both the groundnut shell and lignin through Fourier Transform Infrared Spectroscopy (FTIR).

3. RESULTS AND DISCUSSIONS

3.1 Constituents of Groundnut Shell and Extract

Comparison of the major lignocellulosic components measured for both milled groundnut shell and the extracted lignin are presented in Table 2

Table 2: *Constituents of groundnut shell and extract Lignin*

Component	Groundnut shell (%)	Extract (Lignin)
Lignin	26.97	78.49
Hemicellulose	12.88	2.53
Cellulose	55.24	15.06
Moisture	4.67	3.92
Ash	0.24	0.163

As shown in Table 2, the composition of lignin, hemicellulose, cellulose contained in the groundnut shell are 26.97 %, 12.88 %, and 55.24 % respectively, these are in line with various report on groundnut shell studies. Recent studies confirm that groundnut shell composition varies considerably according to cultivar, geographical origin, maturity, processing and method adopted for analysis. From the work of Almeida-Naranjo *et al.,* (2024), reported 36.2 % lignin, 26.1 % hemicellulose and 19.4 % cellulose, similar trend of 28.4 % lignin, 14.5 % hemicellulose and 47.86 % cellulose was also reported recently by Mousa *et al.,* (2026). In another study, identification was reported for peanut shell to be broadly composed of about 48 % cellulose, 3 % hemicellulose, and 28 % lignin (Zhang *et al.,* 2025). Therefore, 26.97 % lignin, 55. 24 % cellulose, and 12.88 % hemicellulose recorded are within the reported compositional range with a close agreement for lignin and cellulose.

Also, the 78.49 % lignin contained in the extract demonstrates substantial purification but not fully chemically pure lignin due to some fractions of other constituents present, this could be because of the process efficiency. Recent studies also show that groundnut shell is agreeable to effective fractionation, a microwave-assisted diol-deep eutectic solvent (DES) system was reported to have 86.39 % delignification and 91.17 % hemicellulose removal (Xie *et al.,* 2025), while another recent peanut-shell DES study reported 73.22 % lignin removal and 93.05 % hemicellulose removal (Lu *et al.,* 2023). The low ash content in lignin (0.163 %) indicates a low level of inorganic impurities, which makes it a good precursor for adhesive applications because a low inorganic fraction means fewer mineral impurities interfering with subsequent lignin functionalization. Recent studies have similarly associated low-ash, high-purity lignin with greater chemical activity and suitability for lignin-based resin and adhesive synthesis (Ren *et al.,* 2025; Sapenti *et al.,* 2025).

3.2 Lignin Yield from CCD-RSM Optimization

The experimental lignin yields and reactivity obtained under different combinations of ethanol concentration, reaction temperature, and reaction time, as designed by the Central Composite Design (CCD), are presented in Table 3.

Table 3: *Effect of extraction parameters on lignin yield and reactivity index*

Run	Ethanol Conc. (%)	Temperature (℃)	Reaction Time (min)	Yield (%)	LRI
1	60	198	90	63.55	4.11
2	50	180	120	61.06	6.26
3	50	130	60	50.45	5.19
4	50	180	60	61.45	3.98
5	60	155	141	55.23	7.24
6	70	180	120	60.64	6.13
7	60	155	90	54.99	4.45
8	50	130	120	51.24	6.87
9	43	155	90	56.43	5.79
10	77	155	90	53.66	7.14
11	70	130	120	49.78	7.46
12	60	155	39	55.02	4.76
13	70	180	60	58.96	4.47
14	60	155	90	55.2	4.81
15	70	130	60	50.11	6.88
16	60	113	90	47.06	5.96

Lignin yield varied from 47.06 % to 63.55 %, indicating strong dependence on process conditions. The highest experimental yield (63.55 %) was obtained at 60% ethanol, 198 ℃, and 90 min. This suggests that moderate solvent polarity combined with elevated temperature enhances lignin solubilisation and cleavage of lignin carbohydrate linkages. A decline in yield at higher temperature (180 ℃) and shorter residence time (60 min) indicates possible lignin degradation or condensation reactions under harsh conditions. Conversely, insufficient reaction time reduced extraction efficiency due to incomplete biomass delignification. Similar behaviour has been reported in organosolv systems where temperature and residence time strongly govern lignin depolymerisation kinetics (Xu *et al*., 2024). Although the maximum experimental yield (63.55 %) was slightly higher than other runs, the amount of ethanol concentration of 60 % may have prevented the excessive lignin degradation effects, as compared to the 50 % concentration used in runs 2 and 4, similar experience was also reported in the work of Sun *et al*. (2023).

More so, the lignin reactivity index (LRI) was also influenced by the extraction temperature, solvent concentration and the extraction time, but the effects were observed to vary with respect to their operating conditions, which is also consistent with the findings reported by Li *et al*. (2024). LRI was considered independently of lignin yield, which represents the quality of lignin recovered. As presented in Table 3, relatively low lignin reactive index of 4.11 was obtained in experimental run 1 at high temperature of 198 ^{0}C, 90 minutes extraction time and 60 % ethanol concentration, indicating that; despite maximizing the lignin recovery, the structural arrangements may have been disrupted by the

severe extraction temperature, thereby reducing the availability of reactive functional groups. Additionally, the influence of reaction time can be observed by comparing Runs 2 and 4, that were investigated under a similar concentration, extraction temperature but different reaction time (120 and 60 min, respectively). This indicates that, the increase in LRI from 3.98 to 6.26, suggests that extending the extraction time beyond 60 minutes did not substantially improve lignin reactivity. Kim *et al*. (2023) also reported similar trends, indicating that prolonged residence time may have altered the chemical structure of the extracted lignin through partial depolymerization and exposure of additional reactive sites, resulting in a higher lignin reactivity index without significantly increasing extraction efficiency.

3.3 Analysis of Variance (ANOVA) and Model Significance

The ANOVA results for the quadratic response surface model of lignin yield are presented in Table 4. The model was statistically significant ($p = 0.0001$), indicating that the selected variables adequately describe lignin yield behaviour within the studied range.

Table 4: *ANOVA results of the independent variable effects on the yield of lignin*

Source	Sum of Squares	Df	Mean Square	F-value	p-value	
Model	348.36	9	38.71	111.72	0.0001	significant
A-% Ethanol	6.44	1	6.44	18.58	0.0050	
B-Temperature	340.62	1	340.62	983.09	0.0001	
C-Reacting Time	0.3222	1	0.3222	0.9298	0.3721	
AB	0.1540	1	0.1540	0.4445	0.5297	
AC	0.1128	1	0.1128	0.3256	0.5890	
BC	0.0861	1	0.0861	0.2485	0.6359	
A^2	0.0280	1	0.0280	0.0807	0.7859	
B^2	0.1109	1	0.1109	0.3200	0.5921	
C^2	0.0638	1	0.0638	0.1841	0.6829	
Residual	2.08	6	0.3465			
Lack of Fit	2.06	5	0.4114	18.66	0.1739	not significant
Pure Error	0.0221	1	0.0221			
Cor Total	350.44	15				

Nevertheless, their inclusion improved overall model predictability and stability, which is consistent with response surface methodology practices (Weremfo *et al*., 2023).

The lack of fit was not significant ($p > 0.05$), confirming that the model adequately fits the experimental data.

The model exhibited strong predictive capability with $R^2 = 0.9941$, indicating that 99.4% of the variability in lignin yield was explained by the model. The adjusted R^2 (0.9852) and predicted R^2 (0.9499) were in reasonable agreement, confirming acceptable model reliability. The adequate precision value of 36.37 further justified the significance of the model, because it is greater than 4. A good correlation between predicted and experimental values was observed (Figure 4), with data points closely distributed along the regression line, confirming that the model reliably predicts lignin yield within the experimental domain

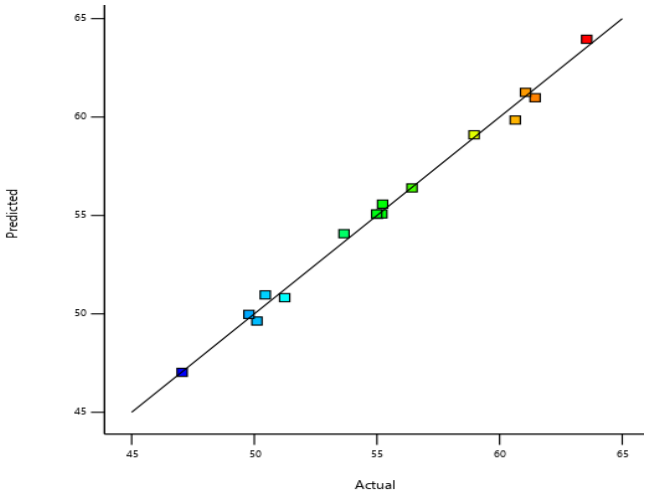

Figure 4: *Relationship between experimental (actual) and predicted data*

Equation 4 depicts the coded model equation generated for the yield which shows the interactions between the independent variables (reaction time and temperature and ethanol concentration) that were investigated.

$$\text{Yield} = 55.08 - 0.6835A + 4.97B + 0.1529C - 0.1387AB + 0.1188AC + 0.1038BC + 0.0543A^2 + 0.1080B^2 + 0.0819C^2 \quad (4)$$

Table 5 presents the ANOVA results of the reactivity index of lignin extraction. As shown in Table 5, the model is significant as the p-value obtained is less than 0.05. The model terms-A, B and C as shown in the Table are also significant as their p-values are less than 0.05.

Table 5: *ANOVA results of the independent variable effects on the lignin RI*

Source	Sum of Squares	df	Mean Square	F-value	p-value	
Model	21.18	9	2.35	75.27	0.0001	significant
A	1.77	1	1.77	56.52	0.0003	
B	5.54	1	5.54	177.21	0.0001	
C	7.87	1	7.87	251.80	0.0001	
AB	0.4608	1	0.4608	14.74	0.0086	
AC	0.3698	1	0.3698	11.83	0.0138	
BC	0.3528	1	0.3528	11.28	0.0152	
A^2	3.90	1	3.90	124.65	0.0001	
B^2	0.2174	1	0.2174	6.95	0.0387	
C^2	2.19	1	2.19	69.89	0.0002	
Residual	0.1876	6	0.0313			
Lack of Fit	0.1228	5	0.0246	0.3790	0.8348	not significant
Pure Error	0.0648	1	0.0648			
Cor Total	21.37	15				

Moreso, the lack of fit with p-value obtained as 0.8387 is not significant as it is greater than 0.05. The model was further subjected to the adequacy test where the R^2 was obtained as 0.9912, with the adjusted R^2 of 0.9781 and predicted R^2 of 0.9424, which 1.0 % and 4.9 % percentage error differences from the R^2 respectively. This was further justified by the value of adequate precision of 25.0126. Figure 5 shows the parity plot of the predicted and experimental variables of the reactivity index. As observed in the Figure, the experimental variables are in close agreement with the predicted variables, which was further justified by the low error difference obtained from the R^2 and the R^2 adjusted values.

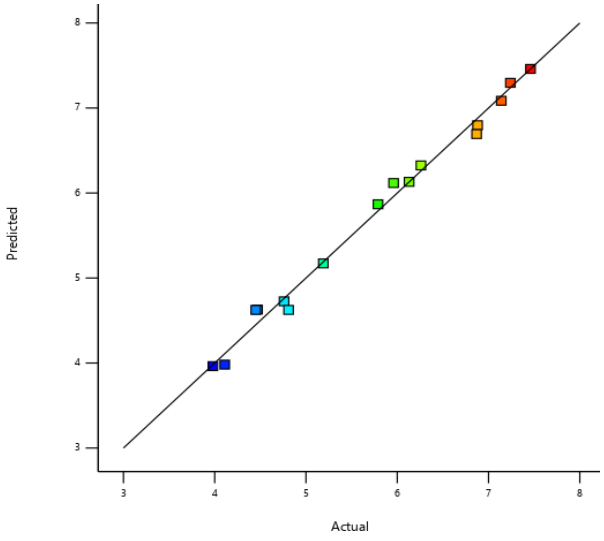

Figure 5: *Parity plot of the predicted and experimental data*

Equation 5 shows the model generated from the statistical analysis carried out. As highlighted in the model, the quadratic regression equation explained the relationship between the reacting time, ethanol concentration, extraction temperature and the lignin reactivity index.

$$\text{LRI Model} = 4.63 + 0.3581A - 0.6343B + 0.7559C - 0.2400AB - 0.2150AC + 0.2100BC + 0.6405A^2 + 0.1512B^2 + 0.4796C^2 \quad (5)$$

3.4 Model Validation and Multi-Response Optimization

The multi-response optimization approach was employed to identify the extraction conditions that simultaneously maximize lignin yield and its reactivity index. The desirability function combines the individual desirability of each response into an overall desirability value ranging from 0 to 1. The optimum condition obtained theoretically are 55 % ethanol concentration, 120 ℃ extraction temperature and 45 min reaction time, with overall desirability of 0.963. This high desirability indicates that the selected operating condition provides favourable response predicted at 87.55 % lignin yield and 5.17 LRI as presented in Table 6.

Table 6: The predicted and validated of the yield and lignin reactivity index

	Ethanol Conc	Temperature	Reaction Time	Yield	LRI
Theorical values	55	`120	45	87.55	5.17
Validated values	55	120	45	86.28	5.25
% Error				1.45	1.52

As shown in Table 6, the validated values at the same operating conditions produced a lignin yield of 87.55 % and an LRI of 5.25, which are in close agreement with the predicted values with their respective error differences of 1.45 % and 1.52 %. These indicates a high level of accuracy in the prediction model, suggesting that the optimization model used to predict the extraction yield and the lignin refractive index values are quite reliable, with minimal deviations observed between the predicted and validated values. These trends, when compared with the works of Li *et al*. (2024); Samson *et al*. (2022); Lannucci and Willows, (2022); Higuchi *et al*. (2021) follow similar percentage deviation.

3.5 FTIR Analysis

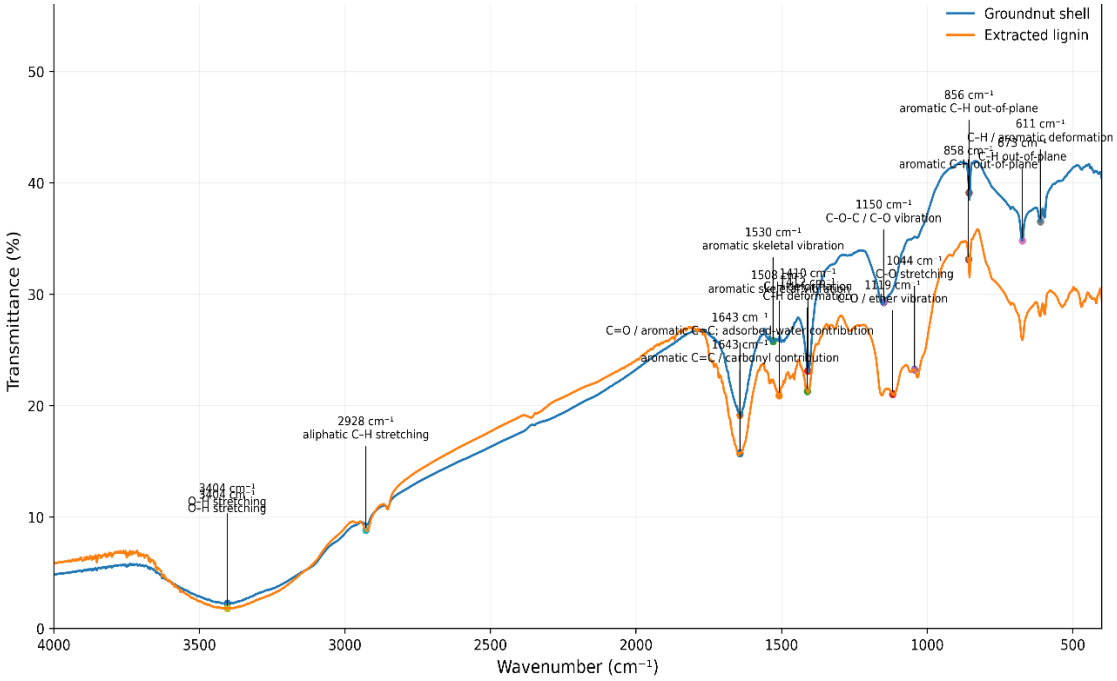

Figure 6: The FTIR spectra of Groundnut Shell and Lignin

The FTIR spectra (Figure 6) provide comparison on functional groups of both groundnut shell and lignin at an optimum extraction condition as presented in Table 6. Both spectra exhibit a broad absorption centred around 3404 cm^{-1}, attributable primarily to O-H stretching of phenolic and aliphatic hydroxyl groups. The presence of this band in the extracted lignin is highly significance because hydroxyl groups are abundant in lignin. Its presence indicates that a substantial proportion of lignin hydroxyl functionalities was retained after undergoing the extraction process, suggesting that the organosolv extraction conditions did not cause extensive degradation of the functional groups. This preservation is important because the hydroxyl groups contribute to the chemical reactivity of lignin and provide active sites for subsequent functionalization. Recent work on peanut/groundnut shell also reported similar trends with bands around 3426 cm^{-1} and 3335 cm^{-1}, these were also attributed to hydroxyl groups associated with lignin, cellulose and moisture (Mousa *et al.*, 2026; Arizpe-Diaz *et al.*, 2025; Almeida-Naranjo-Diaz *et al.*, 2024)

Other functional groups aliphatic C-H with band 2928 cm^{-1}, Bands around 1530 cm^{-1} and 1508 – 1529 cm^{-1} reflects oxygen containing and aromatic skeletal vibrations characteristic of lignin. Similar aromatic bands around 1620, 1509 and 1422 cm^{-1} have been reported for peanut shells (Petraglia, *et al.*, 2024) C-O/ether vibrations represent band 1044 – 1119 cm^{-1}. This pattern agrees with recent groundnut shell FTIR studies which identifies hydroxyl, C-H, aromatic lignin and C-O containing bands as characteristic components of the shell (Mousa *et al.*, 2026; Almeida-Naranjo-Diaz *et al.*, 2024)

The lower wavenumber bands at 856 – 858, 673 and 611 cm^{-1} occur in the aromatic region and are consistent with aromatic C–H ring deformation vibrations. Comparable low-wavenumber bands have been reported for lignocellulosic and peanut shell materials (Arizpe-Diaz *et al.*, 2025; Jadhav, *et al.*, 2022). These distinctive peaks provide strong evidence of lignin enrichment and preservation of characteristic functional groups after extraction process.

4. CONCLUSIONS

This study demonstrated the successful extraction of lignin from groundnut shell using an organosolv process integrated with response surface methodology (CCD-RSM). The optimized predicted conditions were 55 % ethanol concentration, 120 °C, and 45 min, having lignin recovery of 87.55 % and 5.17 LRI with a desirability value of 0.963. Experimental validation confirmed the reliability of the model, indicating strong agreement between predicted and observed responses.

The novelty of this work lies in the combined optimisation of organosolv extraction of groundnut shell lignin, considering the quality and quantity as a leading tool to determine the best extraction parameters. FTIR spectral changes relative to the raw groundnut shell confirmed the fractionation of the lignocellulosic matrix and recovery of a lignin-rich fraction.

Overall, the study establishes groundnut shell as a viable low-cost lignocellulosic feedstock for sustainable lignin-based material development and highlights its potential in eco-friendly adhesive formulations. Future work should focus on modification of the structural property and evaluating of the mechanical bonding performance adhesive system.

ABSTRACT

This empirical study investigates the potential of Oil Palm Empty Fruit Bunch Ash (PFBA) as a partial cementitious replacement in sandcrete block production. The material was produced via a systematic pre-burning process to convert empty fruit bunches into charcoal, followed by controlled calcination to obtain reactive pozzolanic ash. Physical characterization, including specific gravity and fineness (sieve size 45µm), was conducted per BS 1377:1990 and EN 196-6 standards. Mechanical performance was evaluated by substituting Ordinary Portland Cement (OPC) with PFBA at 0%, 5%, 10%, 15%, and 20% levels. Results indicate that while strength development is sustained over a 28-day curing period, increasing PFBA content correlates with reduced compressive strength and density, alongside increased water absorption. The study identifies 10% as the optimal replacement threshold, achieving a 28-day compressive strength of 3.5N/mm², which complies with the minimum requirements of the Nigerian Industrial Standard (NIS 978:2017). Furthermore, the research evaluates technical risks related to chloride content, environmental benefits of a low-emission approach, and the economic viability of controlled incineration. The findings conclude that with rigorous quality control and chemical pre-treatment, PFBA offers a sustainable, eco-friendly solution for masonry production in the Nigerian construction industry.

Keywords: *Sustainable construction; Oil Palm Empty Fruit Bunch; Sandcrete blocks; Cement replacement; Material characterization*

1. INTRODUCTION

The global construction industry is more and more looking for viable replacement to Ordinary Portland Cement (OPC) owing to its high carbon footprint and increasing cost. This cement industry is one among the largest industrial contributors to climate change accounting for approximately 7% to 8% of global CO_2 emissions. About 60% of these emissions happens in the process of the chemical decomposition of limestone ($CaCO_3$) into lime (CaO) which releases CO_2 as a major by product, the remaining 40% comes from the combustion of fossil fuels to heat kilns to temperatures exceeding 1400°C (Ripley et al., 2025).

In addition to that, in locations like Nigeria and Malaysia where palm oil production is higher, the disposal of agricultural waste like Empty Oil Palm Fruit Bunches (EOPFB) presents a significant environmental problem, recent findings is looking toward how these wastes can be processed into Empty Fruit Bunch Ash (EFBA) or Palm Oil Fuel Ash (POFA) through controlled burning to serve as supplementary cementitious materials (SCMs) in masonry units like sandcrete blocks (Yusuf & Hamza, 2023). The high cost of cement has made affordable housing a major challenge in developing nations as also the careless dumping and burning of oil palm fruit bunches lead to land pollution and greenhouse gas emissions lately findings have moved beyond just identifying agricultural waste, they are now looking on the mechanical characterization of combined composites (Sulaiman etal, 2020).

There is a major trend to move from just waste management to circular models which recent studies are developing means to measure the circularity of major materials such as cement, steel, and wood. This study investigates whether the partial replacement of cement with PFBA can produce sandcrete blocks that meet standard compressive strength requirements while offering a more ecofriendly disposal method for palm oil mill residues.

Chemically PFBA contains essential oxides such as silica (SiO_2), alumina ($Al2O_3$), and calcium oxide (CaO), which categorize it as a pozzolan. When mixed with cement and water, these oxides react with the calcium hydroxide byproduct of cement hydration to form additional Calcium Silicate Hydrate

(C-S-H) gel, which is the primary binder responsible for strength in concrete and sandcrete, recent studies suggest that replacement levels between 10% and 20% are optimal for maintaining structural integrity while reducing material costs (Abe & Amu, 2022).

Given the abundance of oil palm residues in Nigeria and other tropical economies, coupled with the pressing demand for affordable, environmentally sustainable building materials, a systematic investigation into the effect of partial replacement of cement with oil palm empty fruit bunch ash in sandcrete block production is both timely and policy-relevant. Such a study can provide empirical data on the influence of EFB ash on key engineering properties of sandcrete blocks such as compressive strength, density, water absorption, and durability at different replacement levels. The findings will contribute to the development of locally appropriate guidelines for incorporating EFB ash in sandcrete production, thereby supporting waste-to- wealth initiatives, reducing environmental pollution, and potentially lowering the cost of masonry units in Nigeria and similar contexts (Ibrahim etal, 2021).

Key engineering properties of sandcrete blocks incorporating PFB ash such as compressive strength, bulk density, water absorption and durability have not been systematically characterized at varying replacement levels. In addition, the influence of ash production parameters such as burning temperature, fineness and local mix practices on block performance is not yet well established, leaving block makers without clear guidance on optimal replacement percentages or performance trade-offs, this lack of context specific data constitutes a critical research gap and without robust experimental evidence on sandcrete blocks produced with partial replacement of cement by PFBA, policymakers, standards bodies and small to medium scale sandcrete producers cannot make informed decisions about its technical feasibility, economic benefits or environmental advantages. As a result, an abundant agricultural residue with demonstrated pozzolanic potential remains largely unused in sandcrete block production, and opportunities for cost reduction, waste valorizations and emissions mitigation are missed.

Accordingly, this study seeks to investigate the effect of partial replacement of cement with oil palm empty fruit bunch ash on the properties of sandcrete blocks, with the aim of identifying replacement levels that satisfy engineering performance requirements while contributing to more sustainable and affordable construction in Nigeria.

Palm fruit bunch (PFB) originates from the palm oil milling process after sterilization and fruit stripping, the fresh fruit bunch (FFB) leaves behind the empty cluster known as the empty fruit bunch (EFB) whereby for every tone of FFB processed, around 20–23% of the mass becomes PFB, making it one of the largest solid residues from palm oil production (Yusoff et al., 2023). As palm oil production expanded, these residues grew into a significant waste management challenge, especially in Malaysia, Indonesia, and Nigeria, from the late 1990s into the 21st century, increasing environmental concerns and sustainability demands pushed researchers and industries to explore beneficial uses of PFB. Its high lignocellulosic composition, availability, and low cost made it attractive for Bioenergy production, Organic fertilizer, Composite materials, Soil stabilization and Pozzolanic ash for construction materials. (Sulaiman et al., 2020).

Recent studies highlight its potential as a supplementary cementitious material (SCM) when converted into ash under controlled burning conditions due to its high silica content. (Nwosu and Adeyemi 2025) conducted thermal conductivity tests on sandcretec blocks in tropical climates. They found that the porous nature of the ash reduces the thermal mass of the block, leading to a reduction in indoor heat gain. Chemically, PFB is composed mainly of cellulose, hemicellulose and lignin, with typical ranges of about 37–63% cellulose, 14–37% hemicellulose and 17–32% lignin, depending on variety and processing conditions (Umar and Bello, 2025). Amorphous Silica Content (SiO2): The primary reactive component is amorphous silica, PFBA incinerated at a controlled temperature of 600°C contains between 55% and 65% SiO2, which is essential for the pozzolanic reaction. (Nwosu and Adeyemi 2025), research indicate that the highly alkaline nature of the ash helps maintain the passivity of the cement environment, which is beneficial for the long-term durability of the masonry units. (Onyechere 2026), Major oxides example from (Nwaiwu et al.2023): $SiO_2 \approx 18\%$, $Al_2O_3 \approx 46.8\%$, $Fe_2O_3 \approx 2.5\%$, $K_2O \approx 20.4\%$, $CaO \approx 4.2\%$, with minor TiO_2, MnO, ZnO and trace elements. In some boiler ashes, the combined ($SiO_2 + Al_2O_3 + Fe_2O_3$) is initially as low as ~15.7% with high carbon (~34%), meaning fresh ash often does not meet ASTM C618 pozzolan thresholds until it is further processed or re-burnt, ash from OPEFB pellets used as biomass fuel shows high K_2O and CaO contents (e.g., ~24%

SiO_2, ~46% CaO, significant K_2O), confirming its basic and alkali-rich character. (Okeke et al. 2025), Recent characterization studies show that the pozzolanic quality of oil palm empty fruit bunch ash (OPEFBA) is highly dependent on its production conditions. (Nwaiwu et al. 2023), for example, reported SiO_2, Al_2O_3 and Fe_2O_3 contents of 18.0%, 46.8% and 2.5% respectively, giving a combined pozzolanic oxide content of about 67.3%, which satisfies the ASTM C618 requirement for Class C but falls slightly below the 70% threshold for Class F pozzolans. In contrast, recent work on PFB ash for silica extraction has reported silica contents ranging from 25% to about 60% under optimal calcination regimes, the combined pozzolanic oxides would comfortably exceed 70%. (Nelson et al. 2023). The pozzolanic activity of PFBA has been confirmed through several studies, indicating that it can enhance compressive strength, workability, and water retention of sandcrete blocks (Suriani et al, 2021).

Studies demonstrate that replacing 10–30% of Portland cement with finely ground, heat-treated EFB ash can maintain or even improve compressive strength at medium to long curing ages, particularly in high-performance concrete. The fineness of the ash is another critical factor, finely ground PFBA improves packing density, reduces voids and enhances strength, whereas coarse ash increases porosity and water demand (Eziefula et al., 2025). According to (Onyechere et al. 2026), the average compressive strength decreases as the PFBA content increases, the maximum compressive strength of the concrete is achieved at 28 days of curing. While the 10% PFBA content is optimum content to achieve a balance between strength and workability (Nwaiwu et al. 2023), and replacing up to 20% of cement with PFBA improved the compressive strength of sandcrete bricks compared to conventional bricks. Their findings suggest that the incorporation of PFBA could effectively reduce the need for Portland cement, thereby lowering associated carbon emissions and replacing more than 30% of cement with PFBA led to a reduction in compressive strength.

PFBA contributes to lower permeability, which translates to improved resistance to chemical attacks and its incorporation of also reduces the carbon footprint associated with block production, aligning with sustainable construction practices and waste management strategies (Ibrahim et al 2021) further confirms this by showing improvements in the durability of concrete mixes containing PFBA when exposed to aggressive environments. Using Palm Fruit Bunch as a partial replacement of cement helps reduce agricultural waste, contributing to environmental conservation (Ibrahim et al 2025).

Moreover, research has established standards for the use of other pozzolanic materials, but similar frameworks for PFBA are still needed. (Suriani et al., 2021) emphasize the importance of developing standardized methods to test the performance of PFBA in construction materials. This gap exemplifies the necessity of further research in order to define best practices for incorporation into industry standards.

Equally important are the burning conditions under which the ash is produced, as controlled combustion at moderate temperatures (600–800 °C) enhances reactive silica formation, while uncontrolled burning increases carbon content and reduces strength contribution (Saldanha & Mallmann 2025). Together, these factors ash chemistry, burning regime, fineness, replacement level, mix/workability control and curing age determine whether PFBA enhances or diminishes the engineering performance of sandcrete blocks.

The use of Oil Palm Empty Fruit Bunch Ash (PFB ash) as a partial replacement for cement in sandcrete block production offers several environmental, economic, and technical advantages and replacing even a small proportion with agricultural waste ash directly lowers the carbon footprint of sandcrete and concrete production. Economically, PFB ash reduces the overall cost of sandcrete production. Cement constitutes the most expensive component in sandcrete blocks, and replacing even 10–15% with locally available PFB ash leads to substantial savings. (Suriani et al., 2021). An additional advantage is improved resource efficiency and waste management, this integrated waste-to-resource approach contributes to cleaner production practices and enhances community-level sustainability (Nwaiwu et al. 2022). Overall, research trends consistently show that PFB ash when processed correctly and used within optimal replacement percentages supports sustainable, cost-effective, and durable sandcrete block production while reducing environmental impacts.

This study will focus on palm fruit bunch (PFB) and to investigate the possibility of using the ash produced from PFB as a partial substitute for cement in sandcrete block production in order to provide an economic and proper way of disposal for palm fruit bunch. In this regard the pozzolanic activity of palm fruit bunch ash (PFBA) in the cement hydration will be investigated, as well as the oxide compositions of the ash and temperature of combustion of palm fruit bunch into ash, Therefor the

primary objectives of this study is to conduct laboratory tests on the Oil Palm Empty Fruit Bunch (OPEFB) ash.

2 METHODOLOGY

Ordinary Portland cement (OPC) of strength 42.5N according to BS EN 197-1 (2011) with a Specific Gravity (SG) of 3.14 obtained from local retailer was used as binder in this work. River sand from a local stream in life camp in Abuja was used as fine aggregate with specific gravity of 2.65 and bulk density of 1605.65kg/m³, Sieve analysis on the fine aggregates was conducted in accordance with ASTM C136 - 06 (2009) procedure after washing and air drying of the samples. The sand complies with grading requirements of ASTM C33 (ACI E-701, 2007), ensuring appropriate grain size distribution for optimal workability and cohesion in sandcrete block.

Palm fruit bunch (PFB) which is gotten from oil palm tree (Elaeis guineensis) was collected by gathering the raw empty bunches after the fruits of the palm tree were removed from a local palm oil mill in Agbaha Otukpa in Ogbadibo Benue state, Nigeria, the bunch was further shredded and sun dried to remove it moisture. After drying, a controlled pyrolysis/carbonization to turn the material into charcoal was performed and the charcoal was further blended making it easier to handle for the final calcination stage. In the laboratory at Nigeria Building and Road Research Institute (NBRRI) the blended charcoal was filled into the muffle furnace for control combustion where the final calcination was carried out, temperature of 751°C was recorded at when the organic carbon was completely burnt off leaving a clean greyish ash.

The furnace was allowed to cooled, the ash was sieved through a 45µm sieve to obtain the finer ash as cement, the sample was further analyzed using X-ray fluorescence (XRF) to obtain it element and composition of oxide for suitability of use as cement replacement. The resultant PFBA used for this work had specific gravity of 2.5 and bulk density of 260.54kg/m^3. Potable water obtained from Nigeria Building and Road Research Institute NBRRI Abuja. A cement-to-sand ratio of 1:6 was adopted, palm fruit bunch ash (PFBA) was introduced as a partial cement replacement at one control and four varying replacement levels of 0%, 5%, 10%, 15%, and 20%. A total of 12 blocks were produced for each replacement level, for mechanical testing, triplicate specimens (n = 3) were crushed at each of the four designated curing ages (7, 14, 21, and 28 days) and the remaining 3 blocks per each replacement level were reserved for non-destructive physical evaluations, including water absorption testing, density determination, and dimensional tolerance checks prior to mechanical testing. Experimental values are presented as the mean ± standard deviation (Mean ±SD). Statistical variability across replacement levels (0%, 5%, 10%, 15%, and 20%) was assessed using one-way Analysis of Variance (ANOVA) at a 95% confidence level ($\alpha = 0.05$) to confirm the statistical significance of observed trends, that is three sandcrete blocks for each replacement percentage and the control were crushed to obtain the mechanical strength tests (compressive strength) at 7, 14, 21, and 28 days as well as water absorption.

Palm fruit bunch ash was incorporated at replacement levels of 0, 5, 10, 15, and 20% by weight of binder in a ratio of 1:6. The mix proportions for concrete specimen are presented in table 1 as well as the batch quantities used for each specimen.

Table 1: *Mix proportioning of aggregates in sandcrete block production*

Mix	**PFBA Replacement (%)**	**Ash (Kg)**	**Cement (kg)**	**FA (kg)**	**W/C Ratio**	**Water (kg)**
1	0	0	4.5302	27.1812	0.40	1.8120
2	5	0.2265	4.3036	27.1812	0.50	2.1518
3	10	0.4530	4.0772	27.1812	0.54	2.2016
4	15	0.6795	3.8507	27.1812	0.59	2.2719
5	20	0.9060	3.6242	27.1812	0.63	2.2832
Total		2.265	20.386	135.906		10.721

Note 1: The 'Total' row represents the cumulative sum of quantities across all mix proportions (Mix 1 to Mix 5), including the control batch (0% replacement).

Note 2: The sandcrete mix was proportioned using a target binder-to-aggregate mass ratio of 1:6 (M_{binder} : M_{FA}), that is Total binder mass (M_{binder}= M_{Cement} + M_{Ash}) was fixed at 2.265+20.386=22.651kg, paired with 135.906kg, ensuring that the overall binder-to-fine aggregate ratio remained strictly constant at 1:6.00 (22.651/ 135.906= 6.00) regarding the percentage of OPC replaced by PFBA

3 RESULTS AND FINDINGS

The quantitative oxide analysis of the palm fruit bunch ash (PFBA) results as presented in table 2 indicate that the oxide composition of the palm fruit bunch ash satisfies Class F pozzolan requirement specified in ASTM C-618 for good pozzolans as the sum of SiO2+Al2O3 +Fe2O3 is at least 70% and satisfies the minimum ≥ 70% requirement (ASTM C618-19). The analysis identified an elevated chloride content of 4.90% which is anomalously higher than typical literature baselines of 0.20%–1.50% reported for palm-based biomass ashes. The observed variance in oxide composition compared to the values reported by Nwaiwu et al. (2023) is primarily attributable to differences in biomass provenance, processing parameters, and soil chemistry, because this concentration exceeds standard durability limits of 0.1%–0.4% by weight of binder unwashed EPFBA with this chemical profile is restricted exclusively to non-reinforced masonry applications, such as sandcrete partition blocks, to eliminate steel rebar corrosion risks. This result suggests the difference in ash source, the high iron of 22% and aluminum content of 16% suggests significant potential for contributing to the early and long-term strength of the sandcrete matrix. The presence of high alkali and chloride levels requires specific structural consideration: The potassium content of 12.03% in EFBA is relatively high compared to traditional coal fly ash and this will contribute to the setting time or hydration which may be beneficial for fast demolding process of the blocks this is confirms by Umar and Bello (2025). The primary risk is the presence of chlorine of 4.9% which is the primary agent of corrosion should not be used in reinforced concrete elements (like beams or columns) but does not pose a structural threat to the block itself.

Table 2: *Chemical Composition of Palm Fruit Bunch Ash*

Compound	**Conc Unit (m/m%)**	**Element**	**Conc Unit (m/m%)**
SiO_2	32.0300	Si	21.3500
Fe_2O_3	22.3300	Fe	14..8700
Al_2O_3	16.0190	Al	10.25000
K_2O	12.0260	K	8.02000
CaO	5.15000	Ca	4.25000
Cl	4.90000	Cl	4.20000
MgO	1.83000	Mg	1.21000
P_2O_5	1.32000	P	0.80000
SO_3	1.20000	S	0.8000

$SiO_2 + Al_2O_3 + Fe_2O_3$= 70.379

The bulk density of Palm Fruit Bunch Ash (PFBA) results as shown in table 3 indicates a low average bulk density of 260.54kg/m^3 contributes a substantial impact on the physical and mechanical properties of the resulting mortar and concrete composites. During the mixing phase, it was observed that the high porosity of the ash increased the water demand to maintain the required workability. Furthermore, the partial replacement of Portland cement with this low-density material is expected to facilitate a significant reduction in the bulk density of the hardened block, a property that is highly

advantageous for lightweight structural applications. Although the initial compressive strength was lower in comparison to the control mix, the pozzolanic activity of the EPFBA is anticipated to contribute to long-term strength development through the strengthening of the aggregate paste contact zone.

Table 3: *Bulk Density of Empty Palm Fruit Bunch Ash (PFBA)*

Parameter	**Trial I**	**Trial II**	**Trial III**	**Mean (±SD)**
Net Mass of Sample (g)	691.00	692.00	691.14	691.38±0.54
Volume of Container (cm^3)	2654.65	2654.65	2654.65	
Bulk Density (kg/m^3)	260.29	260.68	260.35	260.44±0.21

The physical characterization of the Palm Fruit Bunch Ash (PFBA) was carried out in (BS 1377: 1990) yielded a specific gravity of 2.5 as given in table 4. This was cited by (Sulaiman et al 2020). These values are significantly lower than those of conventional Ordinary Portland Cement, establishing the potential of palm fruit bunch ash for the production of lightweight concrete and mortar composites.

Table 4: *Specific gravity of Palm Fruit Bunch Ash (PFBA)*

Specific gravity, BS 1377: 1990				
M1= mass of Pycnometer(g)			M1= mass of Pycnometer(g)	
M2= mass of pyc+ sample(g)			M2= mass of pyc+ sample(g)	
M3=mass of pyc+ sample +water(g)			M3= mass of pyc+ sample +water(g)	
M4= mass of pyc+water(g)			M4= mass of pyc+water(g)	
PFBA	**PFBA**	**PFBA**	**PFBA**	**MEAN±SD**

M3	228.3	229.0	227.7	228.33±0.651
M4	223.4	224.0	223.8	223.73±0.306
	2.8	2.53	2.2	2.5 ±0.399
Specific Surface Area (Blaine), EN 196-6			$295.0m^2/kg$	
Sieve Residue (45um), ASTM C430-96			0.76%	

Furthermore, the fineness of the ash was assessed via the Blaine method, recorded a specific surface area of $295m^2/kg$ and a minimal sieve residue of 0.76% on the 45um sieve. This result conforms to Umar and (Bello 2025), who state that the pozzolanic activity of OPEFB ash is significantly enhanced when ground to a particle size finer than 45μm, as this increases the specific surface area available for chemical reaction. Consequently, the palm fruit bunch ash (PFBA) to contribute to the strength development of the matrix through the strengthening of the aggregate-paste contact zone, alongside

providing a micro-filler effect that enhances the overall densification of the hardened concrete. These properties collectively suggest that palm fruit bunch ash PFBA modified sandcrete block is well suited for non-load bearing structural applications where reducing self-weight is a primary design objective.

The compressive strength results for the varying PFBA replacement levels over a 28-day curing period are given in table 5, however, a progressive reduction in compressive strength is observed with increasing PFBA substitution this behavior is primarily attributed to the dilution effect, whereby the quantity of Portland cements the primary binder is reduced. Furthermore, the ash likely exhibits slower pozzolanic activity compared to the rapid initial hydration of cement clinker.

the control (0%), 5%, and 10% replacement levels meet the regulatory requirement demonstrating that 10% is the optimal threshold for structural applications, this value correspond to 3.5 N/mm^2 at 28 days, of the minimum given by Nigeria Industrial Standard (NIS), this agrees with Nwaiwu et al. (2023) and Eziefula et al., (2023). replacements of 15% and 20% with values of 3.24 N/mm^2 ±0.09 and 2.89 N/mm^2 ±0.09 fail to meet the standard therefore, these higher substitution levels are deemed unsuitable for load-bearing structural applications under existing regulations.

Table 5: Compressive strength (N/mm^2) result of palm fruit bunch ash (PFBA)

Mean ±SD	3.73±0.10	3.61±0.10	3.51±0.10	3.24±0.09	2.89±0.09

The experimental data demonstrates a direct correlation between the percentage of PFBA replacement and the dry density of the sandcrete blocks. As the PFBA content increased from 0% to 20%, the block density decreased from 1969 kg/m^3 to 1640 kg/m^3 as shown in table 6. This reduction is primarily attributed to the lower specific gravity of the PFBA particles compared to the Portland cement they replaced. this conforms to Sulaiman et al (2020) who stated that this lower density allows for the production of lightweight masonry units, which can reduce the overall dead load of a building by up to 8%. But in structural engineering, higher density often acts as an indicator of the block's internal matrix quality.

According to established building standards, a significant drop in density can correlate with increased porosity. At 10% replacement, the unit achieves a density of 1820 kg/m^3, which remains 20 kg/m^3 above the 1800 kg/m^3 threshold commonly used to demarcate standard weight from lightweight structural elements. While this value confirms that the 10% mixture successfully meets normal weight density requirements, it represents a critical transition point in the design envelope, as higher replacement levels (15% and 20%) drop to 1724 kg/m^3 and 1640 kg/m^3 respectively. The drop in density from the control value (1969 kg/m^3) is directly linked to the lower specific gravity of the ash and increased void formation, as evidenced by the progressive increase in water absorption to 5.670%. Consequently, 10% represents the practical upper limit for maintaining standard density, requiring strict

field batching and compaction controls to ensure field production units do not dip below the 1800 kg/m³ minimum due to site variability.

The data in table 6 also revealed a consistent increase in water absorption as the percentage of PFBA replacement increases. The control sample (0% PFBA) exhibited the lowest water absorption at 5.100%, whereas the 20% replacement level recorded the highest value of 6.610%.

This upward trend suggests that the incorporation of PFBA leads to an increase in the porosity of the sandcrete block matrix. This is likely due to the modification of the pore structure, where the presence of ash particles influences the density of the binder matrix. While all observed values remain within the acceptable limits typically prescribed for sandcrete blocks (often capped at 12% by Nigeria Industrial standards NIS 978:2017 Sandcrete Block), the progressive increase indicates that higher replacement levels may negatively impact the durability of the blocks.

Table 6: *Density and water absorption of palm fruit bunch ash (PFBA)*

PFBA Replacement (%)	Wet Mass (kg)	Dry weight (kg)	Water Absorption ±SD (%)	Density ±SD (kg/m^3)

4 CONCLUSION

i. PFBA is a viable partial replacement for Ordinary Portland Cement in sandcrete block production with a replacement level of 10% as the optimal threshold for load bearing applications as the blocks meets the minimum required specification.

ii. The adoption of PFBA modified blocks lower carbon footprint in construction by diverting agricultural waste from open and uncontrolled burning, this practice significantly reduces emission and aligns with global sustainable development goals and local eco-friendly construction mandates.

iii. The chemical composition of the ash particularly high chloride content poses a significant technical risk as it's known to increase the electrochemical corrosion of embedded steel reinforcement in structural elements, therefore the chemical profile of the ash must be strictly validated to prevent long term structural failure.

iv. The use of control burning is paramount to ensuring the production of high-quality reactive pozzolanic ash suitable for masonry.

ACKNOWLEDGMENT

I am deeply grateful to my supervisor, Prof. Tsado, Dr. James and Prof. Auta S. M, for their invaluable guidance, constructive criticisms, and for providing the research topic that made this work possible, also I acknowledge the technical staff of the Nigerian Building and Road Research Institute NBBRI, for their assistance during the test procedures, and Special thanks to my family for their love, support, and encouragement. To God be the glory for His grace and strength throughout this thesis

ABSTRACT

This study evaluated the physico-mechanical properties of sustainable ternary blended concrete incorporating corn cob ash (CCA) and rice husk ash (RHA) as partial cement replacements. The work assessed the suitability of these agricultural by-products as supplementary cementitious materials (SCMs) for sustainable concrete production. Laboratory investigations were carried out on CCA and RHA in accordance with British Standards (BS EN) and ASTM procedures to ensure reliable and accurate results. Physical characterization demonstrated compliance with standard requirements, including a cement soundness of 1.0mm. The cement exhibited a fineness of 97.7%. Aggregate tests, including specific gravity and particle-size grading, also met relevant standards for quality concrete production. Following the procedures and requirements of ASTM C618-2023, RHA was classified as a Class N pozzolan, with a combined SiO_2, Al_2O_3, and Fe_2O_3 of 81.33%, while CCA had 64.85%, which fell short of the Class N oxide composition threshold but contributed actively to the pore refinement and particle packing density of the cement matrix and secondary reactivity in the ternary blend. X-ray fluorescence (XRF) and X-ray diffraction (XRD) identified amorphous silica and other reactive phases in both ashes, confirming their pozzolanic reactivity and ability to participate in cement hydration, thereby enhancing concrete strength and durability. The reference Grade 25 concrete (Control) has the following strength margins of 22.1N/mm2, 25.3N/mm2, 28.0N/mm2 and 32.1N/mm2 for 7, 28, 56, and 90 days, respectively. In ternary-blended concrete, cement was replaced with 5% CCA and 10% RHA, yielding an optimum mix with compressive strengths of 25.5N/mm2, 37.0N/mm2, 39.5N/mm2, and 41.5N/mm2 at 7, 28, 56, and 90 days, respectively. These results showed increases of 15.4%, 46.3%, 41.1%, and 29.3% in the sustainable ternary blended concrete over the referenced concrete at the 7, 28, 56, and 90-day curing periods. The findings demonstrate that CCA and RHA are viable SCMs that reduce cement consumption, lower carbon emissions, promote effective waste management, and support environmentally sustainable concrete production without compromising material quality in practical construction applications and long-term infrastructure development.

1. INTRODUCTION

Concrete remains the most extensively utilized engineered material globally, with annual production exceeding 10 billion tons (Ge et al., 2022). This staggering volume underscores concrete's indispensable role in modern infrastructure development, spanning residential, commercial, and civil engineering applications worldwide. It is one of the oldest and most common construction materials in the world, mainly because of its low cost, availability, long-term durability, and ability to withstand extreme weather conditions. Amartey et al., (2024) asserted that concrete strength, durability, and other physical properties are affected by curing and applying the various types as they relate to the prevailing weather conditions in a particular locality.

Portland Limestone Cement (PLC), the primary binder in concrete production, is, however, associated with substantial environmental degradation. Cement production is an energy-intensive process that accounts for a substantial share of global anthropogenic carbon dioxide emissions. The calcination of limestone and the combustion of fossil fuels, needed for clinkering temperatures over

1400°C, largely drive these emissions. As the construction sector expands to meet the demands of rapid urbanization, particularly in developing regions, the search for sustainable alternatives that can reduce clinker demand while maintaining or enhancing the engineering performance of concrete has become a central research priority.

Supplementary cementitious materials (SCMs) derived from agricultural residues and industrial by-products have emerged as a promising avenue for achieving this objective. Agro-waste ashes such as corn cob ash (CCA), rice husk ash (RHA), sugarcane bagasse ash (SBA), and palm oil fuel ash (POFA) are rich in reactive silica and other pozzolanic oxides. Indumathi et al., (2024) inferred that rice husk ash has a positive impact on the strength and durability of concrete, while also contributing to a reduction in carbon emissions and construction expenses, and encouraging environmentally conscious building methods through the reuse of agricultural waste. The partial replacement of cement with supplementary cementitious materials (SCMs) offers both environmental and practical benefits. It reduces the amount of clinker required in concrete production, thereby lowering carbon emissions, while also providing a productive use for agricultural residues that might otherwise be disposed of through open burning or left to decompose, both of which contribute to environmental pollution. Researchers have extensively documented rice husk's pozzolanic potential in the literature. When burnt under controlled temperatures, this rice husk, a rice milling by-product, produces ash rich in amorphous silica. Corn cob, similarly abundant in maize-producing regions such as Nigeria, has more recently attracted research attention as a complementary agro-pozzolan, although its silica content and reactivity are generally lower than that of RHA and more sensitive to calcination conditions.

Recent studies continue to affirm the technical viability of RHA and CCA in blended cementitious systems. Kariyawasam and Semananda (2025) reviewed the challenges and opportunities associated with rice husk ash utilization in sustainable construction, noting that controlled combustion temperature and fineness are critical determinants of its pozzolanic efficiency. Sathiparan (2025a) similarly conducted a systematic review of corncob ash in construction, reporting that while CCA generally exhibits lower silica-alumina-iron content than RHA, appropriate calcination and particle size reduction can substantially improve its reactivity, and in a companion study applied machine learning approaches to predict the compressive strength of corn cob ash concrete from mix design variables (Sathiparan, 2025b). Okeke et al. (2026) demonstrated that corncob ash calcined within a 400 to 700°C furnace window consistently achieved combined pozzolanic oxide contents above the 70% threshold specified in ASTM C618, with amorphous silica content exceeding 80%, underscoring the importance of processing conditions in determining whether a given batch of CCA meets recognized pozzolan classification limits.

While the individual performance of RHA and CCA as binary cement replacements has received reasonable investigation, the synergistic use of these materials in ternary blended systems remains comparatively under-explored, especially for concrete produced and cured under ambient tropical conditions typical of sub-Saharan Africa. Ternary blending, in principle, allows the complementary strengths of two or more SCMs to be exploited simultaneously: the high pozzolanic reactivity of RHA can compensate for the comparatively lower reactivity of CCA, while the particle packing and micro-filler effects contributed by both materials can further refine the pore structure of the hardened cement matrix. Recent ternary blend studies involving other agro-industrial by-products support this synergy. Oyebisi and Alquraish (2025) reported that ternary blends incorporating shea nutshell ash and ground oyster seashell improved compressive, flexural, and split tensile strength at later curing ages relative to a control mix, alongside improved resistance to acidic and sulfate attack. Navaneetha et al. (2025) similarly developed durable ternary blended concrete using sugarcane bagasse ash and glass powder, while Ashok et al. (2025) demonstrated that ternary combinations of recycled fine aggregate, sugarcane bagasse ash, and ground granulated blast furnace slag markedly reduced rapid chloride penetration values relative to a control mix, confirming that combined SCM systems can enhance both strength and durability performance simultaneously.

Beyond ambient strength development, the behavior of RHA-blended concrete under elevated temperature exposure has also received recent attention because of its relevance to fire safety and structural resilience. Nazari and Toufigh (2024) investigated the effects of elevated temperatures and water re-curing on RHA concrete, reporting that RHA content influences residual strength retention after thermal exposure and that re-curing can partially recover strength lost to thermal damage, while a follow-up study developed predictive models for the ultrasonic pulse velocity and physicochemical

behavior of RHA concrete after fire exposure (Nazari & Toufigh, 2026). Singh and Tiwary (2026) reviewed the high-temperature resistance of silica-rich SCM-blended concretes, including RHA and silica fume systems, concluding that moderate RHA replacement levels generally improve residual mechanical performance up to a threshold temperature beyond which matrix degradation dominates. These findings collectively suggest that ternary RHA-CCA systems may offer both ambient-condition mechano-durability benefits and improved resilience under thermal stress, an area that has not been comprehensively addressed for the specific combination and replacement levels investigated in the present study.

This study, therefore, examines the physico-mechanical properties of Grade 25 ternary blended concrete produced by replacing 10% of cement with RHA and 5% with CCA, evaluated against a conventional Grade 25 control mix. The chemical suitability of both ashes as pozzolans is first assessed through oxide characterization referenced against ASTM C618 and NIS 444-1:2003 provisions, followed by a physical characterization of the cement, and finally the compressive strength development of both mixes is compared at 7, 28, 56 and 90 days. The specific objectives of the study are to: (i) characterize the physical properties (soundness and fineness) of the cement used; (ii) determine the oxide composition of RHA and CCA and assess their conformity to recognized pozzolan standards; (iii) evaluate the compressive strength development of ternary blended concrete relative to a conventional control mix over a 90-day curing regime; and (iv) quantify the percentage strength gain attributable to the ternary blend at each curing age, thereby providing an experimentally grounded basis for recommending RHA-CCA ternary blends for structural applications.

1.1 Environmental Rationale for Agro-Waste Cement Replacement

The environmental case for reducing PLC content in concrete extends beyond carbon dioxide emissions alone. Cement production is also a significant consumer of virgin raw materials, principally limestone and clay, whose extraction contributes to land degradation, biodiversity loss, and dust and particulate emissions in quarrying regions. Concurrently, the disposal of agricultural residues such as rice husk and corn cob presents its own environmental challenge in many rice- and maize-producing economies, where uncontrolled open-field burning of these residues is a common disposal practice, generating particulate matter, black carbon and greenhouse gas emissions that degrade regional air quality. The conversion of these residues into value-added SCMs therefore addresses two environmental problems simultaneously: it reduces the clinker factor of concrete, thereby lowering the embodied carbon of the resulting structure, and it provides an economically incentivized outlet for agricultural residues that would otherwise be burned or landfilled. This circular-economy rationale has been a recurring theme in recent SCM literature, with several studies explicitly framing agro-waste ash valorization within sustainable development goal targets relating to responsible consumption and production, industry innovation, and climate action (Okeke et al., 2026).

From a materials science perspective, its oxide chemistry, its degree of amorphous (non-crystalline) silica content, and its particle fineness govern the suitability of any candidate ash for use as Reactive amorphous silica is essential because it is this phase, rather than crystalline silica, that participates readily in the pozzolanic reaction with calcium hydroxide liberated during PLC hydration. The combustion temperature at which agricultural residues are converted to ash is therefore a critical process variable: excessively high combustion temperatures promote the crystallization of silica into less reactive polymorphs such as cristobalite or tridymite, while insufficient combustion leaves residual unburnt carbon that increases loss on ignition and can adversely affect water demand and durability. This sensitivity to processing conditions has been demonstrated for both RHA and CCA in recent calcination optimization studies, which report that ashes produced within an optimal thermal window consistently outperform both under-burnt and over-burnt ashes in terms of both chemical reactivity and resulting concrete strength (Okeke et al., 2026).

1.2 Rice Husk Ash as a Supplementary Cementitious Material

Rice husk ash has, over the past two decades, become one of the most extensively studied agro-based SCMs, owing to the exceptionally high silica content of rice husk (typically in excess of 90% SiO2 on an ash basis when combustion is properly conducted) and the sheer volume of rice husk generated annually as a by-product of rice milling in major rice-producing countries. When burnt under

controlled conditions, typically in the range of 500 to 700°C, rice husk yields an ash dominated by amorphous silica with a highly porous, cellular microstructure that, once ground to a fine particle size, exhibits substantial pozzolanic reactivity. Numerous studies have confirmed that RHA-blended concretes exhibit improved compressive, flexural and split tensile strength at later curing ages relative to plain PLC concrete, alongside reduced permeability, improved resistance to chloride ion penetration, and mitigation of expansive reactions such as alkali-silica reaction. Kariyawasam and Semananda (2025) provide a comprehensive synthesis of this body of work, highlighting that the principal barriers to widespread RHA adoption are not technical but relate to inconsistent ash quality arising from uncontrolled combustion practices at the point of generation, underscoring the importance of standardized processing protocols of the kind adopted in the present study.

1.3 Corn Cob Ash as a Complementary Pozzolan

Corn cob ash has attracted comparatively less research attention than RHA, but interest has grown markedly in the past two to three years as researchers have sought to diversify the portfolio of viable agro-waste SCMs beyond rice-based residues, particularly in maize-dominant agricultural economies. Corn cob ash typically exhibits a lower combined $SiO_2 + Al_2O_3 + Fe_2O_3$ content than RHA, and a comparatively higher content of potassium oxide, which does not contribute to pozzolanic reactivity and can, in excessive quantities, present concerns relating to alkali content and potential efflorescence. Nonetheless, recent characterization work demonstrates that, when calcined within an appropriate thermal window, CCA can achieve amorphous silica contents and combined pozzolanic oxide values that meaningfully exceed those obtained under uncontrolled open-burning conditions, narrowing the reactivity gap between CCA and RHA (Okeke et al., 2026; Sathiparan, 2025a). Sathiparan (2025b) further demonstrated, using machine learning models trained on a compiled dataset of CCA concrete mixes, that compressive strength outcomes for CCA-blended concrete are strongly influenced by replacement level, water-cement ratio and ash fineness, providing a data-driven confirmation of trends previously established through conventional experimental testing. These findings support the treatment of CCA, in the present study, not as a primary reactive binder component but as a complementary secondary pozzolan whose principal contribution within a ternary system lies in particle packing refinement and supplementary reactivity rather than as the dominant reactive phase.

1.4 Ternary Blending and Research Gap

The rationale for combining two or more SCMs within a single ternary or quaternary cementitious system rests on the principle of complementary particle packing and staggered reactivity. Concrete performance remains unaffected when RHA replaces 10% to 20% of cement, owing to RHA's strong pozzolanic qualities (Endale et al., 2022). They stated that using RHA as a partial cement substitute in concrete offers further environmental advantages, including conserving resources and managing agricultural waste, thereby promoting a circular economy within construction. Where a highly reactive, ultra-fine pozzolan such as silica fume or a well-processed RHA is combined with a comparatively coarser or moderately reactive material, the resulting particle size distribution of the combined binder can more effectively fill the voids between cement grains than either material used alone, producing a denser and less permeable matrix. This principle has been demonstrated across a range of ternary systems in the recent literature, including combinations of metakaolin and palm oil fuel ash with coal bottom ash fine aggregate, which achieved measurable reductions in water absorption and chloride resistance relative to binary and control mixes, and combinations of recycled fine aggregate, sugarcane bagasse ash and ground granulated blast furnace slag, which achieved substantial reductions in rapid chloride penetration values alongside improved compressive strength (Ashok et al., 2025). Despite this growing body of evidence supporting ternary SCM systems generally, and despite RHA and CCA each being individually well characterized, published experimental work specifically evaluating RHA-CCA ternary blends at defined replacement ratios, produced and cured under ambient tropical conditions and evaluated across a full 90-day strength development profile, remains limited. This represents the specific research gap addressed by the present study, which provides laboratory-derived compressive strength data for a 10% RHA plus 5% CCA ternary blend benchmarked directly against a Grade 25 control mix.

2. MATERIALS AND METHODS

2.1 Materials

Portland limestone cement (CEM II/B-L 42.5N), conforming to relevant national and international standards, served as the primary binder. Fine aggregate consisted of clean, well-graded natural river sand, and coarse aggregate comprised crushed granite with a maximum nominal size of 20 mm. Both aggregates were sourced locally and tested using standard sieve analysis and specific gravity procedures before batching. Potable water free of deleterious substances was used for mixing and curing throughout the experimental program.

Rice husk was sourced from a local rice milling facility and subjected to controlled open-air combustion followed by further heating to ensure complete carbon burn-off, after which the resulting ash was air-cooled, ground/ball milled, and sieved through a 75-micron sieve to obtain RHA of pozzolanic fineness as shown in Plates I(a), I(b) and VI. Corn cob was similarly sun-dried, combusted under controlled conditions, and the resultant ash ground and sieved to a comparable particle fineness to obtain CCA as shown in Plates II(a) and II(b)

Both ashes were stored in sealed, moisture-proof containers prior to use to prevent premature hydration or carbonation of reactive constituents.

2.2 Characterization of Materials

The physical properties of the cement were determined in accordance with standard test methods, including the Le Chatelier soundness test, setting time and, the sieve method for fineness using the 75μm single sieve as shown in Plates III and IV. Specific gravity of the cement, fine aggregate, coarse aggregate, CCA and RHA was determined using the pycnometer and specific gravity bottle methods, respectively, while particle size distribution and silt/clay content of the aggregates were established through standard sieve analysis and silt/clay content test to confirm conformity with grading envelope requirements and minimum silt/clay content for normal-weight concrete as shown in Plates V(a) and V(b). The ball milling of the CCA and RHA are shown in Plates VI(a) and VI(b) while the calcination of the CCA and RHA is shown in Plate VII. The chemical composition of CCA and RHA was determined using X-ray fluorescence (XRF) spectroscopy to quantify the principal oxide constituents, including SiO_2 Al_2O_3, Fe_2O_3, CaO, MgO, K_2O, Na_2O and loss on ignition (LOI). The combined $SiO_2 + Al_2O_3 + Fe_2O_3$ content of each ash was compared against the minimum 70% threshold specified by ASTM C618 for Class N natural pozzolans and the equivalent provisions of NIS 444-1:2003, the Nigerian Industrial Standard governing the composition, specification and conformity criteria for cement and pozzolanic materials used in concrete production.

2.3 Mix Design and Specimen Preparation

Two concrete mixes were designed and batched by weight to achieve a target characteristic strength of 25 N/mm² (Grade 25) at 28 days, in accordance with standard absolute volume mix design procedures. The control mix (designated CM) contained 100% PLC as the sole binder, while the ternary blended mix (designated TM) incorporated a combined 15% cement replacement, comprising 10%

RHA and 5% CCA by mass of total binder, with the balance of the mix proportions (water-cement ratio, fine aggregate, and coarse aggregate content) held constant between the two mixes to isolate the effect of the binder substitution on strength development as shown in Table1. Batching by weight was applied.

Table 1: Mix proportion for CM and TM

I.D	RHA (kg)	CCA (kg)	Cement (kg)	Sand (kg)	Grave (kg)	Water (kg)	W/C
CM	0	0	22.1	49.3	72.6	12.6	0.57
TM	2.2	1.1	18.8	49.3	72.6	12.6	0.57

Concrete cubes of 100 mm × 100 mm × 100 mm were cast for each mix, compacted in accordance with standard practice to minimize entrapped air voids, and demoulded after 24 hours before being transferred to a curing tank maintained at ambient laboratory temperature until the respective testing ages of 7, 28, 56, and 90 days.

2.4 Compressive Strength Testing

Compressive strength testing was performed on triplicate cube specimens for each mix at each curing age using a calibrated universal compression testing machine at a uniform loading rate, in accordance with standard cube-crushing procedures. The average of the three specimens at each age was recorded as the representative compressive strength for that mix and curing age. The percentage strength variation of the ternary blend relative to the control at each age was subsequently computed.

2.5 Experimental Rigour and Quality Control

Several quality control measures were adopted to ensure the reliability and reproducibility of the results obtained. All batching was carried out by weight rather than by volume to minimize proportioning error, and a single source of cement, aggregate, and water was maintained throughout the experimental programme to eliminate material-source variability as a confounding factor between the control and ternary mixes. Slump testing was conducted on both fresh mixes to confirm that workability remained within an acceptable range for the compaction method employed, since excessive loss of workability arising from the high-water demand and fine particle size of agro-waste ashes is a commonly reported side effect of SCM incorporation that can, if unmanaged, itself depress hardened concrete strength independently of any pozzolanic effect. Curing water temperature was monitored throughout the 90-day curing period to confirm that specimens were maintained under consistent ambient curing conditions, and cube specimens exhibiting visible casting defects, edge damage, or non-planar bearing surfaces at the time of testing were excluded from the reported average strength values in line with standard practice for compression testing of concrete.

Percentage strength gain (%) = $[(f_{c,TM} - f_{c,CM}) / f_{c,CM}] \times 100$

where $f_{c,TM}$ is the compressive strength of the ternary blended concrete and $f_{c,CM}$ is the compressive strength of the control concrete at the corresponding curing age.

3. RESULTS AND DISCUSSION

3.1 Physical Properties of Cement

The soundness and fineness of the PLC used in this study were determined before concrete production to confirm suitability for structural use. The cement recorded a soundness value of 1.0 mm, well below the 10 mm maximum expansion limit typically specified by BS EN 196-3:2016, indicating a negligible risk of delayed expansion arising from free lime or magnesia content. The fineness of the cement was determined as 97.7%, indicating that a high proportion of cement particles passed the specified sieve, consistent with adequate hydration reactivity and early strength development potential. Both results confirm that the cement used conformed to standard requirements and provided a reliable baseline binder for evaluating the effect of RHA and CCA substitution.

Table 2: Physical properties of the cement used

Parameters	Result	Typical Limit
Soundness (Le Chatelier)	1.0 mm	≤ 10 mm
Fineness	97.7%	90%

3.2 Chemical Composition and Pozzolanic Conformity of CCA and RHA

XRF analysis of the two agro-waste ashes revealed a combined $SiO_2 + Al_2O_3 + Fe_2O_3$ content of 64.85% for CCA and 81.33% for RHA, as presented in Table 2. Figures 1 and 2 show the amorphous and crystalline phases of the two ashes. When referenced against the 70% minimum threshold stipulated by ASTM C618 for Class N natural pozzolans and the corresponding conformity criteria of NIS 444-1:2003, RHA satisfies the pozzolanic classification requirement with a comfortable margin, confirming its suitability as a reactive cement replacement material. CCA, at 64.85%, falls marginally short of the 70% threshold when considered in isolation, a finding consistent with recent characterization studies which report that unmodified or moderately calcined corncob ash frequently records combined pozzolanic oxide values in the 60 to 70% range, with only carefully controlled calcination regimes achieving values consistently above the threshold (Okeke et al., 2026; Sathiparan, 2025a). This is attributable to the relatively higher content of potassium oxide (K_2O) and other non-pozzolanic alkaline constituents typically present in corn-derived ashes, which dilute the proportion of reactive silica-alumina-iron oxides relative to rice-derived ashes.

Despite CCA falling marginally below the individual ASTM C618 threshold, its inclusion at a modest 5% replacement level within a ternary system incorporating a highly reactive RHA component is expected to contribute beneficially through both a secondary pozzolanic reaction, in which residual reactive silica and alumina combine with calcium hydroxide liberated during PLC hydration to form additional calcium silicate hydrate (C-S-H) and calcium aluminate silicate hydrate (C-A-S-H) gel, and a physical filler effect, whereby the fine ash particles occupy pore spaces within the cement matrix, refining pore structure and improving particle packing density. This synergistic mechanism, whereby a highly reactive pozzolan compensates for a moderately reactive one within a ternary blend, has been similarly reported for other combined agro-waste systems, including shea nutshell ash and oyster seashell blends (Oyebisi & Alquraish, 2025) and sugarcane bagasse ash and glass powder blends (Navaneetha et al., 2025), both of which demonstrated improved strength and durability performance relative to single-SCM or plain control mixes.

Table 3: Combined pozzolanic oxide content of RHA and CCA

Parameter	CCA (%)	RHA (%)	ASTM C618/NIS 444-1 Limits
$SiO_2 + Al_2O_3 + Fe_2O_3$	64.85	81.33	≥ 70 (min.)
Conformity status	Marginal / Sub-threshold	Conforms	—

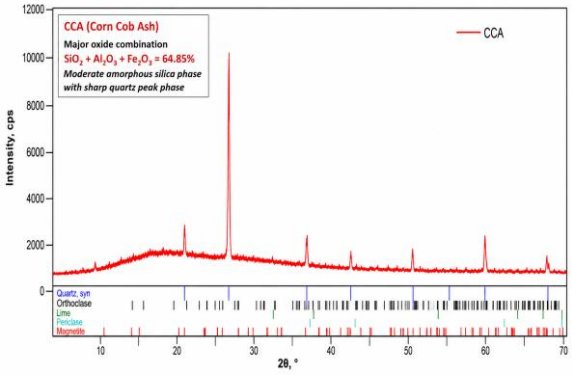

Figure 2: Diffractometer of CCA

3.3 Compressive Strength Development

Table 3 presents the compressive strength results of the control (CM) and ternary-blended (TM) concretes at 7, 28, 56, and 90 days, along with the corresponding percentage strength gain of the ternary blend over the control at each age. The control concrete developed compressive strengths of 22.1, 25.3,

28.0 and 32.1 N/mm² at 7, 28, 56 and 90 days, respectively, consistent with expected strength development trends for Grade 25 concrete. The ternary blended concrete recorded correspondingly higher strengths of 25.5, 37.0, 39.5 and 41.5 N/mm² at the same respective ages, exceeding the control at every stage of curing.

Table 4: Compressive strength and percent strength gain of TM over CM concrete

Curing Age (Days)	Control Concrete, CM (N/mm^2)	Standard Deviation (N/mm^2)	Coefficient of Variation (%)	Ternary Blend, TM (N/mm^2)	Standard Deviation (N/mm^2)	Coefficient of Variation (%)	Strength Gain of TM over CM (%)
7	22.1	2.59	11.70	25.5	0.5	1.96	15.4
28	25.3	1.47	5.80	37.0	0.5	1.35	46.3
56	28.0	0.50	1.80	39.5	0.5	1.27	41.1
90	32.1	0.53	1.65	41.5	0.5	1.20	29.3

At 7 days, the ternary blend exceeded the control by 15.4%, an outcome attributable primarily to the physical filler effect of the finely ground RHA and CCA particles, which improved particle packing and reduced early-age capillary porosity, rather than a substantial pozzolanic contribution, since the pozzolanic reaction between reactive silica and calcium hydroxide is generally slower to activate than primary PLC hydration at early ages. By 28 days, the strength gain rose sharply to 46.3%, the highest recorded improvement across all curing ages, reflecting the onset of significant secondary pozzolanic reactivity as calcium hydroxide liberated from PLC hydration became available for combination with the reactive silica-alumina-iron oxides contributed by both ashes, generating additional C-S-H and C-A-S-H gel that densified the microstructure and enhanced load-bearing capacity beyond what filler action alone could achieve.

The percentage strength gain moderated to 41.1% at 56 days and further to 29.3% at 90 days. This trend, while still representing substantial and consistent superiority of the ternary blend over the control, reflects the progressive strength gain of the control mix itself as PLC hydration continues over time, gradually narrowing the relative gap even as the absolute strength of the ternary blend continues to increase. A similar pattern, in which the percentage advantage of SCM-blended concrete over control concrete is most pronounced at intermediate curing ages before moderating at later ages as the control mix and ternary blended mix continue to gain strength through ongoing cement hydration, has been reported in comparable ternary blend studies (Ashok et al., 2025; Navaneetha et al., 2025), reinforcing the plausibility of the trend observed in the present study. Importantly, the ternary blend's compressive strength at 90 days (41.5 N/mm²) considerably exceeds both the 25 N/mm² target grade and the corresponding 90-day control strength (32.1 N/mm²), confirming that the 15% combined RHA-CCA replacement not only meets minimum structural strength requirements but also delivers substantial long-term strength enhancement.

These results are consistent with the chemical characterization findings discussed in Section 3.2, wherein the high pozzolanic oxide content of RHA (81.33%) due to appropriate calcination temperature as supported by (Ang'ang'o *et al.*, 2024; Su *et al.*, 2024) provided the principal reactive silica source driving secondary C-S-H formation, while CCA, despite its marginally sub-threshold oxide content, contributed complementary filler action and residual pozzolanic activity that collectively enhanced the mechanical performance of the ternary system relative to the single-binder control. This synergy between a highly reactive primary pozzolan and a moderately reactive secondary pozzolan within a ternary blend aligns with observations reported for other combined agro-industrial waste systems in the recent literature (Oyebisi & Alquraish, 2025; Ashok et al., 2025). The consistent strength superiority of the ternary blend across all curing ages also carries favourable implications for the durability performance of the concrete, since a denser, more refined pore structure arising from pozzolanic C-S-H and C-A-S-H formation is typically associated with reduced permeability, lower susceptibility to chloride ion ingress, and improved resistance to aggressive environmental exposure, as reported for comparable ternary SCM systems evaluated through rapid chloride penetration and sorptivity testing (Ashok et al., 2025).

The findings also have relevance to the thermal performance of the ternary blend, an aspect not directly investigated in the present study but of practical significance for structural fire safety. Prior

work on RHA-blended concrete indicates that moderate levels of RHA replacement can improve residual compressive strength retention following exposure to elevated temperatures up to a threshold in the region of 400°C, beyond which progressive dehydration of C-S-H gel and thermal incompatibility between aggregate and paste phases begin to dominate degradation behavior (Nazari & Toufigh, 2024; Singh & Tiwary, 2026). Given the denser microstructure indicated by the enhanced compressive strength of the ternary blend investigated here, it is plausible that the RHA-CCA ternary system would exhibit comparable or improved elevated-temperature resilience relative to plain PLC concrete, a hypothesis that warrants dedicated experimental investigation, as elaborated in the recommendations.

3.4 Strength Development Trend and Rate of Gain

Examining the rate of strength gain between successive curing ages provides further insight into the reaction kinetics of the two mixes. For the control concrete, strength increased from 22.1 to 25.3 N/mm² between 7 and 28 days (a gain of 14.5%), from 25.3 to 28.0 N/mm² between 28 and 56 days (a gain of 10.7%), and from 28.0 to 32.1 N/mm² between 56 and 90 days (a gain of 14.6%), reflecting the comparatively gradual and steady hydration behavior typical of plain PLC systems, in which the bulk of strength development occurs within the first 28 days with more modest subsequent gains as unhydrated cement grains continue to react slowly over time. The ternary blend, by contrast, exhibited a markedly steeper early rate of gain, increasing from 25.5 to 37.0 N/mm² between 7 and 28 days (a gain of 45.1%), before moderating to a gain of 6.8% between 28 and 56 days and a further 5.1% between 56 and 90 days. This pattern, of a sharp acceleration in strength gain concentrated in the 7 to 28-day window followed by a more gradual plateau at later ages, is characteristic of pozzolanic systems in which secondary C-S-H formation is strongly dependent on the availability of calcium hydroxide generated by primary PLC hydration; once a substantial proportion of the available calcium hydroxide has been consumed in the secondary pozzolanic reaction, the rate of further strength gain necessarily slows, even though the absolute strength of the blend remains consistently higher than that of the control at every subsequent age.

This kinetic behaviour has direct practical implications for construction scheduling and formwork removal timelines. The substantial 28-day strength of the ternary blend (37.0 N/mm², corresponding to 148% of the 25 N/mm² design grade) indicates that structural elements incorporating this ternary blend would achieve standard design strength requirements well within conventional construction programme durations, while the continued, albeit more gradual, strength gain observed through to 90 days provides an additional long-term durability and safety margin relative to the control mix.

3.5 Workability and Practical Considerations

Consistent with widely reported behavior for fine, high-surface-area agro-waste ashes, the incorporation of RHA and CCA at the combined 15% replacement level used in this study was observed to increase the water demand of the ternary mix relative to the control at a constant water-cement ratio, necessitating close attention to compaction during specimen casting to avoid entrapped air voids that could otherwise depress hardened strength independently of any pozzolanic benefit. The control mix (CM) recorded a higher slump of 95 mm, which is in the slump class of S2–S3 (borderline, adjacent to S3), indicating relatively better workability, while the ternary mix (TM) recorded 78 mm, slump class S2, and showed medium workability. The lower slump of the TM may be attributed to the fine, porous RHA particles, which increased water demand and reduced the flowability of the concrete (Barbhuiya *et al.*, 2025). This water demand effect arises from the high specific surface area and internal porosity of both RHA and CCA particles, which absorb a proportion of the mixing water during the initial stages of mixing. Where field application of this ternary blend is contemplated at a larger scale, this observation supports the recommendation, discussed further in Section 5, that either a water-reducing admixture be incorporated or the water-cement ratio be modestly adjusted and validated through trial mixes to maintain the target workability without compromising the water-cement ratio upon which the strength results reported in this study were obtained.

3.6 Comparative Discussion with Recent Literature

The magnitude of strength enhancement observed in this study is broadly consistent with, and in some respects exceeds, values reported in comparable recent ternary blend studies. Oyebisi and Alquraish (2025) reported strength increases in the order of 3% at 10% combined replacement of shea nutshell ash and ground oyster seashell relative to control concrete after 90 days of curing, a considerably more modest gain than the 29.3% recorded for the RHA-CCA ternary blend in the present study at the same age, suggesting that the specific combination of RHA and CCA investigated here provides a comparatively more effective pozzolanic and filler synergy than some alternative agro-industrial waste pairings. Similarly, studies combining rice husk ash with extracted microsilica in ternary high-strength concrete systems have reported 28-day compressive strength increases in the range of 6 to 12% relative to a control mix, again below the 46.3% recorded in the present study, although differences in target concrete grade, aggregate type, and baseline mix design between studies necessarily limit the extent to which direct numerical comparison can be drawn. The comparatively larger strength gains recorded here may be partly attributable to the relatively higher combined replacement level (15%) and the specific 10:5 RHA-to-CCA ratio employed, which appears, based on the oxide chemistry discussed in Section 3.2, to have provided a favourable balance between highly reactive silica supply from RHA and complementary filler and secondary reactivity from CCA.

The results also lend indirect support to the durability inferences drawn from ternary systems investigated elsewhere in the literature. Ashok et al. (2025) demonstrated that ternary blends incorporating recycled aggregate and agro-industrial by-products achieved substantial reductions in rapid chloride penetration values, a durability benefit generally attributed to the same pore-refining mechanism responsible for the compressive strength enhancement observed in the present study. While the present investigation was limited in scope to mechanical strength testing and did not directly evaluate permeability or chloride resistance, the consistency of the observed strength trend with mechanisms reported in these durability-focused studies provides reasonable grounds to anticipate that the RHA-CCA ternary blend investigated here would similarly exhibit enhanced durability performance, a hypothesis that should be confirmed through dedicated testing as outlined in the recommendations.

4. CONCLUSION

This study evaluated the physico-mechanical properties of Grade 25 sustainable ternary blended concrete incorporating rice husk ash (10%) and corn cob ash (5%) as partial cement replacements, relative to a conventional control mix. Based on the laboratory characterization and compressive strength results obtained, the following conclusions are drawn. The cement used in the study conformed to standard requirements, with a soundness of 1.0 mm and fineness of 97.7%, providing a reliable baseline for assessing the effect of SCM substitution. XRF characterization confirmed that RHA possessed a combined $SiO_2 + Al_2O_3 + Fe_2O_3$ content of 81.33%, satisfying the ASTM C618 and NIS 444-1:2003 minimum pozzolanic threshold of 70%, while CCA recorded 64.85%, marginally below the individual threshold but still capable of contributing complementary filler and residual pozzolanic action within a ternary system.

The ternary blended concrete outperformed the control concrete in compressive strength at every curing age investigated, recording percentage strength gains of 15.4%, 46.3%, 41.1% and 29.3% at 7, 28, 56 and 90 days, respectively, with the most pronounced improvement occurring at 28 days. The 90-day strength of the ternary blend (41.5 N/mm^2) substantially exceeded both the Grade 25 design target and the corresponding control strength, confirming that a 15% combined cement replacement using RHA and CCA in a 10:5 ratio is not only technically feasible but mechanically advantageous. These outcomes are consistent with a mechanism in which RHA supplies the principal reactive silica source for pozzolanic C-S-H formation, while CCA contributes complementary micro-filler action and secondary reactivity, together producing a denser and mechanically superior cementitious matrix relative to plain PLC concrete.

The study demonstrates that RHA-CCA ternary blended concrete represents a technically sound and environmentally beneficial alternative to conventional concrete for structural applications requiring Grade 25 strength, offering a pathway to reduce clinker demand, valorize agricultural residues, and lower the overall carbon footprint of concrete production, particularly in agrarian economies where rice

husk and corn cob are abundantly and consistently available as by-products of existing agricultural value chains.

5. RECOMMENDATION

Based on the findings of this study, it is recommended that a combined cement replacement of 10% RHA and 5% CCA be considered for the production of Grade 25 structural concrete where enhanced compressive strength and sustainability objectives are desired, subject to confirmation through site-specific trial mixes and quality control testing of locally sourced ashes, since the chemical composition of agro-waste ashes can vary with combustion temperature, source material, and processing method.

Further research is recommended to investigate the durability properties of the RHA-CCA ternary blend, including water absorption, sorptivity, rapid chloride penetration, and resistance to sulfate and acid attack, to comprehensively establish its long-term performance in aggressive service environments. Given the demonstrated relevance of elevated-temperature performance for RHA-blended systems reported in recent literature, dedicated experimental investigation of the residual mechanical properties of the RHA-CCA ternary blend after exposure to elevated temperatures is also recommended, to establish its suitability for structural elements with fire-resistance requirements. Additionally, microstructural investigation using scanning electron microscopy (SEM), energy dispersive spectroscopy (EDS), X-ray diffraction (XRD) and thermogravimetric analysis (TGA-DSC) is recommended to directly characterize the C-S-H and C-A-S-H reaction products responsible for the observed strength enhancement, thereby providing mechanistic confirmation of the trends established through mechanical testing in this study. Finally, optimization studies varying the individual and combined replacement ratios of RHA and CCA beyond the 10:5 combination examined here are recommended to identify the threshold beyond which further replacement begins to compromise workability or strength, thereby establishing the optimal ternary blend ratio for practical field application.

ABSTRACT

Nanoporous materials are among the most actively studied and rapidly advancing materials for carbon dioxide (CO_2) capture. This study investigated the fabrication of nanocomposites using bamboo fibre nanopowder (BFNP) and waste expanded polystyrene (WEPS) for CO_2 removal. The bamboo fibres were chemically modified with sodium hydroxide (NaOH) to eliminate lignin, pectin, and other impurities while enhancing their adhesion to the polymer matrix. The influence of NaOH treatment on the surface morphology and crystallinity of the bamboo fibres was examined using Fourier-transform infrared spectroscopy (FTIR), scanning electron microscopy coupled with energy-dispersive X-ray spectroscopy (SEM/EDS), and X-ray diffraction (XRD). A Box–Behnken design (BBD) within the response surface methodology (RSM) framework was employed to construct the experimental matrix and optimize the mixing conditions. The optimized parameters were predicted to be a bamboo fibre content of 35.9wt%, a mixing time of 3.9 minutes, and a mixing temperature of 27.5°C. The nanocomposites were fabricated using the lay-up technique, and their properties were characterized by FTIR, XRD, SEM, and Brunauer–Emmett–Teller (BET) analysis. The nanocomposites exhibited a BET surface area of 847.6 m^2/g and an average pore diameter of 1.85nm confirming their microporous nature, a CO_2 adsorption capacity of 2.034 mmol/g at 110℃ under 1 bar pressure confirming their suitability for CO_2 adsorption.

Keywords: *Carbon capture; bamboo fibre; waste expanded polystyrene; nanocomposites; CO2 adsorption*

1. INTRODUCTION

Carbon capture is an essential technology for reducing carbon dioxide (CO_2) emissions, particularly because fossil fuels continue to provide a substantial proportion of the world's energy. It is expected to play a central role in achieving net-zero emissions by 2050 and beyond. Existing carbon-capture technologies are primarily designed for heavy industries but require further refinement because they often involve hazardous chemicals and substantial energy consumption. Consequently, these systems are costly and complex to construct. Captured carbon can either be stored or reused, potentially creating an additional revenue stream (Nikita *et al*., 2025).

The development of adsorbents with high adsorption capacities is fundamental to achieving effective adsorption performance. Various materials have been investigated for CO_2 adsorption, including zeolites, metal oxides, mesoporous silica, and activated charcoal (Gowthaman *et al*., 2021). Solid sorbents, such as porous organic polymers, activated carbon, zeolites, and metal–organic frameworks, have gained increasing attention because of their high adsorption efficiency, durability, and operational simplicity (Ting *et al*., 2020).

Plastic pollution remains a persistent global problem, as the large-scale production of disposable plastics exceeds the capacity of existing waste-management systems. Waste plastics can be engineered for pollutant removal and carbon capture, providing a practical and sustainable pathway for managing plastic waste while contributing to efforts to mitigate global warming associated with carbon emissions. This approach supports the development of a cleaner and more sustainable future (Jiacheng & Qian, 2024). Such materials address plastic-waste challenges while offering cost-effective and efficient solutions for environmental remediation, in some cases outperforming commercial adsorbents (Pritesh *et al.*, 2024).

Bamboo fibre, a renewable and biodegradable material, can be combined with waste expanded polystyrene, a common packaging-related pollutant, to reduce landfill demand and plastic contamination (Peng *et al*., 2022). This strategy supports a circular economy by reducing reliance on virgin polymers and lowering the carbon footprint through the use of environmentally friendly reinforcement. Nanocomposites produced from these materials may demonstrate improved mechanical properties, including greater tensile strength, as a result of bamboo's high cellulose content and strong fibre–matrix bonding. They may also offer low density, good thermal stability, and reduced water absorption compared with conventional plastics (Chin-Hao & Teng-Chun, 2020).

This study is strongly motivated by the need for sustainable, environmentally friendly, and cost-effective materials capable of addressing both agricultural-waste management and plastic pollution. Integrating bamboo fibre with waste expanded polystyrene can produce a high-performance, lightweight composite while transforming waste materials into valuable industrial resources (Chen *et al*., 2016). Both raw materials are widely available; however, WEPS is a significant contributor to landfill pollution because of its high volume-to-mass ratio (Farid & Ahad, 2022).

2. MATERIALS AND METHODS

The primary materials used in this investigation were waste expanded polystyrene (WEPS) (Fig. 1), collected from electronics shops along Ahmadu Bello Way in Kaduna State, Nigeria, and bamboo (Bambusa vulgaris) fibres (BF), sourced from Basawa Market in the Zaria district of Kaduna State, Nigeria.

2.1 Preparation of Bamboo Fibre Nanopowder

Fresh bamboo culms were collected and washed thoroughly to eliminate soil, debris, and other contaminants from their surfaces. The cleaned culms were then reduced to chips approximately 2.0–5.0 cm in length (Fig. 1b) with a manually operated mechanical cutter, this preliminary size reduction increased the surface area exposed during chemical treatment. The chips were immersed in a 10wt% sodium hydroxide (NaOH) solution for 2–4 hours (Fig. 1a). The alkaline treatment was used to remove hemicellulose, lignin, and pectin, thereby loosening the fibre bundles and promoting cellulose separation. A bamboo-chip-to-NaOH-solution ratio of 1:10 (w/v) was maintained to ensure sufficient alkali penetration. The fibres were oven-dried for 8 hours at 80°C until a constant weight was obtained. The dried bamboo fibres were ground using a ball until they were reduced to fine powder sized particles of 75 nm (Fig. 1c).

Figure 1: (a) Bamboo Fibres Soaked in NaOH solution (b) Dried Bamboo Fibres (c) Bamboo Fibre Powder

Dynamic light scattering (DLS) was employed to establish the particle-size distribution of the bamboo fibre nanopowder. In this analysis, a laser beam was passed through the dispersed sample, and the scattering generated by particle–beam interactions was evaluated with a DLS instrument.

2.2 Characterization of Bamboo Fibre Nanopowder (BFNP)

The bamboo fibre nanopowder was characterized through physical, chemical, and thermal analyses. The assessment covered its proximate composition, morphology, crystalline structure, surface characteristics, and mechanical and thermal properties.

2.2.1 Fourier transform infrared spectroscopy (FTIR)

The functional groups in the bamboo fibre samples were identified with a Fourier transform infrared spectrometer (FT/ IR-4700, JASCO International Co., Ltd., Pfungstadt, Germany). Samples were analyzed both before and after NaOH treatment to identify the existing functional groups and determine the changes induced by alkalization. Particular emphasis was placed on hydroxyl (OH) groups because of their role in moisture uptake by cellulosic fibres. Approximately 2 mg of each sample was blended with KBr and compressed into pellets. Spectra were collected between 4000 and 500 cm^{-1} at a resolution of 4 cm^{-1}

2.2.2 Scanning electron microscopy (SEM)

Scanning electron microscopy was performed in accordance with ASTM E766 to investigate the surface morphology and microstructure of the untreated and treated fibres. The raw bamboo nanopowder was examined with a scanning electron microscope (Phillips XL 30 ESEM, FEI Company, Hillsboro, OR, USA) fitted with a large-field detector. Micrographs were acquired at an accelerating voltage of 15 kV and magnifications of 100× and 500×. For examination, 10 µL of sample was placed on a copper grid and dried under light for 15 minutes. SEM analysis yielded information about fibre roughness, surface imperfections, and the likelihood of interfacial adhesion, which are significant factors in composite-material applications (Hobtemariam *et al*., 2025)

2.2.3 X-ray diffraction (XRD)

The bamboo fibre was analyzed by X-ray diffraction using a PANalytical Empyrean diffractometer equipped with a cobalt target, rotating sample stage, and goniometer operating in the 2θ configuration. The cobalt source produced radiation with a wavelength of 0.179 nm. The generator settings were 40 kV and 45 mA. Diffraction intensities were measured across a 2θ range of 5°–110°, with a step interval of 0.0167° and a scan rate of 0.015°/s. The crystallinity index was determined using the Segal equation (Equation 1), which estimates the relative amounts of crystalline and amorphous phases that influence fibre strength and thermal stability (Szaosky *et al*., 2024):

$$CrI\ (\%) = [(I_{oo2} - I_{am})/I_{oo2}] \times 100 \quad (1)$$

In this equation, I_{oo2} is the maximum intensity of the 002 lattice reflection, representing the primary peak of native cellulose at 2θ = 22.5°, whereas I_{am} is the diffraction intensity associated with the amorphous region (Yang *et al*., 2023).

2.3 Design of Experiments (DoE)

Response surface methodology (RSM) using the Box–Behnken design (BBD) implemented in Design-Expert software was used to analyze the experimental data, generate the design matrix, and determine the optimum mixing conditions. The experimental design incorporated three factors at three levels. Numerical optimization was conducted with fibre loading (wt%), mixing time (min), and mixing temperature (°C) as the independent variables, while tensile strength (TS) served as the response variable.

2.4 Preparation of BFNP/WEPS Nanocomposite

The bamboo fibre nanopowder/waste expanded polystyrene (BFNP/WEPS) nanocomposite was fabricated through solution casting followed by compression molding. A schematic of the preparation process is provided in Fig. 2.

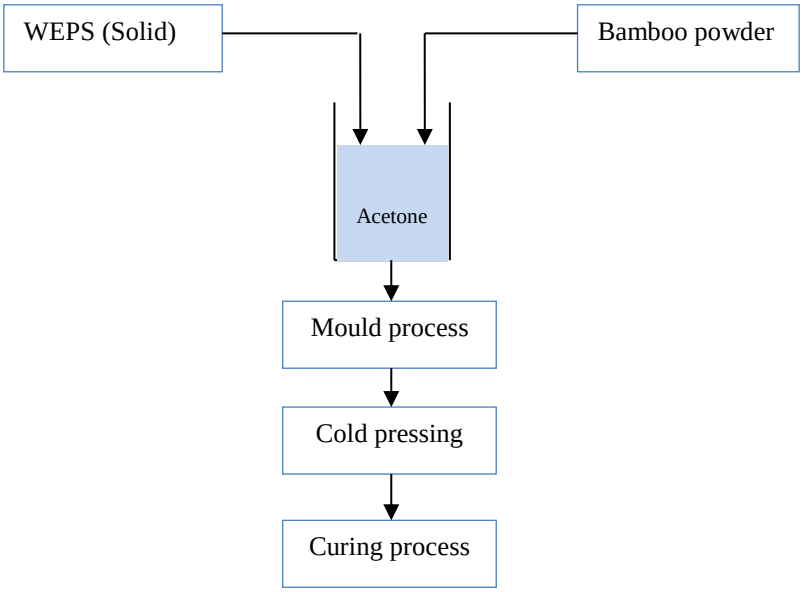

Figure 2: Block Flow Diagram for Preparation of BFNP/WEPS Nanocomposite

A 1.5 kg quantity of solid WEPS waste was dissolved in 1 L of acetone and stirred until a consistent solution formed. The bamboo fibre powder was then combined with the dissolved WEPS in a container and thoroughly blended with a mechanical mixer. The mixture contained 35wt% bamboo fibre powder, corresponding to the optimum loading identified through BBD optimization, and 65wt% dissolved WEPS paste. Mixing was continued until a uniform blend was obtained. The blend was poured into a wooden mold coated with petroleum jelly to minimise adhesion and manually compacted using a 150kN compression-molding machine (Hemel Hempstead, Hertfordshire, England). The molded BFNP/WEPS nanocomposite was cured and dried for 21 days before being removed from the mold and subjected to further analysis.

2.5 Characterization of BFNP/WEPS Nanocomposites

The prepared BFNP/WEPS nanocomposites were examined through physical, mechanical, and chemical analyses to assess their properties and performance.

2.5.1 Brunauer–Emmett–Teller (BET) analysis

BET analysis involved exposing the porous solid to nitrogen molecules at the boiling point of the inert gas. The procedure was conducted in accordance with ASTM B922-10. Approximately 0.5 g of sample was placed in a sample cell and degassed to eliminate moisture, volatile substances, and other impurities. The degassed material was subsequently installed in a BET analyzer (Quantachrome Nova Instruments, version 11.03) and exposed to nitrogen across a range of relative pressures. The equilibrium volume of adsorbed gas was measured to produce a Type IV adsorption isotherm.

2.6 CO_2 Adsorption Experiment

As shown in Fig. 3, a fixed-bed reactor was assembled to measure the CO_2 adsorption capacity of the adsorbent and evaluate the effects of important operating variables through a

gravimetric technique. This method is especially appropriate at low pressures because almost the entire measured gas dose is adsorbed.

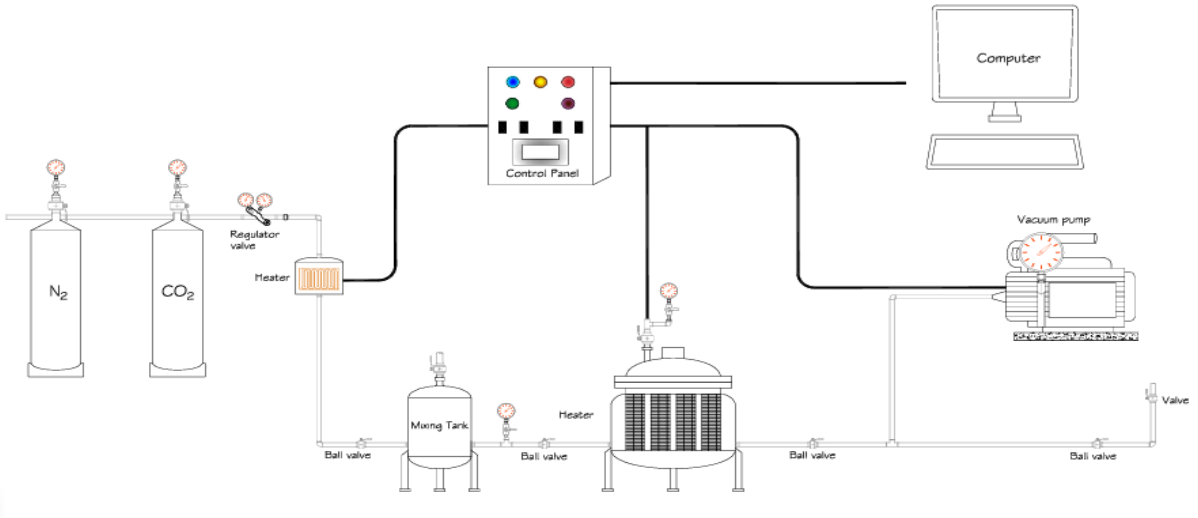

Figure 3: The Experimental Setup for Measuring CO_2 Adsorption

The reactor was cylindrical, with an internal volume of 100 cm³. For each run, 1.5 g of solid adsorbent was placed in an internal reactor compartment. Prior to every experiment, the adsorbent was heated under a pure N_2 stream for 30 minutes at 110℃ and subsequently evacuated for 30 minutes to remove previously adsorbed CO_2 and moisture. High-purity CO_2 from the cylinder was adjusted to the desired pressure with a pressure regulator and gauge before being introduced into the mixing tank. Stable gas was delivered to the adsorbent reactor and the mass of adsorbent after adsorption was measured using a digital weighing balance. The CO_2 uptake was calculated using equation 3.

$$q = \Delta m/M \quad (3)$$

Where, q is the CO_2 uptake, $\Delta m = m_1 - m_0$ (m_0 is the mass of adsorbent before adsorption, m_1 is mass of adsorbent after adsorption) and M is the molar mass of CO_2 (44.01 g/mol).

3. RESULTS AND DISCUSSION

This section presents and analyzes the results obtained from the experimental investigations. It is divided into two principal parts. The first addresses the characterization of bamboo fibres, whereas the second presents the characterization results for the nanocomposite produced from bamboo fibres and waste expanded polystyrene (WEPS).

3.1 Characterization of Bamboo Fibres

The experimental design (BBD/RSM optimization of mixing parameters) and multi-technique characterization (FTIR, SEM/EDS, XRD, and BET) show methodological rigor and critically analyze the bamboo fibre material.

3.1.1 FTIR analysis of raw bamboo fibre

Fourier transform infrared (FTIR) analysis was used to identify the absorption peaks and their corresponding wavenumbers, thereby determining the functional groups present and evaluating the chemical changes associated with the alkaline treatment of the bamboo fibres. The spectra obtained for the raw bamboo fibres are shown in Figure 4.

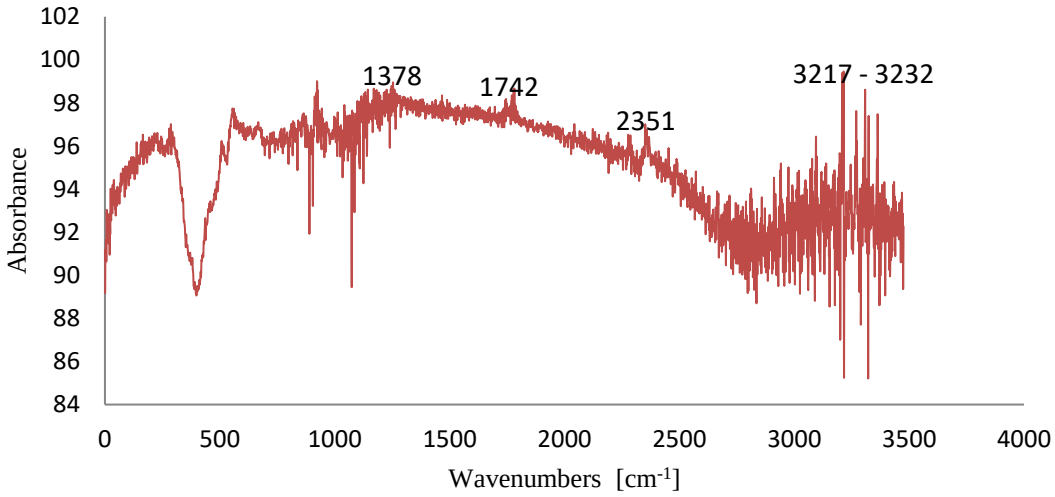

Figure 4: FTIR Spectrum of Raw Bamboo Fibre

The spectrum indicates the presence of several undesirable constituents, including hydroxyl (OH) groups, pectin, wax, hemicellulose, and lignin. The principal absorption peaks are clearly identified in the spectrum. The absorption band near 3200 cm^{-1} is associated with fatty acids and is attributed to O=H stretching vibrations. A weak absorption band also appears at 1378 cm^{-1}, indicating the presence of lignin and corresponding to C=C stretching vibrations. In addition, the peak observed at 1742 cm^{-1} indicates the presence of waxes and fatty-acid esters and is attributed to C=O vibrations.

3.1.2 XRD analysis of bamboo fibre

The X-ray diffraction (XRD) patterns presented in Fig. 5 compare the raw and chemically treated bamboo fibres. The patterns show a broad diffraction feature near 2θ = 22°, confirming the crystalline nature of the fibre. Three principal diffraction peaks occur at 2θ = 15.4°, 17.4°, and 22.5°, corresponding to the 1–10, 110, and 200 planes, respectively. The sharp peak near 2θ = 22° is characteristic of cellulose. Specifically, the diffraction peak at 22.0° corresponds to the 002 crystallographic plane of the cellulose I lattice. These three characteristic reflections are commonly associated with cellulose Iβ in natural fibres, in which the cellulose chains are arranged in parallel and connected by hydrogen bonding. Although cellulose occurs naturally in both the Iα and Iβ forms, cellulose Iβ is the form predominantly found in higher plants and was therefore considered in this analysis.

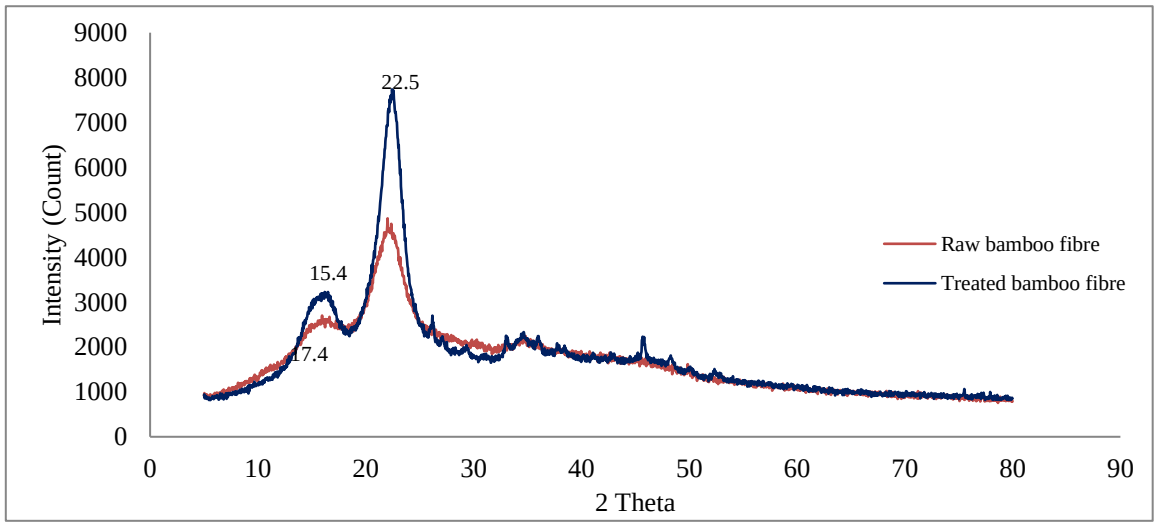

Figure 5: XRD Spectrum of Raw and Treated Bamboo Fibres

The crystallinity index (CrI) was determined using the empirical Segal method. The crystallinity indices calculated for the raw and treated bamboo fibres are presented in Table 1.

Table 1: Crystallinity Index of Bamboo Fibres

Bamboo Fibre	I (002)	I_{am}	CrI (%)
Raw	4778	2515	47
Treated	7596	3045	60

The treated bamboo fibre shows higher crystallinity than the raw bamboo fibre and lower than those of most of natural fibres like jack tree fibre with crystallinity index of 86% (Shahin *et al.*, 2025) and hemp with crystallinity index of 88% (Gedik *et al.*, 2021). High crystallinity means excellent strength of the fibre and they can provide better reinforcement for composite production, the crystallinity index also has effect on water absorption as amorphous region can absorb more water.

3.2 Optimization of Mixing Parameters Using BBD

The mixing parameters for the BFNP/WEPS Nanocomposite were optimized using the Box–Behnken design (BBD) module of response surface methodology. The responses obtained for the selected mixing conditions used to prepare the nanocomposite are presented in Table 2.

Table 2: Responses of the Mixing Parameters for the BFNP/WEPS Nanocomposite

Std	Run	Factor 1 A: Fibre Loading (wt %)	Factor 2 B: Mixing Time (min)	Factor 3 C: Mixing Temp (C)	Response Tensile Strength (MPa)
17	1	15	3	27.5	43.6
3	2	50	5	27.5	31.1
16	3	35	1	27.5	42.9
12	4	50	5	50	44.1
7	5	50	3	50	24.2
4	6	35	1	27.5	39.6
11	7	35	5	50	41.5
14	8	50	5	27.5	42.7
15	9	35	1	2 7.5	43.3
2	10	15	3	27.5	37.3
1	11	15	3	27.5	26.6
6	12	50	3	35	21.2
13	13	50	5	27.5	42.9
9	14	35	5	35	26.7
8	15	35	1	50	44.2
10	16	50	5	35	31.9
5	17	50	3	35	20.2

A second-order polynomial regression model was developed to establish the relationship between the processing factors and the tensile strength response. The resulting equation, expressed in terms of coded factors, is given as follows:

$$TS = +43.08 + 5.03A + 1.83B + 6.75C + 0.55AB + 4.75AC - 0.65BC - 9.02A^2 - 0.42B^2 - 6.61C^2 \quad (2)$$

Desirability converts each response variable into a dimensionless scale ranging from 0, representing an undesirable result, to 1, representing an ideal result. The individual desirability values are then combined to produce an overall desirability score, D, as shown in Table 3. This procedure facilitates the simultaneous evaluation of multiple responses by providing a single optimization metric and thereby supporting more efficient decision-making. The score reflects the preferred range established for each response.

Table 3: Response Optimization and Desirability of the Mixing Parameters

Number	Fibre Loading.	Mixing Time	Mixing Temp	Tensile Strength	Desirability
1	35.112	3.291	25.788	44.271	1
2	35.654	3.915	25.014	45.429	1
3	35.618	3.738	25.752	45.228	1
4	35.239	3.394	25.714	44.552	1
5	35.827	3.226	25.775	45.538	1
6	35.859	3.957	25.946	45.551	1
7	35.963	3.963	25.763	45.716	1
8	35.147	3.908	25.951	44.311	1
9	35.891	3.619	25.987	45.581	1
10	35.369	3.572	25.747	44.798	1

To provide additional validation of the model, two conditions, corresponding to the first and seventh experimental runs, were selected. The predicted values were calculated from the centre points between the high, intermediate, and low factor levels. Confirmatory experiments were subsequently conducted to assess the reliability of the model. The percentage error for tensile strength was calculated by comparing the predicted values with the experimentally measured values. The validation results are presented in Table 4.

Table 4: Confirmatory Experiments

Fibre Loading (g)	Mixing Time (min)	Mixing Temp (^oC)		TS (MPa)
35.112	3.291	25.788	Actual	42.21
			Predicted	44.27
			Error%	3.06
35.963	3.963	25.763	Actual	43.78
			Predicted	45.716
			Error%	1.936

The absolute relative errors between the predicted and experimental values were 3.06% and 1.96%, respectively. Because both values are below 5%, the developed prediction models for the tensile strength (TS) of the BFNP/WEPS nanocomposite can be considered accurate and reliable.

3.3 Characterization of BFNP/WEPS Nanocomposites

To obtain a comprehensive understanding of the behavior of the BFNP/WEPS nanocomposites, a series of mechanical, physical, and thermal tests were conducted on the prepared materials.

3.3.1 FTIR analysis of the BFNP/WEPS nanocomposite

The FTIR spectra of the BFNP/WEPS nanocomposite presented in Fig. 6 contain distinct absorption bands associated with cellulose and hemicellulose, confirming the characteristic lignocellulosic composition of the bamboo fibres. The broad band cantered at 3480 cm^{-1} is assigned to the O–H stretching vibrations of hydroxyl groups. This band indicates the presence of absorbed water, free phenols, and primary and secondary aliphatic alcohols occurring in cellulose and hemicellulose.

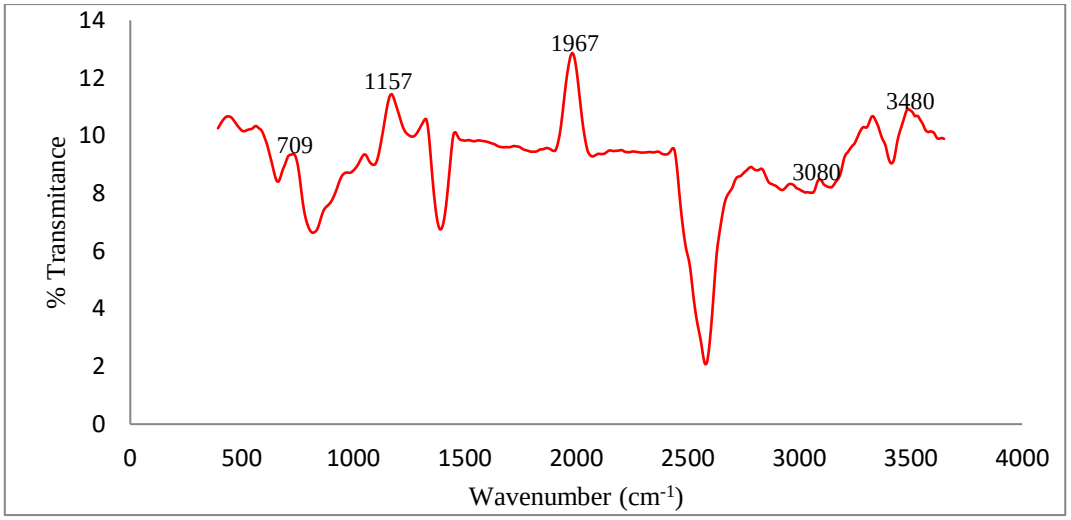

Figure 6: FTIR Spectrum for BFNP/WEPS Nanocomposites

The band at 1967 cm^{-1} is related to the stretching vibrations of aliphatic C–H groups, particularly CH_2, and further confirms the presence of cellulose and hemicellulose. The absorption band at 1157 cm^{-1} corresponds to C=O stretching vibrations associated with carbonyl groups, which are attributable to the acetyl groups commonly found in hemicellulose. In spectra containing WEPS, the bands observed between 3000 and 2800 cm^{-1} are assigned to C–H stretching vibrations associated with hydrocarbons in the WEPS. The band at 709 cm^{-1} is related to phenyl-ring substitution. Its presence alongside the cellulose-related signals confirms the incorporation of bamboo natural fibres.

3.3.2 SEM analysis of BFNP/WEPS nanocomposites

SEM analysis was conducted to examine the morphology of the produced nanocomposite. The micrograph in Fig. 7 shows that the bamboo fibres were distributed uniformly throughout the polymer matrix. This homogeneous dispersion is responsible for the strong interfacial adhesion between the fibres and the polymer matrix (Mohan *et al*., 2020). In addition, the expansion of gas bubbles within the freshly dissolved expanded polystyrene paste, caused by acetone evaporation under reduced pressure, forced the thin layer of the paste into contact with the particle surfaces. This process may have influenced the compounding behaviour and mechanical interlocking between the bamboo fibres and the WEPS matrix. The SEM examination also revealed microstructural damage mechanisms, including fibre–matrix debonding, fibre swelling, and matrix cracking. These features are broadly comparable to those reported for date-palm-leaf-fibre-reinforced composites (Hobtemariam *et al*., 2025). The polymer matrix was observed to wet the fibres effectively, thereby promoting strong interfacial bonding.

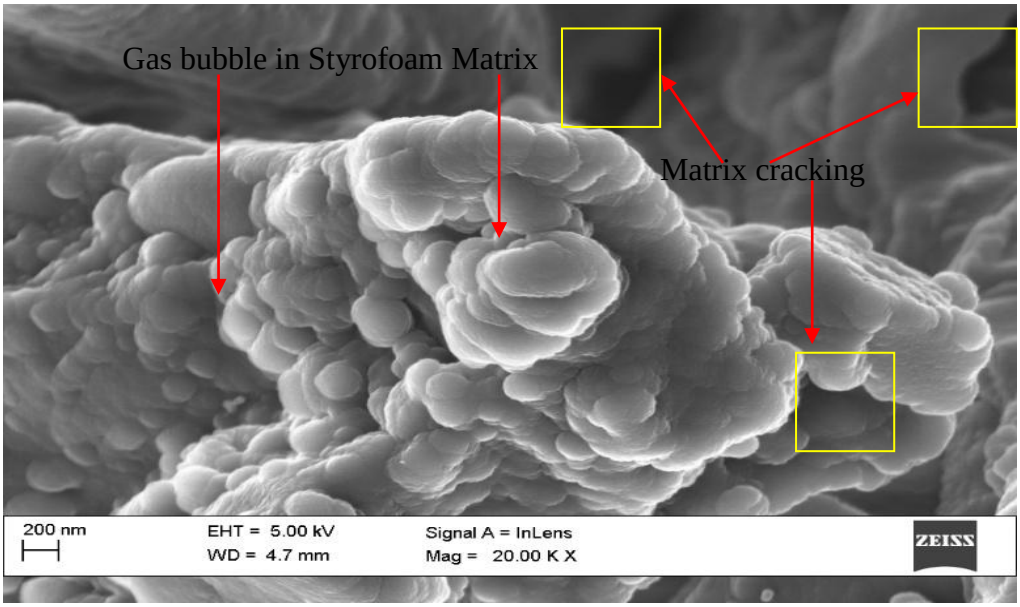

Figure 7: SEM Spectrum of BFNP/WEPS Nanocomposite

3.3.3 BET analysis of BFNP/WEPS nanocomposite

The BET analysis demonstrated that the BFNP/WEPS nanocomposite is highly porous. As shown in Table 5, the material exhibited a Brunauer–Emmett–Teller surface area of 847.6 m^2/g and an average pore diameter of 1.85 nm, indicating a predominantly microporous structure. According to the International Union of Pure and Applied Chemistry (IUPAC), microporous materials have pore diameters not exceeding 2nm. Based on the 1972 recommendations for physisorption, pores are classified as micropores when their diameters are below 2nm, mesopores when they range from 2 to 50nm and macropores when they exceed 50nm.

Table 5: Porosity Properties

Parameter	BFNP/WEPS nanocomposites
BET Surface area	181.9 m^2/g
BJH pore volume	0.16 cm^3/g
BJH pore diameter	1.85 nm
Langmuir surface area	847.6 m^2/g
DR micropore volume	0.164 cm^3/g

Under the IUPAC classification, materials with a high proportion of micropores and a uniform micropore size distribution below 2nm possess important characteristics for effective and selective CO_2 adsorption. The measured micropore volume of 0.16cm^3/g and average micropore diameter of 1.85nm can readily accommodate the relatively small CO_2 molecule, which has a kinetic diameter of approximately 0.33 nm. Micropores therefore provide favourable structural conditions for CO_2 adsorption in porous adsorbents (Telmo *et al*., 2025). The narrow pore structure corresponds well with the kinetic diameter of CO_2, enhancing adsorbate–adsorbent interactions and selectivity relative to N_2 (Lei *et al*., 2025). Similarly, metal–organic frameworks (MOFs) and zeolites benefit from narrow pores, typically measuring approximately 3.5–8 Å, to achieve high CO_2 uptake.

4. CONCLUSION

Waste expanded polystyrene and bamboo fibres were converted into a nanocomposite through a simple and cost-effective process, producing a material with potential application as an adsorbent for CO_2 capture. FTIR, SEM, XRD, and BET analyses were conducted to investigate the structure and

morphology of the nanocomposite. The material exhibited a specific surface area of 847.6m²/g and an average pore diameter of 1.85nm, confirming its microporous nature. The adsorbent material demonstrates a CO_2 uptake capacity of 2.034mmol/g at 110℃ and 2 bars. Because micropores are particularly favourable for the adsorption of small molecules, confirming their suitability for CO_2 adsorption the uniform porous structure of the BFNP/WEPS nanocomposite indicates its potential as an effective, low-cost precursor for the production of adsorbents for CO_2 capture.

ABSTRACT

The study investigated the probabilistic effect of NaOH Molarity (Mc), Na_2SiO_3:NaOH (ALr), and alkaline-liquid:Metakaolin (ALm), on the reliability of metakaolin-based geopolymer concrete beams reinforced with two (2) 8 mm bars as tension reinforcement under a failure load of 39 kN. The assessment was performed using the First Order Reliability Method (FORM). Compressive strength models were developed for the investigated variables, which were incorporated into the failure modes limit-state equations through the FORM5 package to evaluate the beam's reliability. The probabilistic analyses were conducted by varying Mc (6-16 M), ALr (0.5-2.5) and ALm (0.4-1.0). Results from the analyses showed that the models explained 63.4% and 93.2% of the compressive strength variations, respectively, for Mc/ALr and ALm/Wc. Additionally, increasing Mc from 6 M to 10 M improved the reliability of the Reinforced Metakaolin Based Geopolymer concrete (RMBGC), whereas further increase to 12 M and beyond reduced reliability. Increasing ALr from 0.5 to 2.5 and ALm from 0.4 to 1.0 consistently enhanced the reliability. Among all variables, ALm exerted the greatest influence, producing the largest improvement in safety index across all failure modes. It was also noted that the Moment failure mode was most sensitive to mix-parameter variations, followed by shear, while deflection was least affected. In general, the study demonstrates that optimising ALm, ALr, and Mc (approximately 10 M) provides the greatest improvement in the reliability and structural safety of metakaolin-based geopolymer reinforced concrete beams.

1.0 INTRODUCTION

Research into alternatives to ordinary Portland cement (OPC) has been ongoing due to the fact that OPC is not sustainable. This is connected to the amount of carbon dioxide emitted during cement production. One of the most promising alternatives is geopolymer cement, which is produced by activating aluminosilicate materials such as metakaolin with alkaline solutions. Unlike OPC concrete, the binding phase in geopolymer concrete is formed through a geopolymerization process. The resulting concrete from the geopolymerisation has better mechanical properties, improved durability, and lower environmental impact (Davidovits, 1991).

The performance of geopolymer concrete depends largely on its mix composition. It was reported that the chemical composition in terms of the concentration of sodium hydroxide, the ratio of sodium silicate to sodium hydroxide, the alkaline liquid-to-binder ratio, and the water content significantly influences the geopolymerization reaction and consequently the strength and durability of the hardened product (Diaz et al., 2010). For metakaolin-based geopolymer concrete in particular, these parameters determine the extent of aluminosilicate dissolution, gel formation, and the development of compressive strength. Hence, a proper selection of these mix variables is important in achieving the desired structural performance.

Several studies have investigated the influence of mix proportions on the compressive strength and durability of geopolymer concrete. The studies did not incorporate uncertainties and did not study the effects on the safety of a structural member. This is because, in reality, material properties are associated with uncertainties that may influence the behavior and safety of structural members. These uncertainties can only be adequately considered through probabilistic methods, where the variability of the governing parameters is incorporated into the structural assessment rather than relying solely on characteristic values. A few studies checked the effect of the variability of the concrete mix materials on the reliability of structural members; some of these studies include Adamu et al, (2023), who considered the effect of mix variability on the structural safety of Nano-Engineered concrete and found that Mix design variability significantly changes the reliability index and failure probability. Adamu et al. (2024) also checked the reliability of Nano-Engineered RC beams and demonstrated the integration of material variability into Eurocode reliability assessment.

The performance of geopolymer concrete in terms of structural safety can be evaluated using probabilistic reliability analysis. In structural engineering, reliability is defined as the ability of a structural component to perform its intended function for a specified period under stated conditions without failure (Mohammed et al., 2014). Qianru and Ang (2013) stated that reliability-based analysis provides a rational means of accounting for uncertainties in material properties, geometry, and applied loads. The reliability of a structural member is commonly expressed in terms of its probability of failure or safety (reliability) index. The reliability of reinforced concrete members is also influenced by the adopted design provisions and the uncertainties associated with the constituent materials. García-Soto et al. (2017) opined that structural safety should be evaluated within a reliability framework to ensure that acceptable safety levels are maintained under different design conditions.

Based on the above statements, this study checks the effects of sodium hydroxide molarity, sodium silicate-to-sodium hydroxide ratio, and alkaline liquid-to-metakaolin ratio on the reliability of reinforced metakaolin-based geopolymer concrete beams using the First-Order Reliability Method (FORM). Developed compressive strength models developed from are incorporated into the failure modes for reliability analysis to evaluate the influence of material variability on the safety indices associated with flexural moment (In compression and Tension), shear, and deflection failure modes. The results from this study will be useful in identifying the failure mode that is most affected by the geopolymer materials and identifying the mix parameter that is most sensitive to the failure modes and hence, the structural reliability and safety of reinforced metakaolin-based geopolymer concrete beams.

2.0 MATERIAL AND METHODS

2.1 Materials:

The material use for the research were Metakaolin (Processed from kaolin calcination at 800^0C for 3 h, based on Moodi *et al.* (2011). The fine and coarse aggregates, NaOH and Na_2SiO_3 were sourced locally. Potable water available in the heavy-duty laboratory of the Civil Engineering Department, A.B.U, Zaria, was used.

2.2 Methods

2.2.1: Concrete Production: The proportioning of the mix constituents is mostly done by weight, as captured in Mustafa *et al*. (2011) and Sameer (2015). The fine and coarse aggregate ratio used was 1:2. The cement (metakaolin-based geopolymer cement) content used in the mix was based on the average 2400kg/m^3 concrete density. The NaOH Molar concentration, the ratio of Na_2SiO_3 to NaOH, and that of metakaolin to alkaline liquid were respectively 8 M, 3, and 0.9. The mixing and casting were in accordance with BS EN 12390-1 (2000) and BS EN 12390-2 (2000).

2.2.2: Production of Beam Specimen: Metakaolin-based geopolymer concrete beams reinforced with two (2) 8 mm diameter bars as tension reinforcement were produced. The beams had dimensions of 100 × 100 × 450 mm (short beam, because L/H <5 and shear span-to-depth ratio of 1 to 2.5).

2.2.3: Beam Test: The test was conducted per BS EN 12390 -5 (2009) (Plate I). Three (3) beams were produced with the same mix batch and reinforcement details were loaded to failure. The average failure load computed for the three beams was 39 kN.

Plate I: Centre Point Test of the Beam (3-point Bending Test)
The beam shown in Plate 1 was loaded at the centre point with rollers as supports

2.2.4 Compressive Strength Models: The models presented in equations (1) and (2) were developed by Aliyu (2021) using the Datafit statistical package (2019) to predict the compressive strength of the metakaolin-based geopolymer reinforced concrete beams.

$$f_{ck1} = -109.69 + 18.9Mc + 48.01ALr - 0.7163Mo^2 - 6.41ALr^2 - 1.98Mo * ALr \quad (1)$$

$$f_{ck2} = 80.109(ALm^{3.553}) \times 0.991^{Wc} \quad (2)$$

2.2.5 Probabilistic Reliability Analysis

Structural reliability according to Bai *et al.* (2018) is defined by:

$$R_r = 1 - P_f \quad (3)$$

Where P_f is the probability of failure. For the reliability (Probabilistic) analysis, the performance function or limit state function $(G(x))$ is defined by $G(x) = R - S$

2.2.5.1 Limit state functions

a) Performance Function for Moment Capacity

$$\boldsymbol{G_{mx}} = M_r - M_a \quad (4)$$

$$\text{where } M_a = \theta_S(0.25pl + 0.125\gamma_c bhgl^2 \times 10^{-9}) \quad (5)$$

Equation (5) is the applied moment as a function of the applied point load and the beam's self-weight. For the probabilistic analysis, the partial factors of safety for steel (1.15) and concrete strength (1.5) recommended by EC2 were removed, and the moment capacity equations (based on compressive and tensile capacity in EC 2) were re-derived to yield;

i. MOMENT OF RESISTANCE OF THE CONCRETE COMPRESSIVE STRUT.

$$M_r = 0.251\theta_R f_c bd^2 \quad (6)$$

ii. TENSILE MOMENT CAPACITY (MOMENT OF RESISTANCE)

$$\boldsymbol{M_r} = \theta_R f_{yk}\rho bd(d - \frac{f_{yk}\rho bd}{1.7f_c b}) \quad (7)$$

b) Performance Function for Shear Capacity

$$G_{vx} = V_c - V_a = \theta_R(0.18(1 + \frac{\sqrt{200}}{d})(\rho f_c)^{1/3})bd - \theta_S(0.5p + 0.5\gamma_c bhlg \times 10^{-9}) \quad (8)$$

Where M_r and M_a are the moments of resistance and applied moments, and V_c and V_a are the shear capacity and applied shear, respectively. $f_c, f_{yk}, p, g, \gamma_c, b, \rho, and\ \rho'$ are the concrete strength, steel yield strength, applied load, acceleration due to gravity, unit weight of concrete, beam width,

tensile reinforcement ratio, and compression steel reinforcement ratio, respectively. θ_R is the model uncertainty.

2.2.5.2 Form Process. FORM5 is a reliability analysis software developed based on the manual presented by Gollwitzer et al. (1988). It was used for the probabilistic analysis.

2.2.5.3 Stochastic (Statistical) Parameters

Table 1: Stochastic Table of Variables

S/No	Variable	Unit	Mean	COV	Distribution Type
1	Unit Weight of concrete (Y_c)	Kg/m^3	2400	0.01	Normal
2	Breath (B)	mm	100	0.002	Normal
3	Depth (D)	mm	100	0.003	Normal
4	Length (L)	mm	450	0.0006	Normal
5	Steel yield Stress (f_{yk})	N/mm^2	397.3	0.15	Normal
6	Compressive strength (f_{ck})	N/mm^2	32.8	0.09	Normal
7	Reinforcement ratio (ρ)	Nil	1.24	0.17	Normal
8	Live Load (Q_k)	kN	39	0.35	Gumbel
9	Molar Concentration (Mc)	Mol/L	varied	0.05	Normal
10	Alkaline Liquid ratio (ALr)	---	varied	0.05	Normal
11	Alkaline Liquid ratio Metakaolin (ALm)	---	varied	0.05	Normal
12	Resistance Model Uncertainty (θ_R)	---	1	0.07	Lognormal
13	Load Model Uncertainty (θ_S)	---	1	0.2	Lognormal

Source: Aliyu (2021), Adamu et al. (2014), Abejide (2014), and Mohammed et al. (2014)

It should be noted that the COV and distribution types for Mc, ALr, and ALm were assumed to be 0.05 based on 95% confidence in deviation from target value and because Lane (2020) reported that many natural phenomena are at least approximately normally distributed.

3.0 RESULTS AND DISCUSSIONS

3.1 Compressive Strength Predictive Models

The plots (Figures 1a and 1b) present the experimental values used as input data to develop the models and the predicted values by the developed models. In other words, the plots present the experimental compressive strength values and the predicted compressive strength values by Equations (1) and (2), respectively. The statistical package (Datafit) reported a coefficient of multiple determination (R^2) of 0.634 for eqn (1) (Proportion of variance explained = 63.4%), meaning that, based on eqn (1), ALr and Mc have explained 63.4% of the variation in the MBGC compressive strength, while eqn (2) has an R^2 value of 0.932 (Proportion of variance explained = 93.2%) for Alkaline liquid ratio metakaolin content (ALm) and water content (Wc). When using the R^2 approach, the unexplained proportion of the variation, based on Andrew (2017), is attributed to other factors not measurable by the researcher or not considered in the model. The author further noted that many models developed by researchers with small R^2 values produce useful predictions. It can be said that, although the model captures a substantial portion of the behaviour, the unexplained 36.6 % variance might propagate into the safety computation. This cannot be avoided except if a model explains 100% of the variation.

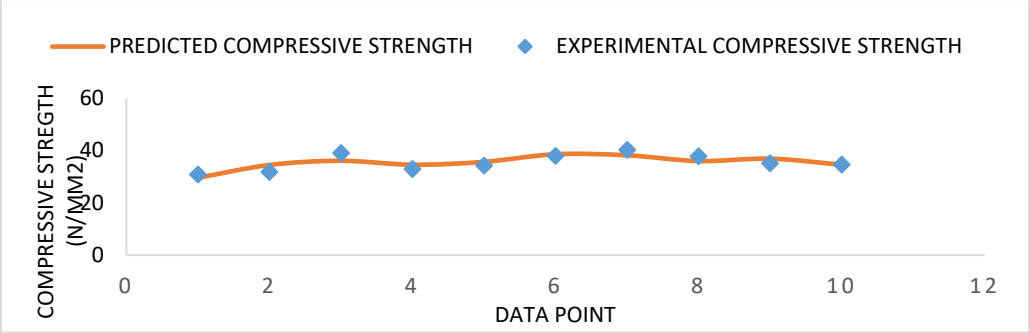

Figure 1a: Experimental and Predicted Data Points for equation 1 (f_{c1}=*f(Mc & ALr)*

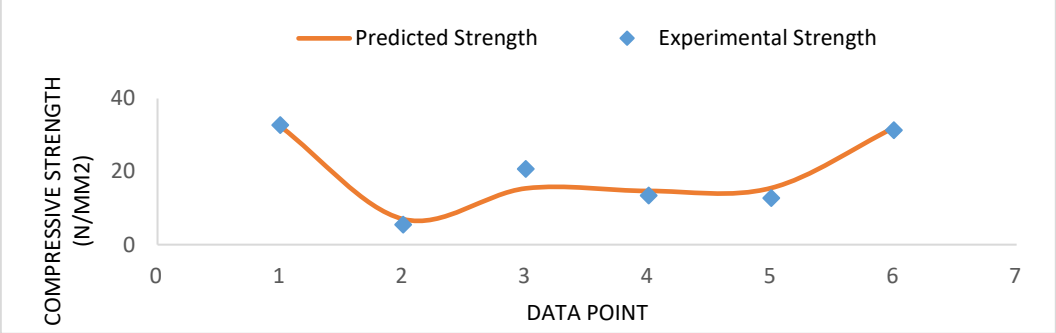

Figure 1b: Experimental and Predicted Data Points for equation 2 (f_{c1}=*f(ALm & Wc)*

3.2 Effect of Variations in Mc and ALr on the Safety Index

The effects of Mc, ALr, and ALm variations on the safety index are presented in Figures 2, 3, 4, and 5, respectively. Each parameter affects the safety index of beam failure modes positively or negatively. An increase in molar concentration (Mc) from 6M to 10M (Figure 2) increases the safety index but from 10M to 16M a decrease was recorded; this is because, for the ALm (0.9) used in the mix, between 6M and 10M, the geopolymer gets increasing ionic species necessary for geopolymeristion and hence higher strength and safer structure, but beyond 10M the alkalinity (Ph or Mo of NaOH) of the solution might have been non-conducive for the reaction as reported by Alonso and Palomo (2001), therefore, the safety index drops as a consequence of lower strength of the concrete. When ALr was increased from 0.5 to 2.5 at 8M (Figure 3), the safety index increased since the geopolymeriastion reaction is enhanced in the presence of more Na_2SiO_3.

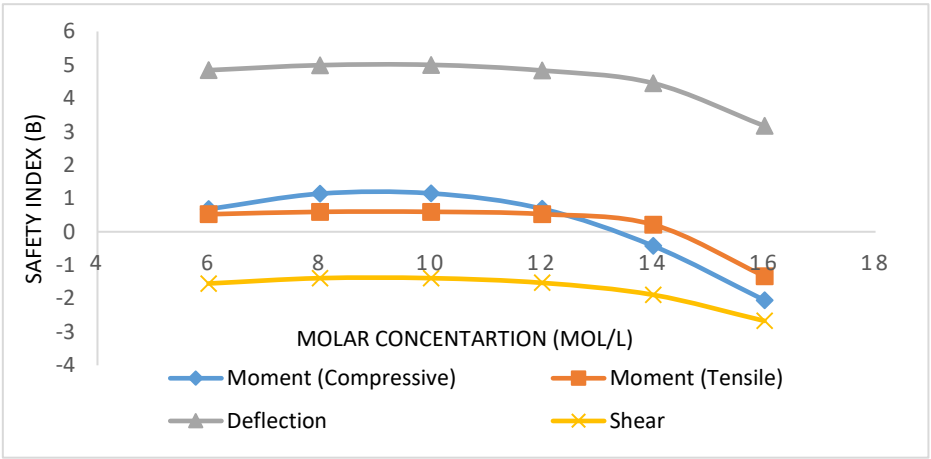

Figure 2: Molar Concentration (Mc) Effect on the Safety Index

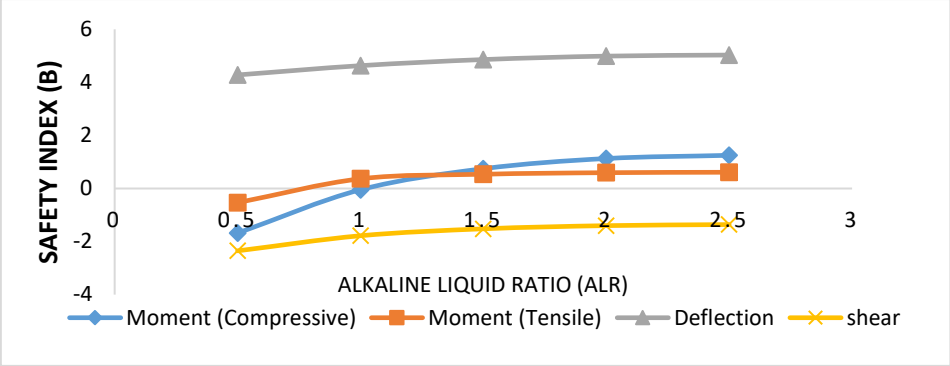

Figure 3: Alkaline Liquid ratio (Na_2SiO_3: NaOH or ALr) effect on the safety index

3.3 Effect of Variations in ALm on the Safety Index

The factor that has the most significant effect on the safety index is the alkaline liquid ratio Metakaolin (ALm) (Figure 4). The safety index values increase distinctly with an increase in ALm; this might be for the reason that, with lower ALm ratios, the mix does not have sufficient alkaline liquid (AL) to break down the Al and Si precursors, but with an increase in AL, more of the Al and Si precursors react, forming more geopolymer cement and achieving better concrete compressive strength. The moment (flexural) failure mode is the most affected, followed by the shear failure mode, and the least affected is the limiting deflection.

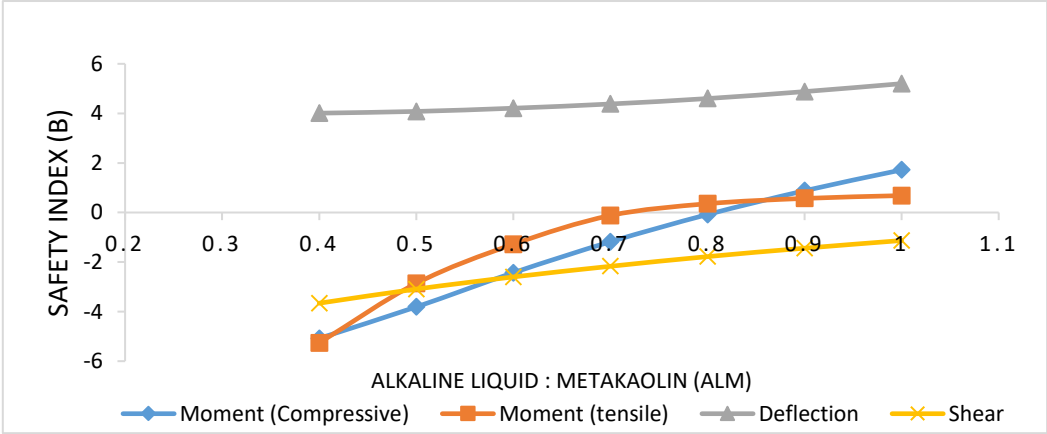

Figure 4: Alkaline Liquid: Metakaolin (ALm) Effect on the Safety Index

In summary, for all failure modes, an increase in Mc beyond 10M drops the safety index, while an increase in ALr up to 2.5 increases the safety index; Furthermore, an increase in ALm leads to a notable safety index increase.

Generally, the study also demonstrated that material variability significantly changes reliability index and failure probability, in agreement with Adamu et al. (2024).

4.0 CONCLUSIONS AND RECOMMENDATIONS

4.1 Conclusions

The conclusions derived from the study are;

1. The developed compressive strength models explained variation in compressive strength by 63.4% ($R^2 = 0.634$) for the Mc/ALr model, and by 93.2% ($R^2 = 0.932$) for the ALm/Wc model. This showed that the alkaline liquid-to-metakaolin ratio (ALm) is the primary variable controlling the compressive strength.
2. The mix composition that has the greatest influence on the safety/reliability index of metakaolin-based geopolymer reinforced concrete beam is the alkaline liquid-to-metakaolin ratio (ALm). Among the failure modes considered, the flexural (moment) failure was the most sensitive to the mix parameters.

3. Increasing the alkaline liquid ratio (ALr) up to 2.5 and molar concentration (Mc) from 6 M to 10 M improved the safety index. However, further increase beyond 10 M reduced structural safety.

   It is recommended that, for safety reasons, the production of metakaolin-based geopolymer concrete intended for structural members should place greater emphasis on the metakaolin-to-alkaline liquid ratio, as this parameter has the greatest influence on the safety and structural performance of the member.

ABSTRACT

ABSTRACT

Microbial cell immobilization confers protection, reusability, and enhanced tolerance to toxic and fluctuating environments, and is increasingly applied in bioremediation, biocatalysis, and fermentation. Silica and silica-hybrid matrices are attractive due to their mechanical strength, chemical stability, biocompatibility, and ability to shield cells from ultraviolet light and heavy-metal ions. This review examines silica-based precursors and matrices for microbial encapsulation, spanning sol–gel silicas (tetraethyl and tetramethyl orthosilicate, and the water-miscible THEOS), aminosilane (APTES) coatings applied layer-by-layer to alginate beads, silica–alginate hybrids, silica–poly(ethylene glycol) composites, and low-cost biosilica recovered from agro-industrial residues such as rice husk ash and sugarcane bagasse ash. Reported systems are compared by precursor purity, microbial compatibility, and encapsulation efficiency, cell viability, and mechanical stability. A recurring theme is the trade-off between porosity and stability: high porosity eases substrate diffusion but weakens the capsule, while dense matrices protect cells at the expense of mass transport, so that pore-forming additives are used to create this balance. Biosilica precursors offer low cost, antimicrobial character, and circular-economy benefits, though feedstock variability and purification remain limitations. The review confirms that silica matrices, especially porosity-engineered silica-alginate systems, are well suited to encapsulating hydrocarbon-degrading microorganisms to treat petroleum refinery effluent, and identifies controlling diffusivity, mechanical stability, and scale-up as the principal challenges to wider application.

Keywords: *microbial encapsulation; silica–alginate matrices; cell immobilisation; sol–gel silica; hydrocarbon biodegradation*

1. INTRODUCTION

Microbial cell immobilization retains viable microorganisms within a supporting phase while allowing access to substrates and products. Free cells can be lost through washout, sedimentation or shear, and may be inhibited by toxic pollutants in environmental biotechnology. Immobilized systems enhance biomass retention, boost recovery and permit repeated operation, depending on carrier properties and operating conditions (Partovinia & Rasekh, 2018; Wadhawan *et al*., 2026; Abdulmumin *et al*., 2025).

This review critically examines silica-based matrices for microbial cell encapsulation and immobilization, with emphasis on precursor chemistry, microbial compatibility, encapsulation performance, porosity, mass transfer, mechanical stability, reusability and hydrocarbon biodegradation. The specific objectives are to: (i) compare major silica and silica-hybrid matrix classes; (ii) identify agreements, disagreements and limitations in published studies; (iii) examine APTES-derived silica coatings on alginate capsules; (iv) assess the relevance of microbial consortia and low-cost biosilica; (v) identify engineering requirements for applying immobilized hydrocarbon-degrading microorganisms to petroleum-refinery effluent.

2. METHODOLOGY

The relevant literature concerning microbial encapsulation, immobilization, and silica-based matrices was found through targeted searches using keywords. Studies published mostly between 2018 and 2026 were chosen, and in some cases older foundational studies were included as well. Articles were selected on the basis of their relevance to microbial compatibility, matrix properties, mass

transfer, stability, hydrocarbon biodegradation, and wastewater treatment. The information from these studies was then arranged in structured literature tables and thematically combined in order to compare the different types of matrix, microbial performance, and application potential.

2.1 Silica-Based Matrices for Microbial Cell Encapsulation and Immobilization

Studies establish that microorganisms can remain metabolically active after incorporation into silica-based matrices. (Holzmeister et al., 2018) reviewed inorganic biohybrids, while (Li et al., 2020) investigated viable bacteria related to sawdust–silica for phenanthrene removal in soil. These findings support immobilization but highlight a major challenge: silica synthesis and matrix formation must be compatible with living cells. Alkoxide hydrolysis can generate alcohol, while sol–gel processing may involve conditions that stress microorganisms. (Wadhawan et al., 2026) emphasized that matrix chemistry, processing conditions and matrix properties determine the performance and useful lifetime of immobilized cells.

2.2 Sol–Gel Silica and Precursor Chemistry

TEOS and TMOS are common alkoxide precursors for sol–gel silica, while APTES introduces amine functionality and participates in silica–alginate hybrid formation. (Hernández-González et al., 2020) showed that TEOS/APTES ratios, water, and catalyst conditions affect silica-alginate hybrid structure and mechanical properties. (Abdulmumin et al., 2025) demonstrated that hydrolyzed APTES forms silica coatings on alginate capsules and that glucose can be used as a pore-forming agent to increase diffusivity. The evidence supports mixed precursor chemistry over absolute choice for one precursor. For microbial applications, precursor concentration, hydrolysis conditions, and coating architecture must be selected with cell tolerance and mass transfer requirements. (Dragomirescu et al., 2021)

2.3 Silica–Alginate and APTES-Based Hybrid Matrices

Alginate and silica provide complementary functions. Alginate offers mild ionic gelation and a hydrated environment, while silica reinforces the capsule and provides mechanical stability (Szopa et al., 2022; Hernández-González et al., 2020). Hybridization represents a rational compromise rather than a simple replacement of polymer by inorganic material. APTES is particularly relevant because it participates in silica formation and introduce surface functionality. (Abdulmumin et al., 2025) demonstrated that pore engineering of APTES-derived silica–alginate capsules increases diffusion. However, performance reported for fermentation systems should be transferred with caution to hydrocarbon treatment because hydrocarbons differ in solubility, hydrophobicity and partitioning behaviour. The transferable principle is that pore architecture should be designed around the actual substrate and process.

2.4 Porosity, Diffusion and the Protection–Transport Trade-Off

Mass transfer is a principal mechanism linking matrix architecture to biological performance. As illustrated in Figure 1, matrix architecture influences the balance between microbial protection and substrate transport, ultimately affecting biodegradation performance (Abdulmumin et al., 2025). A hydrocarbon must move from the bulk liquid to the capsule surface, traverse external and internal diffusion barriers, reach the cells, and allow metabolites to leave the matrix. A simplified description is given by Fick's first law:

$$J = -D_{eff}\,(dC/dx) \qquad (1)$$

where J is the diffusive flux, D_{eff} is the effective diffusion coefficient in the matrix, C is the concentration of the transported species, and x is the diffusion distance.

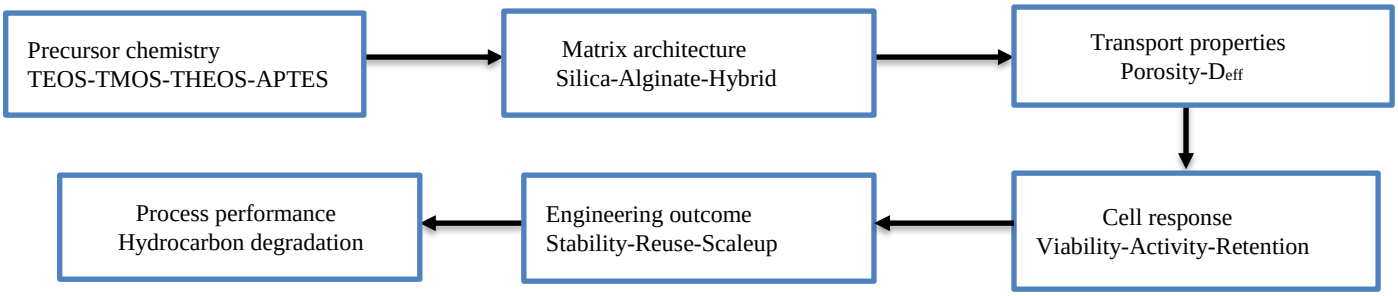

Figure 1: Conceptual relationship between silica precursor chemistry, matrix architecture, mass transfer, microbial response and engineering performance.

(Hernández-González et al., 2020)

2.5 Microbial Consortia and Hydrocarbon Biodegradation

Complex petroleum mixtures of various hydrocarbons justify microbial consortia because different organisms may possess synergistic catabolic pathways. (Tang et al., 2023) described synergistic metabolic functions in crude-oil biodegradation, while (Partovinia et al., 2023) showed that interactions among consortium members can include both synergism and antagonism. (Ganesh Kumar et al., 2019) reported crude-oil degradation using a self-immobilized hydrocarbonoclastic consortium, and (Partovinia et al., 2023) found that immobilization improved crude-oil biodegradation under their conditions. These findings favour functional screening over isolates selection. Consortium design should consider complementary degradation pathways, compatibility growth behaviour, and resistance to the intended wastewater conditions, therefore careful consortium and matrix design are core to improving stability and efficient petroleum hydrocarbon degradation. Consortium design should systematically investigate species ratio, individual and combined growth kinetics, inter-strain compatibility, complementary hydrocarbon-degradation activity, tolerance to relevant wastewater conditions (e.g., pH, salinity and hydrocarbon concentration), and consortium stability over repeated cultivation or treatment cycles. Compatibility can be assessed through pairwise co-culture or interaction tests before selecting the final consortium, while species ratios can be optimized by comparing degradation performance and biomass stability across defined inoculation ratios. (Haq et al., 2024) demonstrated hydrocarbon-removal potential in petroleum-refinery wastewater, while (Al-Mur et al., 2021) reported treatment of refinery wastewater using a hydrocarbon-degrading bacterial consortium under extreme conditions. An additional interpretive issue is the distinction between pollutant removal and biodegradation. Hydrocarbon concentration loss can arise from biological transformation as well as adsorption or partitioning into the carrier. (Younis et al., 2020) demonstrated the importance of partition behaviour in silica–alginate microbeads, while (Zhang et al., 2020) examined degradation by immobilized crude-oil-degrading bacteria. Future validation should therefore include abiotic, free-cell and matrix-only controls so that biological transformation is not inferred from concentration loss alone.

2.6 Evidence and Research Gap

Table 1: Comparative characteristics of some microbial immobilization carriers.

Matrix	**Main advantage**	**Limitation**	**Evidence implication**	**Relevance to target**
Alginate	Mild, cell-compatible gelation	Swelling; low mechanical strength	Good biological starting phase	High
Sol–gel silica	Rigidity; tunable porosity	Synthesis stress; diffusion barrier	Feasible but chemistry-sensitive	High
Silica–alginate	Combines hydration and strength	Porosity–strength trade-off	Strong hybrid strategy	Very high
APTES–silica coating	Functional coating; tunable architecture	Coating thickness must be controlled	Promising for pore-engineered capsules	Very high
Si–PEG hybrid	Organic–inorganic compatibility	More complex formulation	Useful where flexibility is needed	Moderate
Biosilica	Potentially low-cost and circular	Purity/feedstock variability	Requires standardization	Future option

Table 1 shows the key design trade-offs, silica–alginate hybrids emerge as promising systems because alginate supports microbial compatibility while silica enhances mechanical stability. Biosilica from agricultural residues is also promising and potentially attractive because rice-husk and sugarcane-bagasse residues can provide silica feedstocks, although their feedstock composition and purification require standardization (Nzereogu et al., 2023; September et al., 2023; Taiye et al., 2024). The main research gap lies in enhancing hydrocarbon transport especially for poorly water-soluble petroleum hydrocarbons. This gap justifies evaluating APTES-based encapsulation for treating petroleum-contaminant. Relevance to the target was assessed qualitatively based on material cost, microbial compatibility, suitability for hydrocarbon biodegradation, and maturity of supporting evidence. “Very high” indicates strong overall suitability and evidence, while “Moderate” or “Future option” reflects greater limitations or less mature evidence.

Table 2: Representative microbial immobilization matrices and performances

Carrier / matrix	**Target system and microorganism**	**Reported quantitative performance**	**Reference**
Agar	Waste lubricating-oil-contaminated soil; *Paenibacillus* sp. OL15	45 ± 3% degradation after 30 days	(September et al., 2022)
Alginate	Diesel-contaminated groundwater; *Pseudomonas aeruginosa*	71.2% diesel degradation after 10 days; suspended cells achieved 32.0% after 30 days	(Park et al., 2021)
PVA–alginate–clay	Crude-oil system; marine bacterial isolates	74.0–66.6% degradation with PVA–alginate; up to 78.8–75.0% with attapulgite-containing beads	(Farid et al., 2024)
Silica-containing carrier	Phenanthrene-contaminated soil; bacteria immobilized on Sawdust@silica	>95% phenanthrene removal after 48 h; adsorption–degradation was reported as the dominant mechanism	(Li et al., 2020)

Table 2, shows, that immobilized systems outperform free-cells in hydrocarbon removal or degradation under specific conditions. However, comparing matrices is flawed due to differing microorganisms, hydrocarbons, matrix composition, incubation periods and analytical methods. Silica-containing systems standout combining high pollutant removal with matrix stability and tunable transport characteristics. Quantitative evidence supports their enhanced transport capabilities: pore forming modification of an APTES derived silica-alginate capsule increased characteristics when appropriately engineered; for example, pore-forming modification of an APTES-derived silica–alginate capsule increased the diffusion coefficient by approximately 3.2-fold at 308 K, pH 5, and 150rpm demonstrating that silica reinforcement does not necessarily impose mass-transfer penalty (Abdulmumin et al., 2025).

3. FUTURE OUTLOOK

3.1 Advanced Controlled Matrix and Smart Materials

Future trend should focus on matrices that can be tuned to provide controlled mass transfer, mechanical stability, durability and practical recovery. This includes advances in pore engineering, such as the use of pore-forming agents demonstrated for APTES-derived silica–alginate capsules. (Abdulmumin et al., 2025). Reusability, stability, separation and scale-up are also identified as continuing challenges (Wadhawan et al., 2026; Abdulmumin et al., 2026). Magnetic or other recoverable hybrid matrices may offer additional routes to reuse, but their suitability for refinery wastewater should be established experimentally rather than assumed. Future studies should therefore prioritize long-term repeated-use testing, real-effluent validation and assessment of adsorption versus genuine biodegradation. Immobilized bacterial pellets have also shown promise for petroleum-contaminated soil remediation, although such evidence should be treated as complementary rather than direct evidence for silica systems (Zhao et al., 2024).

4. CONCLUSION

The review shows that silica-based matrices are promising platforms for microbial cell immobilization because their structural and surface properties can be controlled to provide protection while maintaining biological accessibility. The literature supports improved biomass retention and operational robustness with immobilized systems, but it does not establish that immobilization is universally superior to free cells. The principal determinant is whether matrix system permits substrate and product transport while maintaining cell viability and mechanical stability. Various matrix systems each offer unique advantages: sol–gel silica, silica–alginate hybrids, APTES-derived coatings, and other silica–polymer systems. Among these, porosity-controlled silica–alginate systems provide a strong basis for hydrocarbon treatment because they combine a hydrated, cell-compatible phase with an inorganic reinforcing network. APTES is therefore a choice precursor for the proposed silica-coated microbial cell, provided that coating thickness, porosity and synthesis conditions are controlled. Microbial consortia should be selected for synergistic hydrocarbon-degrading functions rather than simply for species number. Future work should experimentally establish diffusivity, viability, mechanical stability, hydrocarbon biodegradation, adsorption controls and reusability under petroleum-refinery conditions before scale-up to continuous treatment.

ACKNOWLEDGEMENTS

ABSTRACT

The construction industry remains a major contributor to global carbon emissions, resource depletion, and energy consumption, with traditional materials such as cement and steel carrying significant environmental costs. Green materials derived from renewable, recycled, or low-impact sources offer a sustainable alternative to conventional building practices. This study examines the current state of green materials adoption in the Nigerian construction industry through a mixed-methods approach combining literature synthesis and questionnaire survey of construction firms operating in Kaduna, Plateau, and the Federal Capital Territory, Abuja. The research assesses awareness levels, identifies barriers to adoption, and evaluates the extent to which green building principles are integrated into current practices. Findings reveal that while green materials demonstrate significant potential to reduce embodied energy and carbon footprint—with hempcrete and bamboo composites providing excellent insulation and renewability, recycled aggregates and fly ash reducing reliance on virgin cement, and mycelium-based blocks showing promise in biodegradability—adoption in Nigeria remains critically low. Only 29.6% of respondents confirmed that green materials principles are being considered by construction firms, and 66.7% indicated that the Nigerian building industry is not progressing toward green building construction. Key barriers include inadequate awareness and education (33.3% of respondents), lack of standardised materials and technology (48.1%), absence of regulatory enforcement, high initial costs, limited large-scale production, and regulatory gaps in certification. The study concludes that achieving sustainable construction in Nigeria requires increased professional education, mandatory site waste management, strengthened regulatory frameworks, financial incentives, and enhanced cooperation among stakeholders. The findings contribute to the growing body of knowledge on sustainable construction practices in developing economies and offer practical recommendations for policymakers and industry practitioners.

Keywords: *Green building materials; Sustainable construction; Bio-based composites; Nigerian construction industry; Low-carbon building technologies*

1. INTRODUCTION

1.1 Background

The Inter-governmental Panel on Climate Change (IPCC) has asserted that greenhouse gases generate impacts sufficient to alter global climate patterns. The construction industry generates the greatest environmental impacts among all industries, accounting for approximately 30-40% of global energy use and significant proportions of carbon emissions worldwide. Green building practices have emerged as a key strategy for achieving sustainability in the construction industry, with green materials designs and standards developed to improve building operation energy and embodied energy efficiencies while minimizing energy consumption and waste.

Green materials encompass those which are renewable and/or cause the least impact on the environment. In design, it is the creative initial layout—both of spaces and structure—that takes full advantage of building 'green'. These materials can be considered waste products that hold no harmful effects, are considered at the end of their useful life, and can be used in conjunction with other construction materials for building construction. The concept has been adopted by many nations as the best way forward in preserving resources and sustaining the environment.

1.2 Statement of the Problem

Construction activities, while essential for infrastructural growth and economic development, generate substantial environmental impacts including large quantities of solid waste, noise pollution, air pollution, land degradation, and water pollution. These impacts threaten quality of life and environmental sustainability. Since construction activities cannot be halted due to human demand and socio-economic development requirements, there exists a critical need to balance human requirements with environmental protection. Green building materials offer a pathway to reduce or avoid the environmental impacts of construction activities while ensuring that developmental initiatives and their benefits are sustained.

1.3 Aim and Objectives

The aim of this study is to examine the different construction methods and practices and their general impact on the use of green materials in building construction. The specific objectives are:

1. To identify the most prominent sustainability issues related to site practices of building construction firms;
2. To undertake a review of the concept of green materials in building construction;
3. To evaluate the extent of application of green materials concepts in the construction of buildings in Nigeria;
4. To make appropriate recommendations towards increased adoption of green materials in the Nigerian building industry.

2. LITERATURE REVIEW

2.1 Green Materials and Environmental Sustainability

Sustainable development is a necessary condition for the continuation of the earth, while healthy and comfortable living is a necessary condition for the continuation of life. The building sector is the largest source of greenhouse gas emissions globally, including energy used for heating, lighting, and operating devices (Larsson, 2004). Environmental indicators for green materials have the potential to serve as means of making environmental impacts and possibly benefits of buildings visible to all relevant stakeholders.

Green building helps support a broader sustainable development agenda. If sustainable development goals are to be truly reached, buildings should consume minimal energy, water and materials, and produce minimal emissions, noise and waste over their lifespan. Even at a more realistic level, there is global interest in improving building performance: governments want to reduce the use of scarce resources and airborne emissions, owners want to reduce operating costs, and developers are finding that customers are demanding higher quality and performance (Zhang et al., 2011).

2.2 Examples of Green Materials

Fly Ash: A residue from coal-fired power plants used in cement making. Usage of fly ash decreases the cost of concrete and results in higher quality products (Reddy, K.M., & Patni, J.C, 2026). When cement is produced, huge quantities of carbon dioxide are released, resulting in air and water pollution. The pozzolanic and cementitious properties of fly ash make it ideal as a substitute for cement in concrete, removing the need for disposal. High-performance fly ash concrete can improve workability, ultimate strength, and durability.

Straw Bales: Used as main structural components or as soft insulation. Packed closely and made hard, they can withstand considerable load and impact. Contrary to common perception, straw bales are not a fire hazard and provide three times more fire resistance than conventional homes (Balu,2012).

Cement-bonded Composites: Value-added wood products made from particles from wood and agricultural byproducts, cement, and a catalyst. These materials are useful for ceiling, walling, roofing, flooring, claddings, partitioning, and shuttering (Ajayi, 2005). They are resistant to termites,

insects, fungi, moisture movement, and fire, with good insulating properties, durability, and excellent nailing ability.

Bamboo: Often misunderstood as a light, slender wood, bamboo is lighter than steel but five times stronger than concrete. It absorbs four times more carbon dioxide than most trees, can grow faster than any normal tree (usually several feet per day), and provides significant cooling effects. The main positive aspect is that it is a renewable source (Xu et al, 2025).

Mycelium-based Blocks: Show promise in biodegradability and low-energy production. Mycelium composites are lightweight, fire-resistant, and fully biodegradable; offering architects a versatile medium for sustainable construction (Sharma, R., and Sumbria, R. 2022).

2.3 Importance of Green Materials

Green materials offer numerous benefits including cost savings over the lifecycle, energy efficiency (reducing both embodied and operating energy consumption), water efficiency, material efficiency, temperature regulation, improved indoor air quality, enhanced indoor environmental quality, reduced maintenance requirements, higher property value, and tax benefits (Adedeji, Y.M.D., 2011).

2.4 Barriers to Green Materials Adoption in Nigeria

Several factors impede the adoption of green materials in the Nigerian construction industry:

Ignorance/Illiteracy: With adult literacy rate at approximately 56.9% of the total population, the focus of most citizens on buildings tends toward quick gains without consideration of environmental sustainability (Murtala et. al., 2013).

Poverty: An estimated 54% of Nigeria's population lives below the poverty line, making the procurement of green materials financially challenging (Dinwoodie and Paxton, 1990).

Lack of Awareness: Most Nigerians are not aware that buildings can influence the environment and climate, being more concerned with aesthetic values and modern technological gadgets without understanding the negative implications.

Availability of Materials: While green materials can be found more easily in urban areas, rural areas face significant scarcity. Many eco-friendly materials are not available in Nigeria, making them hard to find and increasing transportation costs (Balu, 2012).

Cost: Many believe the cost of green materials is prohibitive, requiring significant initial investment despite long-term energy savings.

Regulatory Gaps: The absence of comprehensive green building codes, standards, and enforcement mechanisms limits widespread adoption (Al-kaabi et al, 2011).

3. RESEARCH METHODOLOGY

3.1 Research Approach

This study employed a survey research method to investigate current trends in green materials construction in the Nigerian building industry. The survey method was chosen for its suitability in studying both large and small populations by selecting and studying samples to discover the relative incidence, distribution, and interrelation of sociological and psychological variables.

3.2 Sample Size and Population

The population comprised professionals selected from building construction firms including Dantata and Sawoe, Arab Construction, Julius Berger in Abuja, Datum Construction Limited in Kaduna, and Eagle Construction, Akiorganic Partnership, and Rick Rock Building and Engineering Construction Limited in Plateau State. A total population of 50 respondents was selected for the study. Data were initially collected from all 50 respondents using the same set of research questions. Of these, twenty-seven (27) respondents provided their responses through a structured questionnaire, while twenty-three (23) respondents participated through face to face interviews.

The interviews constituted a primary source of data collection, as the information was obtained directly from the respondents based on their knowledge, experience, and opinions concerning the subject under investigation. However, although the interview responses were collected

as part of the preliminary data-gathering process, the interview data will not be used in the final analysis or interpretation of findings for this research.

This decision was made to ensure consistency and uniformity in the method of data analysis and presentation. Consequently, only the responses obtained from the 27 respondents who completed the structured questionnaire will constitute the empirical data used for the study.

The interview exercise should therefore be regarded as a supplementary or preliminary primary data collection activity, rather than a source of data for the final research analysis. The exclusion of the interview responses does not imply that the information provided by the interviewee was invalid; rather, it reflects the methodological decision to restrict the study's final analysis to questionnaire-based responses. Accordingly, all statistical analysis, tables, discussions, and conclusions arising from the empirical data will be based exclusively on the 27 valid questionnaire responses.

The study adopted a purposive sampling technique in selecting the firms and geographical locations included in the research. The selection was based primarily on the relevance of the firms to the objectives of the study, their involvement in construction activities, availability of respondents with relevant professional knowledge, and accessibility for data collection. The study focused on Plateau, Kaduna, and the Federal Capital Territory (FCT), Abuja, which were considered appropriate locations for obtaining information relevant to the research.

The choice of these locations was also informed by the researcher's prior geographical, educational, and industrial familiarity with the areas. The researcher was born in Plateau state, undertook his Bachelor of Engineering (B.Eng.) studies in Zaria, Kaduna state, and completed his Students Industrial Work Experience Scheme (SIWES) at Setraco Nigeria Limited. These experiences provided him with geographical locations, construction industry environment, and relevant firms within the selected states. Such familiarity facilitated the identification of appropriate firms, communication with potential respondents, and access to the field.

3.3 Data Collection Methods

Primary data was collected through questionnaires administered to building construction firms randomly selected in Kaduna, Plateau, and the Federal Capital Territory Abuja. Secondary data was collected from textbooks, journal articles, encyclopedias, published documents, and internet reports.

3.4 Data Analysis

The data analysis was restricted to univariate descriptive statistics, including frequencies, percentages, mean, median, and mode. Consequently, the study did not employ cross-tabulation, correlation analysis, or inferential statistical techniques to examine possible relationships between respondents' demographic characteristics and the identified barriers to adoption. Therefore, the findings should be interpreted primarily as a description of respondents' characteristics, perceptions, and reported adoption barriers rather than as evidence of statistically significant relationships or causal effects.

The decision to adopt a purely descriptive analytical approach was deliberate and consistent with the primary purpose of the study, which was to describe and summarize respondents' views and identify the most prominent adoption barriers. Frequencies and percentages were appropriate for presenting categorical responses, while mean, median, and mode provided useful summaries of responses to relevant items. The approach also enabled the researcher to present the distribution and central tendencies of the data in a straightforward and accessible manner without making statistical claims beyond what the study design and data could adequately support.

Nevertheless, the absence of cross-tabulation and inferential testing limits the study's ability to determine whether adoption barriers vary significantly according to demographic characteristics such as age, gender, educational level, occupation, or years of experience. Future studies could address this limitation by employing cross-tabulation, chi-square tests, correlation analysis, regression, or other appropriate inferential techniques to investigate relationships and predictors of adoption.

Data analysis was conducted using standard percentages and simple statistics to analyse questionnaire responses. Responses were categorised using Likert-scale rankings from Agree to Disagree, Believe to Disbelieve, and Yes/No responses.

4. RESULTS AND DISCUSSION

4.1 Respondent Demographics

The demographic analysis revealed that 92.6% of respondents were male and 7.4% female. The majority (63.0%) were aged 20-35 years, followed by 22.2% aged 36-50 years. Marital status distribution showed 51.9% married and 48.1% single. Educational qualifications indicated 51.9% held B.Sc./B.A degrees, 33.3% held HND, and the remainder held OND or SSCE qualifications. All respondent organisations (100%) had been in existence for 10 years or more.

4.2 Data Presentation and Analysis

Some members of staff of Datum construction Nigeria Limited in Kaduna state; Dantata & sawoe Construction Company Limited, Julius Berger Nigeria Plc., and Arab contractors Nigeria Limited in Federal Capital Territory (FCT) Abuja; and Rick Rock building and engineering Construction Limited, akiorganic patternship, and Eagle Construction Company in Plateau state participated in the study. A total of 50 respondents were involved in the data collection, comprising 27 respondents who completed the questionnaires and 23 respondents who were interviewed using the same set of questions contained in the questionnaire. The responses were coded and analysed using Statistical Package for the Social Sciences (SPSS). The findings were presented using frequency tables and percentages to ensure that the results were clear, concise, and easily understood.

4.5 Discussion

The findings reveal a significant gap between awareness and adoption of green materials in the Nigerian construction industry. While 92.6% of respondents acknowledged the need to switch to green materials, only 29.6% confirmed that green materials principles are being considered in current practices. This awareness-adoption gap aligns with findings from other developing economies where knowledge of sustainable practices does not necessarily translate into implementation.

The study confirms that the building sector is the largest source of greenhouse gas emissions globally, with buildings responsible for significant carbon emissions. Green materials demonstrate substantial potential to reduce embodied energy and carbon footprint. However, the Nigerian construction industry faces persistent barriers including inadequate professional education, limited availability of materials, absence of regulatory enforcement, and economic constraints.

The findings align with previous research identifying government-related barriers as primary impediments to sustainable building projects in Nigeria. The absence of comprehensive green building codes, financial incentives, and enforcement mechanisms limits widespread adoption.

5. CONCLUSION AND RECOMMENDATIONS

5.1 Conclusion

Based on the research findings, the following conclusions are drawn:

1. Green materials construction is not well understood by professionals in the Nigerian building industry, with familiarity with sustainability concepts remaining critically low.

2. Very few respondents acknowledged that construction activities contribute to waste, energy consumption, and environmental pollution, indicating a significant awareness gap.

3. Economic and social aspects of sustainability are more frequently considered than environmental aspects in site practices. The comprehensive definition of green materials encompassing suitable practices in materials choice, sources, construction methodologies, and design philosophy for improved performance, reduced environmental burden, minimised waste, and ecological friendliness has not been fully achieved.

4. While the Nigerian construction industries are not on a sustainable path with some professionals possessing theoretical knowledge of green materials construction, actual practice

remains limited due to lack of incentives, absence of penalties in the code of practice, and insufficient translation of research findings into practice.

5.2 Recommendations

1. Increase Awareness and Education: The level of awareness must be increased through inclusion of environmental issues and sustainability concepts in university curricula and continuing professional development for practitioners.

2. Strengthen Regulatory Framework: Government should undertake a review of existing building regulations to identify measures and policy options to improve sustainability, particularly energy and water efficiency of both residential and non-residential structures.

3. Mandatory Site Waste Management: Site waste management should be compulsory for all construction projects to improve resource efficiency by requiring measurement of waste produced and recording whether it is reused, recycled, or disposed.

4. Financial Incentives: Tax provisions and financial incentives should be introduced to encourage green materials adoption, including building tax credit programmes and reduced taxes on green materials.

5. Stakeholder Collaboration: All interested stakeholders should pool resources in a cooperative strategy, with federal, state, and local governments, educational and research institutions, government parastatals, trade organisations, professional firms, and private individuals collaborating to create the needed synergy for achieving sustainability.

6. Research Implementation: Research findings should be translated into practice rather than serving only as library decorations. Increased cooperation among professionals, particularly joint research work between builders and traditional builders, should be encouraged.

5.3 Areas for Further Research

1. Assessment of the extent of incorporation of green materials-related issues in existing Bachelor of Building curricula in Nigerian universities.

2. Research on energy efficiency in buildings in use, as the greatest proportion of energy consumption occurs during the operational phase.

3. Zero net emission studies in existing and new buildings, including zero energy buildings, to determine energy use through annual accounting.

ABSTRACT

Asphalt pavements absorb large amounts of solar radiation and develop pronounced through-thickness temperature gradients that thermoelectric generators (TEGs) can, in principle, convert into electricity. The magnitude of the recoverable heat depends on the thermal properties of the asphalt concrete, which are in turn governed by mixture composition. This study evaluates the mechanical and thermal behaviour of asphalt concrete for pavement thermoelectric energy harvesting and examines the influence of aggregate type and gradation. Four mixtures were produced from basalt and granite aggregates in wearing-course (WC) and binder-course (BC) gradations: BWC, BBC, GWC and GBC. Marshall mix design (ASTM D6927) established optimum bitumen contents of 5.0–5.5%. Mechanical performance was assessed through Marshall stability, flow and indirect tensile strength (ITS) tests; the apparent thermal conductivity (k_{app}) and specific heat capacity were measured using a steady-state electrical (Searle-type) apparatus. A three-dimensional transient heat-transfer model was built in Abaqus to compare the relative thermal response of the mixtures. Basalt mixtures gave the highest stability (BBC = 7.83kN) and ITS (BBC = 493kPa). The measured k_{app} values (2.90–4.03W/m·K) lie above the range normally reported for asphalt concrete and are treated here as relative, comparative indicators rather than absolute material constants. Within this comparative framing, GWC exhibited the highest apparent conductivity and the largest simulated heat flux (2371W/m²), indicating the greatest thermal potential for subsequent thermoelectric generator integration among the mixtures studied. Electrical power output was not directly evaluated; the thermal characterisation provides a basis for subsequent assessment of TEG integration and power generation. The finite-element results were internally consistent with the analytical Fourier solution to within 13%. Aggregate type and gradation significantly influenced both mechanical and thermal behaviour, providing guidance for material selection in TEG-integrated pavements.

Keywords: *Asphalt concrete; thermoelectric generators; energy harvesting; apparent thermal conductivity; aggregate type*

1. INTRODUCTION

Rising global energy demand, the depletion of fossil resources and the environmental burden of conventional generation have intensified interest in renewable and waste-energy technologies (Gholikhani et al., 2020; Pei et al., 2021). Road networks are attractive in this context because their surfaces are continuously exposed to solar radiation and traffic loading, storing large quantities of thermal and mechanical energy that is otherwise dissipated to the environment (Zhu et al., 2019). Recovering even a fraction of this energy could power road lighting, sensors and monitoring devices while reducing the surface temperatures associated with the urban heat island effect.

Among pavement energy-harvesting approaches, piezoelectric, photovoltaic and thermoelectric generation is well suited to asphalt because the material routinely develops the temperature differentials on which the technology relies. TEGs are solid-state devices that convert a temperature difference directly into electricity through the Seebeck effect, and can operate wherever a gradient exists (Champier, 2017; Shaaban et al., 2019). Experimental and prototype studies have demonstrated combined power-generation and pavement-cooling functions, with cold-side (heat-sink) design frequently controlling field performance (Jiang et al., 2018; Zhu et al., 2019).

The efficiency of a pavement TEG system depends on the available temperature gradient and on the thermal properties of the surrounding asphalt concrete-principally its thermal conductivity and

specific heat capacity (Aridi et al., 2021). These properties are, in turn, governed by mixture composition. Because aggregate typically constitutes the majority of the mixture by volume, aggregate mineralogy and gradation exert a strong influence on heat transfer, whereas the binder-present in small proportion-has a comparatively minor effect (Mrawira & Luca, 2006; Demirtürk et al., 2024; Pasetto et al., 2025). Much of the existing literature focuses on enhancing conductivity through conductive additives such as graphite, steel fibres or slag (Abbas & Alhamdo, 2023), while the comparative effect of conventional aggregate type and gradation on the thermal response relevant to TEG applications has received less systematic attention.

This study therefore evaluates the mechanical and thermal behaviour of asphalt concrete produced from two common aggregate sources (basalt and granite) in two standard gradations (wearing and binder course) and assesses their relative suitability for pavement thermoelectric energy harvesting using combined laboratory testing and three-dimensional finite-element (FE) simulation. The work is framed around locally sourced Nigerian materials, for which such thermal characterisation is currently limited. The use of locally sourced Nigerian aggregates also supports the development of sustainable and locally adaptable pavement materials, while the thermal characterisation provides a basis for future pavement-based energy-harvesting applications relevant to Nigeria's infrastructure and energy needs.

2. MATERIAL AND METHODS

2.1 Materials and mix design

Crushed basalt (Kore quarry) and granite (Barawa quarry), both from Batagarawa LGA, Katsina State, and 80/100-grade bitumen sourced in Kano State were used. Aggregate and bitumen properties were verified against the Federal Ministry of Works (FMW) general specification and the relevant ASTM/BS standards (Tables 1 and 2). Four mixtures were designed-Basalt Wearing Course (BWC), Basalt Binder Course (BBC), Granite Wearing Course (GWC) and Granite Binder Course (GBC)-using the Marshall method in accordance with ASTM D6927. Optimum bitumen contents, obtained from stability, flow, unit-weight and voids plots following the Asphalt Institute procedure, were 5.5% for BBC and 5.0% for GBC, BWC and GWC.

2.2 Mechanical testing

Marshall stability and flow were determined on compacted cylindrical specimens (101.6mm diameter×63.5mm height) at 60°C, and indirect tensile strength (ITS) was measured to assess cracking resistance. Three replicates were tested per mixture and the mean reported.

2.3 Thermal property determination

Thermal conductivity was measured in the laboratory on Marshall-derived sub-specimens using a steady-state electrical (Searle-type) apparatus (this steady-state, effectively one-dimensional test relates only to the laboratory measurement of the material properties, and is distinct from the transient three-dimensional finite-element model of Section 2.4), with the conductivity computed as $k = VIL/(A \cdot \Delta T)$, where V and I are the applied voltage and current, L the specimen thickness, A the cross-sectional area and ΔT the temperature difference across the specimen. Three replicates were averaged for each mixture. Specific heat capacity was determined by the method of mixtures using a copper calorimeter,

It should be noted that this formulation attributes the full electrical power ($V \cdot I$) to one-dimensional conduction through the specimen and neglects lateral and convective heat losses. For a comparatively low-conductivity, heterogeneous material such as asphalt concrete, these losses are not negligible, so the method tends to over-estimate the absolute conductivity. The values reported here are therefore designated apparent thermal conductivity (k_{app}) and are used primarily as relative indicators for comparing mixtures and as comparative inputs to the FE model, rather than as absolute material constants. Because the FE simulations use these apparent conductivities as material inputs, the calculated heat-flux and reaction-heat-flow magnitudes inherit the uncertainty and possible systematic bias of the conductivity measurements. Therefore, these numerical quantities are interpreted comparatively rather than as independently validated absolute heat-transfer values.

Three replicate measurements were conducted for each asphalt mixture, and the mean, standard deviation (SD) and coefficient of variation (CV) were used to assess measurement repeatability. The SD was calculated as the sample standard deviation, $s = \sqrt{\frac{\Sigma(ki - \bar{k})^2}{n-1}}$ while the CV was calculated as: $CV = (s / \bar{k}) \times 100$. The resulting CV values ranged from 0.63% to 2.70%, indicating relatively low within-mixture variability. However, the observed repeatability does not eliminate possible systematic bias associated with the steady-state Searle-type method. Therefore, independent testing using a transient method (e.g., transient plane source) or a guarded steady-state cell would be required to establish absolute thermal conductivity values (Demirtürk et al., 2024). This limitation is revisited in Section 3.3.

2.4 Finite element model and Mesh Sensitivity Analysis

A three-dimensional transient heat-transfer model of the Marshall specimen (101.6mm × 63.5mm) was developed in Abaqus/CAE using DC3D8 eight-node linear heat-transfer elements. The measured density, apparent thermal conductivity and specific heat capacity of each mixture were assigned as isotropic and homogeneous properties. An initial temperature of 298.15K was applied, while fixed temperatures of 335K at the upper face and 310K at the lower face were prescribed for BBC, BWC and GWC. For GBC, 334K and 310K were prescribed at the upper and lower faces, respectively, corresponding to the measured temperature difference. A surface film condition with a film coefficient of 10W/m²·K and an ambient temperature of 298.15K was applied to the lateral surface to account for heat loss to the surroundings. Temperature (NT11), heat flux (HFL3), and reaction heat flow (RFL11) were extracted for analysis.

A mesh-sensitivity analysis was performed (Table 5) using nominal mesh sizes of 2, 3, and 4mm. For the representative BWC specimen, the corresponding HFL3 values were approximately 1351.55, 1312.95, and 1293.70W/m², respectively. The 3mm mesh differed by approximately 2.94% from the 2mm mesh and 1.47% from the 4mm mesh, indicating that further mesh refinement caused only minor changes in the calculated heat flux. Therefore, the 3mm mesh was adopted as a suitable balance between numerical accuracy and computational efficiency.

3. RESULT AND DISCUSSION

3.1 Material properties

Both aggregates satisfied the specification limits (Table 1). Basalt showed a higher specific gravity (2.82 vs 2.64), while granite recorded lower impact, abrasion and crushing values, indicating marginally greater resistance to mechanical degradation; both had acceptable flakiness and elongation indices. The bitumen properties (Table 2) were consistent with a 80/100 paving-grade binder.

Table 1: *Physical properties of basalt and granite aggregates*

Property	Basalt	Granite	Specification
Specific gravity (coarse)	2.82	2.64	2.5–3.0
Aggregate impact value (%)	11.1	7.7	30 max
LA abrasion (%)	24.3	20.0	30 max
Aggregate crushing value (%)	20.0	16.6	45 max
Flakiness index (%)	17.0	21.0	30 max
Elongation index (%)	15.0	25.0	30 max

Table 2: *Physical properties of the bitumen*

Test	Result	Standard
Penetration (0.1mm)	89	ASTM D5
Softening point (°C)	54	ASTM D36
Flash point (°C)	239	ASTM D92
Fire point (°C)	319	ASTM D92

Note: Values in the Specification column are presented as either permissible ranges or limiting requirements (minimum/maximum), as indicated.

3.2 Mechanical properties

Marshall stability, flow and ITS varied systematically with aggregate type and gradation (Table 3, Figure 1). The basalt mixtures outperformed the granite mixtures: BBC recorded the highest stability (7.83kN) and ITS (493.2kPa), followed by BWC, while GBC gave the lowest stability (3.86kN). The superior performance of the basalt mixtures is consistent with their higher specific gravity and better aggregate-bitumen interlock. The Marshall stability values of all four mixtures exceeded the minimum 3.5kN requirement specified for asphalt concrete in the Nigerian General Specifications for Roads and Bridges. GWC and GBC recorded 4.66kN and 3.86kN, respectively, and therefore satisfied the minimum stability requirement, although further optimisation may be required for higher traffic demands.

Table 3: *Marshall stability, flow and indirect tensile strength of the mixtures*

Mixture	Stability (kN)				Flow (mm)				ITS (kPa)			
	Replicate value (n = 3)	Mean	SD	CV (%)	Replicate value (n = 3)	Mean	SD	CV (%)	Replicate value (n = 3)	Mean	SD	CV (%)
BWC	6.56	6.56	0.27	4.04	3.40	3.40	0.00	0.00	485.60	475.90	10.18	2.14
	6.83				3.40				465.30			
	6.30				3.40				476.80			
BBC	7.83	7.83	0.17	2.17	3.80	4.03	0.21	5.16	531.10	493.20	34.09	6.91
	8.00				4.10				483.60			
	7.66				4.20				465.00			
GBC	3.90	3.86	0.24	6.28	3.40	3.47	0.12	3.33	445.30	466.10	29.69	6.37
	3.60				3.40				500.10			
	4.08				3.60				452.90			
GWC	4.58	4.66	0.20	4.26	2.40	2.77	0.51	18.36	460.60	439.30	22.25	5.07
	4.89				3.35				416.20			
	4.52				2.56				441.10			

Note: The values under the 'Replicate value' represent three independent measurements, SD = standard deviation; CV = coefficient of variation

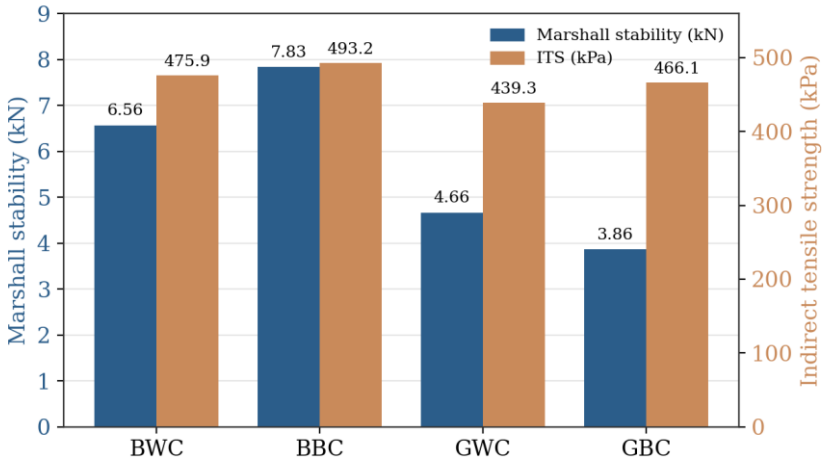

Figure 1: *Marshall stability and indirect tensile strength of the four mixtures.*

3.3 Thermal properties

The measured apparent thermal conductivity (k_{app}) ranged from 2.90W/m·K for BWC to 4.03W/m·K for GWC, with BBC and GBC recording 3.18 and 2.97W/m·K, respectively (Table 4, Figure 2). Specific heat capacity ranged from 765J/kg·K for GWC to 832J/kg·K for BWC. GWC therefore exhibited the highest apparent thermal conductivity and the lowest specific heat capacity, indicating a comparatively greater tendency for heat transfer through the mixture under the test conditions.

The measured k_{app} values should, however, be interpreted with caution. Reported thermal conductivities for conventional dense-graded asphalt concrete are typically around 1.7-2.1W/m·K (Mrawira & Luca, 2006) and rarely exceed 3W/m·K. The GWC value of 4.03W/m·K is therefore higher than expected for an asphalt concrete mixture containing binder and air voids. This overestimation is attributed to the steady-state electrical method, which assumes that the applied electrical power is transferred entirely by axial conduction while neglecting lateral and convective heat losses. These losses may be significant and may differ among mixtures, particularly for GWC, which exhibited the highest heat-transfer rate. Consequently, the measured values are treated as apparent thermal conductivities and are used primarily as comparative indicators and as inputs to the FE model rather than as absolute material constants.

Based on the measured values, the apparent thermal conductivity followed the order GWC > BBC > GBC > BWC. However, because lateral and convective heat losses may affect the mixtures to different degrees, this ranking should not be interpreted as an absolute ranking of intrinsic thermal conductivity. The mixture ranking is therefore considered a comparative indication of thermal response, and GWC's apparent advantage may be partly influenced by its greater unaccounted heat loss. The trend also indicates an interaction between aggregate type and gradation: for granite, the wearing-course mixture had a higher k_{app} than the binder-course mixture (GWC > GBC), whereas for basalt, the binder-course mixture was slightly higher than the wearing-course mixture (BBC > BWC). Thus, the effect of gradation on thermal response depends on the aggregate type.

Table 4: *Apparent thermal conductivity and specific heat capacity of the mixtures*

Mixture	Apparent thermal conductivity, k_app (W/m·K)				Specific heat capacity (J/kg·K)			
	Replicate value (n = 3)	Mean	SD	CV (%)	Replicate value (n = 3)	Mean	SD	CV (%)
BWC	2.9313	2.902	0.039	1.350	829.2175	832.240	7.550	0.910
	2.9167				841.0377			
	2.8571				827.0027			
BBC	3.2411	3.180	0.085	2.670	788.2649	793.310	4.970	0.630
	3.2174				793.4597			
	3.0819				798.2073			
GBC	2.952	2.972	0.029	0.630	792.7049	802.390	8.450	1.050
	2.9741				806.19			
	2.989				808.2716			
GWC	4.0783	4.026	0.050	1.240	781.4167	765.070	23.380	3.060
	3.9788				775.5046			
	4.0216				738.2893			

Note: The values under the 'Replicate Value' represent three independent measurements, SD = standard deviation; CV = coefficient of variation

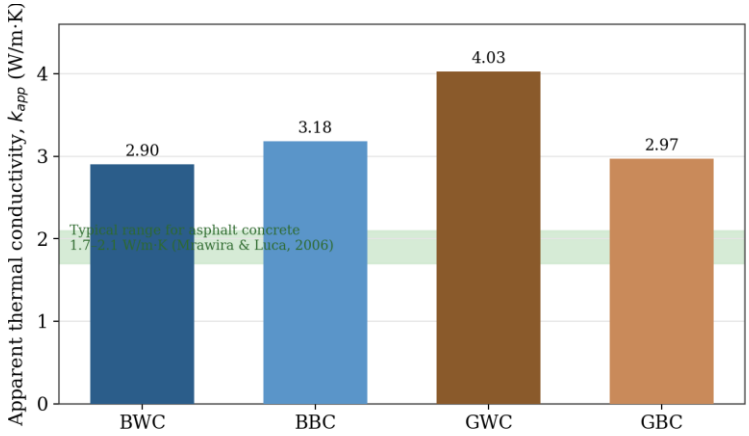

Figure 2: Apparent thermal conductivity of the mixtures relative to the range typically reported for asphalt concrete (Mrawira & Luca, 2006).

Table 5: *Mesh-sensitivity check for BWC specimen*

Mesh size (mm)	HFL3 (W/m²)	Difference from 3mm (%)
2	1351.55	2.94
3	1312.95	Reference
4	1293.7	1.47

Note: HFL3 represents the numerical heat flux extracted from the central region of the specimen. The 3 mm mesh was selected for the FE simulations.

The trend also shows an interaction between aggregate type and gradation: for granite the wearing course exceeded the binder course (GWC > GBC), whereas for basalt the binder course slightly exceeded the wearing course (BBC > BWC). Gradation therefore does not act in a single consistent direction independent of aggregate source, which is relevant when selecting mixtures for thermal performance.

3.4 Numerical thermal response

The transient simulations produced comparable temperature differences across all specimens ($\Delta T \approx 24–25K$), confirming that the mixtures were subjected to similar thermal loading and that differences in heat transfer arise from material properties rather than boundary conditions. Representative contour plots for GWC are shown in Figure 3. Peak heat flux (HFL3) and reaction heat flow (RFL11) differed markedly between mixtures (Table 6, Figure 4): GWC gave the highest heat flux (2371W/m²) and reaction heat flow (up to 263W), consistent with its higher apparent conductivity,

followed by BBC. This indicates that, among the mixtures studied, GWC offers the greatest capacity to transfer heat through the layer and therefore the greatest relative potential for thermoelectric harvesting.

GWC was selected for the representative contour plots because it exhibited the highest apparent thermal conductivity and the highest simulated thermal response among the four mixtures. The remaining mixtures showed the same general through-thickness heat-transfer pattern, with differences primarily in the magnitude of the heat flux.

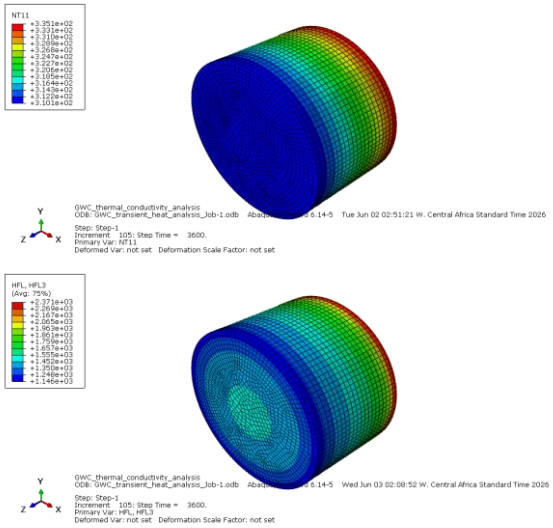

Figure 3: *Simulated temperature distribution (NT11, top) and heat flux (HFL3, bottom) for the GWC mixture.*

Table 6: *Summary of simulated thermal response of the mixtures*

Mixture	ΔT (K)	Peak heat flux, HFL3 (W/m²)	Peak reaction heat flow, RFL11 (W)
BWC	25.0	1912	178.3
BBC	25.0	2018	211.2
GWC	25.0	2371	263.1
GBC	24.1	1875	187.1

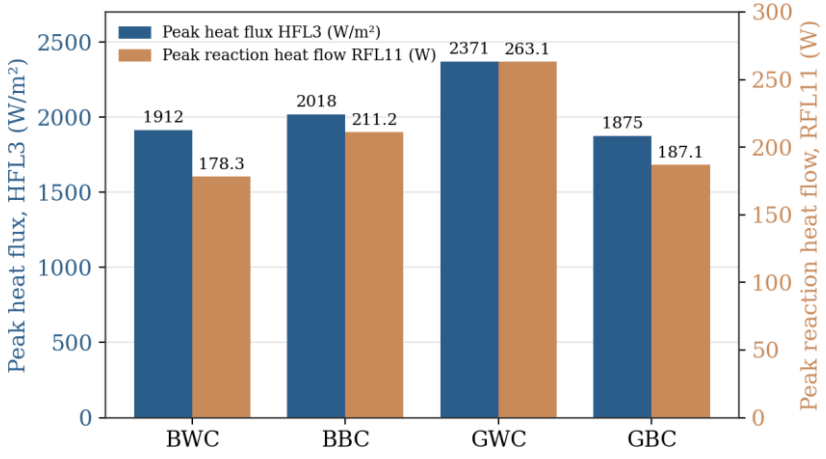

Figure 4: *Simulated peak heat flux and reaction heat flow for the four mixtures.*

3.5 Model verification

The FE model was checked against the analytical Fourier solution $q = k \cdot \Delta T/L$ using the same apparent conductivities, specimen thickness (0.0635m) and simulated temperature differences. Agreement was within 13% for all mixtures (Table 7). This confirms that the model correctly reproduces one-dimensional conduction and is internally consistent; it is a verification of the numerical

implementation rather than an independent experimental validation, since both the analytical and numerical fluxes derive from the same measured conductivity. What is reported here is a code verification of the numerical solution against the analytical (closed-form) Fourier result; independent experimental validation against measured heat-flux or temperature-field data was outside the present scope and is recommended for future work.

Table 7: *Verification of numerical against analytical heat flux*

Mixture	ΔT (K)	k_{app} (W/m·K)	Analytical flux (W/m²)	Abaqus flux (W/m²)	Difference (%)
BBC	25.00	3.18	1252	1425	12.11
BWC	25.00	2.90	1142	1313	12.98
GBC	24.10	2.97	1123	1287	12.74
GWC	25.00	4.03	1585	1759	9.86

4. CONCLUSION

The mechanical and thermal behaviour of four asphalt concrete mixtures, produced from basalt and granite aggregates in wearing- and binder-course gradations was evaluated for pavement thermoelectric energy harvesting through laboratory testing and three-dimensional transient FE simulation. The main findings are:

- Aggregate type strongly influenced mechanical performance: basalt mixtures gave higher Marshall stability and ITS than granite mixtures, with BBC the strongest (7.83kN; 493kPa).
- Aggregate type and gradation both affected thermal response, with an interaction between them; GWC showed the highest apparent conductivity and the largest simulated heat flux (2371W/m²), indicating the greatest relative thermal-harvesting potential.
- The mixture ranking is therefore considered a comparative indication of thermal response rather than an absolute ranking of intrinsic thermal conductivity, as heat losses may affect the mixtures differently.
- The FE model reproduced the analytical Fourier solution within 13%, providing internal verification of the numerical implementation; this should not be interpreted as independent experimental validation.
- The study provides thermal characterisation and numerical assessment relevant to TEG investigation; electrical power output was not directly evaluated. Future work should couple the thermal model with experimentally determined TEG/Seebeck parameters to quantify actual electrical generation.
- Future work should establish absolute thermal conductivities using a transient or guarded steady-state method, validate the model against independent measurements, and couple the thermal model to a Seebeck-based estimate of electrical output to quantify harvesting feasibility.

ACKNOWLEDGEMENTS

The authors thank the Department of Physics, Ahmadu Bello University, Zaria, for access to the thermal-conductivity and calorimetry facilities.

ABSTRACT
This study investigates the tribological behaviour and multi-response optimization of austempered high-carbon steel processed using sulfate salt-modified sesame oil as a bio-based quenching medium. Potassium sulfate (K_2SO_4) and sodium sulfate (Na_2SO_4) concentrations, austempering time and temperature were varied using a Taguchi L9 orthogonal array. Wear rate and coefficient of friction (CoF) were evaluated under dry sliding conditions, while scanning electron microscopy (SEM) was used for qualitative microstructural examination. Grey Relational Analysis (GRA) was employed to simultaneously optimize the two smaller-the-better responses. The nine experimental runs produced wear rates of 0.0003 – 0.0036 mm³/Nm and CoF values of 0.048 – 0.118. Run 4, corresponding to 1.5% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C, produced the highest experimentally observed GRG of 0.8519. The Taguchi response-mean analysis predicted a combined optimum of 3% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C, with an estimated GRG of 0.8721. However, this predicted condition was not included in the L9 matrix and therefore remains experimentally unverified. Pooled ANOVA indicated that austempering temperature contributed 47.74% to GRG variation, followed by Na_2SO_4 concentration at 19.92%, although neither retained factor was statistically significant at the 5% level. SEM observations suggested associations between comparatively refined transformation morphologies and favourable tribological responses, but definitive phase identification requires complementary XRD or EBSD analysis. The findings demonstrate the potential of sulfate salt-modified sesame oil for tailoring the combined wear and friction response of austempered high-carbon steel.

Keywords: *Austempering; Sesame oil; Sulfate salts; Tribology; Grey Relational Analysis*

1. INTRODUCTION

The increasing demand for engineering components capable of operating under severe service conditions has stimulated interest in heat treatment processes that provide a favourable combination of strength, toughness and tribological performance. Austempering is particularly attractive because isothermal transformation of austenite above the martensite-start temperature produces bainitic ferrite and retained austenite, which can improve hardness, toughness, dimensional stability and wear resistance (Bhadeshia, 2015). Such tribological performance is important in gears, shafts, bearings, railway components, mining equipment and automotive parts, where sliding and abrasive interactions can cause material degradation and premature failure (Stachowiak & Batchelor, 2025).

The wear behaviour of bainitic steels depends not only on hardness but also on the morphology, distribution and stability of retained austenite. During sliding, retained austenite may transform to martensite through a deformation-induced transformation, producing a TRIP effect that enhances strain hardening and resistance to material removal (Chen *et al.*, 2024). Chen et al. (2025) associated improved wear resistance with strain partitioning between retained austenite and ferritic phases, while Jiang *et al.* (2026) showed that retained-austenite stability influences crack initiation, propagation and transformation-induced strengthening. Controlling these microstructural features during austempering is therefore important for optimizing tribological behaviour.

Quenching medium characteristics strongly influence heat extraction and subsequent phase transformation. Although mineral oils are widely used, environmental, safety and sustainability

concerns have increased interest in vegetable-oil-based quenchants because of their renewability, biodegradability and favourable cooling characteristics. Sesame oil is a promising candidate owing to its favourable fatty-acid composition, relatively high oxidative stability and flash point. However, previous studies have focused predominantly on the thermal, physicochemical, cooling, mechanical and microstructural characteristics of vegetable-oil quenchants, with comparatively limited attention to their modification for improved tribological performance.

Inorganic salt modification provides a potential means of controlling the heat transfer behaviour of vegetable oils. Aminu *et al.* (2025) reported that sulfate salts can modify the thermal behaviour, cooling characteristics and heat transfer efficiency of vegetable-oil-based quenchants. Such changes may affect bainitic transformation, retained-austenite stability and consequently the tribological behaviour of austempered steels. From an industrial perspective, sulfate salt-modified sesame oil could potentially be prepared using existing oil-quenching systems, while its renewable base fluid offers sustainability advantages. However, practical adoption would depend on raw-material and additive costs, salt dispersion and suspension stability, bath maintenance, thermal degradation, reusability, process consistency and equipment compatibility. Thus, although the approach has commercialization potential, pilot-scale testing, repeated-cycle evaluation, life-cycle assessment and techno-economic comparison with conventional mineral oils are required before industrial implementation can be established.

Despite increasing interest in bio-based quenchants, the tribological behaviour of austempered high-carbon steel processed using sulfate salt-modified sesame oil remains insufficiently documented. This study therefore evaluates the effects of K_2SO_4 concentration, Na_2SO_4 concentration, austempering time and temperature on the wear rate and coefficient of friction using a Taguchi L9 orthogonal array. Grey Relational Analysis (GRA) was employed to simultaneously optimize the tribological responses, while Analysis of Variance (ANOVA) quantified the relative contribution of the process parameters. Microstructural examination was used to relate the observed tribological behaviour to the resulting microstructural features.

The novelty of this study lies in integrating sulfate-salt modification of sesame oil, austempering and Taguchi–GRA multi-response optimization to establish the relationship between quenchant composition, austempering parameters and simultaneous control of wear rate and coefficient of friction. The findings provide an initial basis for evaluating sulfate salt-modified sesame oil as a bio-based alternative to conventional petroleum-derived quenchants and for subsequent pilot-scale and commercialization studies.

2. MATERIALS AND METHODS

2.1 Materials

High-carbon steel and *Sesamum indicum* (sesame) oil were used as the workpiece material and base quenchant, respectively. The steel, supplied in flat-spring form, was machined into samples for tribological and microstructural characterization. K_2SO_4 and Na_2SO_4 were used as quenchant modifiers, while standard metallographic consumables and reagents were used for sample preparation.

The chemical composition of the steel is presented in Table 1.

Table 1: *Chemical composition of the selected high-carbon steel sample*

Elements	C	Si	Mn	Cr	Ni	Cu	V	W	Fe
Compositions (% wt)	1.26	1.20	2.14	2.35	2.80	0.79	0.74	0.20	balance

2.2 Quenchant Preparation and Experimental Design

Sesame oil was preheated to 100 °C before K_2SO_4 and Na_2SO_4 were added at 0, 1.5 and 3.0 wt.%. The mixtures were magnetically stirred for 10 min to promote uniform salt dispersion. The resulting sulfate-modified sesame oils were used as quenching media for austempering.

A Taguchi L9 orthogonal array was employed with four three-level control factors: K_2SO_4 concentration, Na_2SO_4 concentration, austempering time and temperature. The complete experimental matrix is presented with the experimental results in Table 3.

2.3 Heat Treatment of Samples

The as-received samples were normalized at 850 °C for 1 h and air cooled to obtain a relatively homogeneous initial microstructure. Austempering involved austenitizing at 850 °C for 1 h, followed by transfer into the selected sulfate-modified sesame-oil bath maintained at 260, 290 or 320 °C. The samples were held for 30, 45 or 60 min and subsequently air cooled.

The selected temperature range was within the expected bainitic transformation range of the steel. It was also supported by the thermal behaviour of sulfate-modified sesame oil reported by Aminu *et al.* (2025), who observed increased thermal stability following sulfate modification.

2.4 Tribological Testing

Wear rate and coefficient of friction (CoF) were evaluated using a ball-on-disk tribometer (model 50324) under dry-sliding conditions in accordance with ASTM G99 (2020). Samples were prepared to the required dimensions and tested against a 6 mm diameter stainless-steel ball using a normal load of 10 N, sliding speed of 0.1 m/s, test duration of 5 min and wear-track diameter of 8 mm. All samples were cleaned and dried before testing.

CoF was recorded continuously by the tribometer software. Wear rate was determined from the mass loss before and after testing and expressed as volumetric wear per unit load and sliding distance (mm^3/Nm):

$$\text{Wear rate (WR)} = \frac{\Delta m}{\rho . F . L} \tag{1}$$

where Δm is mass loss, ρ is material density, F is applied load and L is sliding distance. The identical test duration and conditions were maintained for all samples to permit comparative evaluation. The relatively short test duration should, however, be regarded as a limitation when extrapolating the results to long-term service wear.

2.5 Microstructural Characterization

For SEM examination, samples were sectioned to approximately 10 × 10 × 5 mm, ground using 400–1200 grit SiC papers, polished with 6 and 1 µm diamond pastes, and etched with 2% nital for approximately 30 s. SEM observations were conducted at 1000× magnification.

The micrographs were used to compare morphological features associated with the different heat treatment conditions and to relate microstructural variations to the observed tribological responses. Phase assignments were made cautiously from morphology and heat treatment history; definitive identification of phases such as retained austenite would require complementary techniques such as X-ray diffraction.

2.6 Taguchi–Grey Relational Analysis

The experimental data were analyzed using Taguchi signal-to-noise (S/N) analysis, Grey Relational Analysis (GRA) and ANOVA in Minitab 17. Since both wear rate and CoF are smaller-the-better characteristics, the corresponding S/N criterion was employed:

$$ϩ = -10 \log_{10}\left(\frac{1}{n}\sum_{i=1}^{n} y_i^2\right) \tag{2}$$

Where ϩ is the S/N ratio, y_i is the observed response and n is the number of observations. As each L9 condition was tested once, n=1.

For simultaneous optimization of wear rate and CoF, the responses were normalized using the smaller-the-better criterion:

$$\text{yi (s)} = \frac{maxx_i(s) - x_i(s)}{maxx_i(s) - minx_i(s)} \tag{3}$$

The grey relational coefficient (GRC) was subsequently calculated from the normalized responses:

$$\epsilon i\,(s) = \frac{\Delta_{min} + \varphi\Delta_{max}}{\Delta_{oi}\,(s) + \varphi\Delta_{max}} \tag{4}$$

$$\Delta_{oi}\,(s) = |x_o(s) - x_i(s)| \tag{5}$$

where the identification coefficient was set to 0.5. The grey relational grade (GRG) was calculated as the equally weighted mean of the GRCs for wear rate and CoF:

$$\mathrm{GRG}i = \frac{1}{n}\sum_{i=1}^{n} \epsilon ij \tag{6}$$

The factor level producing the highest mean GRG was selected as the optimum level. The predicted optimum GRG was subsequently obtained using the Taguchi additive model (Roy, 2010):

$$\gamma = \mu + \sum_{i=1}^{q}\left(\gamma_{i,opt} - \mu\right) \tag{7}$$

where μ is the overall mean GRG of all N experimental runs and $\gamma_{i,opt}$ is the mean GRG at the selected optimum level of factor *i*.

2.7 Analysis of Variance (ANOVA)

Pooled ANOVA was used to estimate the relative contributions of K_2SO_4 concentration, Na_2SO_4 concentration, austempering time and temperature to wear rate, CoF and GRG. The sum of squares (SS), mean square (MS) and percentage contribution were calculated using:

$$\mathrm{SS} = \sum_{i=1}^{L}\frac{T_i^2}{n_i} - \frac{T^2}{N} \tag{8}$$

$$\mathrm{MS} = \frac{SS}{DOF} \tag{9}$$

$$P(\%) = \frac{SS_i}{SS_T} \times 100 \tag{10}$$

The percentage contribution of each factor was calculated from its sum of squares relative to the total sum of squares. Because the L9 array contained no experimental replication, the ANOVA results were interpreted primarily as estimates of the relative contribution of the process parameters rather than as definitive tests of statistical significance. The Taguchi–ANOVA procedure followed the established methodology described by Roy (2010).

3. RESULTS AND DISCUSSION

3.1 Tribological Performance

The tribological results (Tables 2 and 3) demonstrate substantial improvement following quenching and austempering compared with the normalized condition. The normalized steel exhibited a wear rate of 0.0096 mm³/Nm and CoF of 0.279, compared with 0.0005 mm³/Nm and 0.220, respectively, after water quenching. Raw sesame-oil quenching produced still lower values of 0.0001 mm³/Nm and 0.127, indicating the favourable tribological response achievable with sesame-oil heat treatment.

Table 2: *Wear rate and coefficient of friction tests for normalized, water-quenched and raw sesame oil-quenched samples*

Experiments	Wear rate (mm^3/Nm)	Coefficient of friction
Normalized	0.0096	0.279
Water quenched	0.0005	0.220
Raw sesame oil	0.0001	0.127

3.1.1 Wear test

The wear rate of the nine austempered conditions ranged from 0.0003 to 0.0036 mm³/Nm, with the minimum occurring at Run 1 and the maximum at Run 5. All austempered conditions therefore exhibited lower wear rates than the normalized steel (0.0096 mm³/Nm), although the raw sesame-oil reference produced the lowest value (0.0001 mm³/Nm).

The improved wear resistance is associated with the development of bainitic ferrite and retained-austenite-rich regions during isothermal transformation. Bainitic ferrite provides a strong load-bearing framework, while retained austenite can accommodate deformation and undergo transformation-induced strengthening during sliding (Zhao, 2025). This agrees with Chen *et al.* (2024), who linked improved wear resistance in bainitic steels to the synergistic effects of bainitic ferrite and retained austenite.

3.1.2 Coefficient of friction (CoF) test

The coefficient of friction values obtained from the tribological tests are presented in Table 3. CoF varied from 0.048 to 0.118 among the austempered conditions, with the minimum recorded at Run 5 and the maximum at Run 1 (Table 3). The lower friction observed under some conditions may be associated with retained-austenite-rich regions, which possess greater deformability and can accommodate localized deformation, thereby reducing interfacial stress concentrations during sliding (Chen *et al.*, 2025).

Table 3: L9 orthogonal array layout showing results for tribology tests (wear rate and coefficient of friction) for austempered samples

Run	Factors				Responses	
	A: K_2SO_4 (%)	B: Na_2SO_4 (%)	C: Austemp. Time (min)	D: Austemp. Temp. (°C)	WR (mm^3/Nm)	CoF
1	0	0	30	260	0.0003	0.118
2	0	1.5	45	290	0.0014	0.088
3	0	3	60	320	0.0007	0.081
4	1.5	0	45	320	0.0004	0.059
5	1.5	1.5	60	260	0.0036	0.048
6	1.5	3	30	290	0.0010	0.107
7	3	0	60	290	0.0005	0.094
8	3	1.5	30	320	0.0008	0.074
9	3	3	45	260	0.0004	0.069

3.2 Taguchi analysis signal-to-noise ratio (S/N) for tribological responses

3.2.1 Wear rate response

The Taguchi S/N analysis (Table 4) identified Na_2SO_4 concentration as the most influential factor on wear rate, followed by K_2SO_4 concentration, austempering time and temperature. The

optimum levels for minimizing wear rate were 1.5% K_2SO_4, 1.5% Na_2SO_4, 60 min and 290 °C, as indicated by the main-effect plot (Figure 1).

Table 4: *Response for S/N ratios (wear rate vs K_2S0_4, Na_2SO_4, austempering time and austempering temperature*

Level	K_2S0_4 (%)	Na_2SO_4 (%)	Austempering Time (min)	Austempering Temperature (^oC)
1	63.54	68.15	64.13	62.43
2	**58.94**	**55.96**	64.33	**61.03**
3	65.31	63.69	**59.33**	64.33
Delta	6.36	12.18	5.00	3.30
Rank	2	1	3	4

*Bold value signifies to show the level at which the optimum condition is achieved for each process parameter.

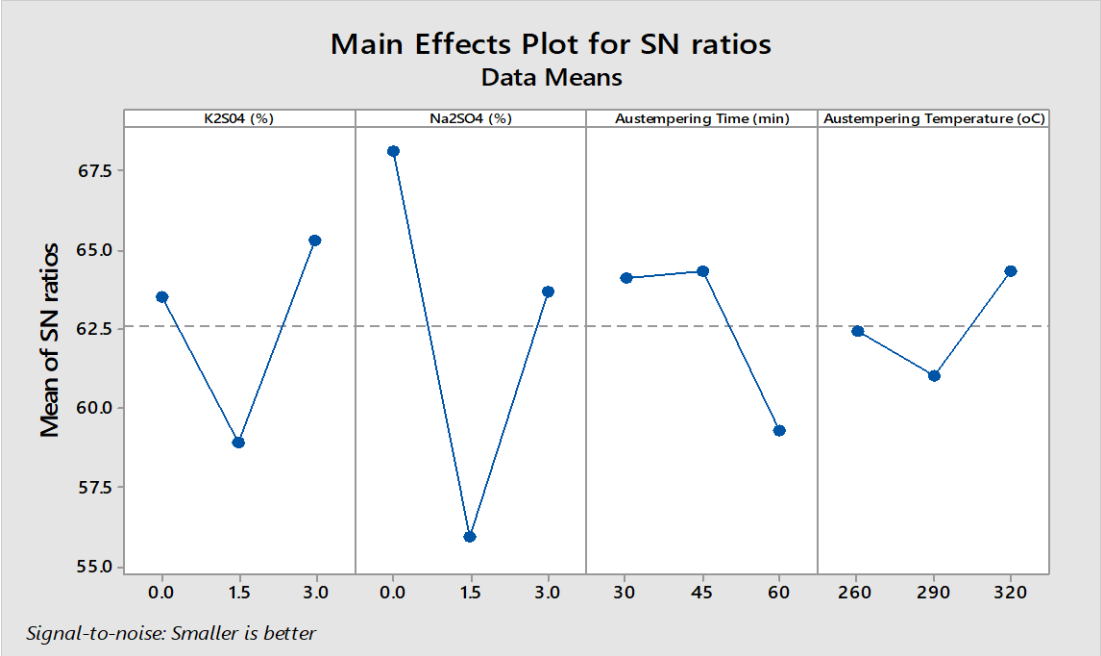

Figure 1: The main effect plots for S/N ratios on wear rate (Taguchi)

3.2.2 Coefficient of friction (CoF) response

For CoF, austempering time was the most influential parameter, followed by temperature, Na_2SO_4 concentration and K_2SO_4 concentration (Table 5). The optimum condition for minimizing CoF was 0% K_2SO_4, 3% Na_2SO_4, 30 min and 290 °C (Figure 2). The stronger influence of holding time suggests that completion and development of the bainitic transformation substantially affect the friction response, while salt concentration modifies the cooling behaviour and consequent microstructural development. Similar time-dependent effects have been reported for austempered niobium-alloyed ductile iron (Garcia *et al.*, 2025).

Table 5: *Response for S/N ratios (coefficient of friction vs K_2S0_4, Na_2SO_4, austempering time and austempering temperature)*

Level	K_2S0_4 (%)	Na_2SO_4 (%)	Austempering Time (min)	Austempering Temperature (°C)
1	**20.50**	21.23	**18.93**	22.72
2	22.19	23.37	22.97	**19.08**
3	22.13	**20.22**	22.91	23.01
Delta	1.68	3.15	4.05	3.93
Rank	4	3	1	2

*Bold value signifies to show the level at which the optimum condition is achieved for each process parameter.

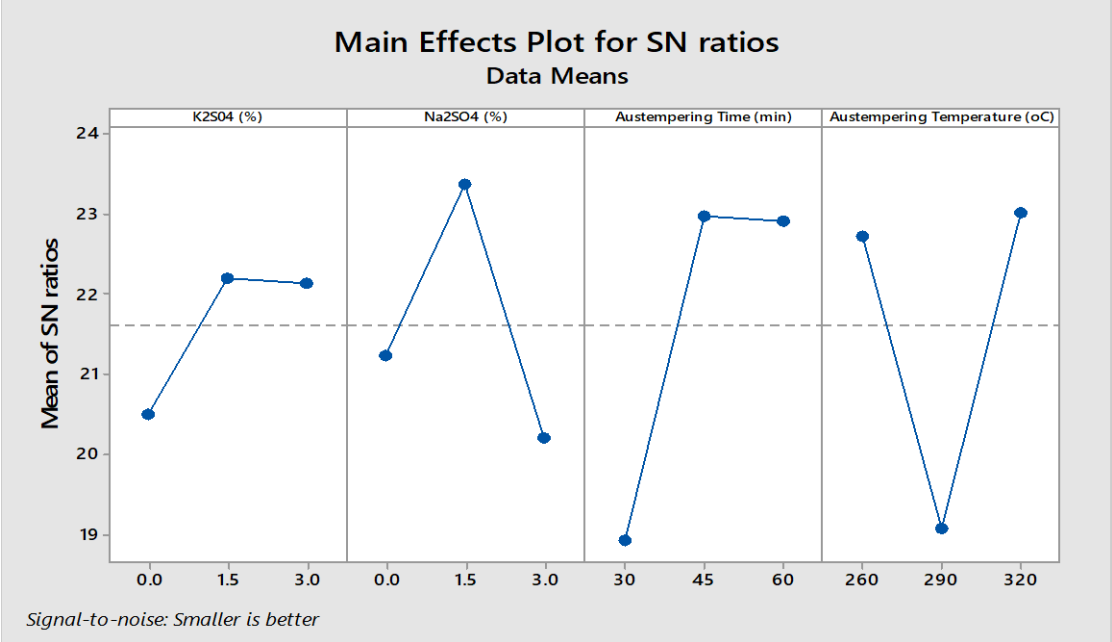

Figure 2: The main effect plots for S/N ratios on coefficient of friction (Taguchi)

3.3 Analysis of Variance (ANOVA) for Tribological Responses

Pooled ANOVA was applied to the L9 experimental results to estimate the relative contributions of the four process parameters to the wear-rate and CoF S/N responses. Because the design was not replicated, the factors with the smallest contributions were pooled to provide an error estimate following the Taguchi approach (Roy, 2010).

Table 6: *Pooled ANOVA for S/N ratio of wear rate and coefficient of friction*

Factor	Wear contribution (%)	F	p	CoF contribution (%)	F	p
K_2SO_4	18.12	2.01	0.249	26.75	1.26	0.377
Na_2SO_4	63.81	7.06	0.047	Pooled	—	—
Time	Pooled	—	—	30.70	1.44	0.337
Temperature	Pooled	—	—	Pooled	—	—
Error	18.07	—	—	42.55	—	—

3.3.1 Wear rate response

The pooled ANOVA results (Table 6) show that Na_2SO_4 concentration was the dominant contributor to the wear-rate S/N response (63.81%), followed by K_2SO_4 concentration (18.12%). Na_2SO_4 was the only retained factor reaching the adopted 95% significance criterion ($F = 7.06$, $p = 0.047$), whereas K_2SO_4 was not statistically significant ($F = 2.01$, $p = 0.249$). Austempering time and temperature were pooled as error, accounting for 18.07%.

The strong contribution of Na_2SO_4 suggests that quenchant chemistry had a greater influence on wear behaviour than the investigated austempering parameters within the experimental range. This may arise from changes in cooling behaviour and the resulting transformation products; however, the specific microstructural mechanisms require further investigation.

3.3.2 Coefficient of friction response

For CoF (Table 6), austempering time contributed 30.70%, followed by K_2SO_4 concentration (26.75%). However, neither factor was statistically significant at the 95% confidence level (time: $F = 1.44$, $p = 0.337$; K_2SO_4: $F = 1.26$, $p = 0.377$). Na_2SO_4 concentration and temperature were pooled into the error term, which accounted for 42.55% of the observed variation.

Although statistical significance was not established, the higher percentage contributions of austempering time and K_2SO_4 indicate their greater relative influence within the tested parameter space and may therefore be useful for process control (Roy, 2010). The relatively large pooled error may reflect experimental variability, unaccounted interactions or the limitations of the unreplicated L9 design. Similar limitations have been noted in Taguchi-based tribological investigations (Asha *et al.*, 2024). Future studies using replication or a larger orthogonal array such as L27 could better resolve interactions and experimental variability (Ramalingam *et al.*, 2022).

3.4 Grey Relational Analysis (GRA)

Grey Relational Analysis (GRA) was used to combine wear rate and coefficient of friction (CoF) into a single performance indicator. As shown in Table 7, Run 4 produced the highest grey relational grade (GRG) of 0.8519, indicating the best overall balance between the two tribological responses among the nine experimental conditions. According to Kuo *et al.* (2011), the highest GRG represents the best combined performance across the selected responses.

The need for multi-response optimization is evident from the contrasting individual responses. Run 1 produced the lowest wear rate but relatively high CoF, whereas Run 5 produced the lowest CoF but the highest wear rate. Their identical GRG of 0.6667 despite different individual responses illustrates the trade-off between wear resistance and friction reduction. Thus, optimization of either response independently may not provide the most suitable overall condition. Run 4, corresponding to 1.5% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C, provided the most balanced response. Similar findings have been reported in Taguchi-GRA tribological studies, where the multi-response optimum differs from the optimum of individual responses (Ibrahim *et al.*, 2022; Altas, 2024).

Table 7: *GRA integrate multiple responses (wear rate and CoF)*

Runs	Norm - WR	Norm - CoF	Δ-WR	Δ-CoF	GRC - WR	GRC – CoF	GRG	Rank
1	1.0000	0.0000	0.0000	1.0000	1.0000	0.3333	0.6667	5
2	0.6667	0.4286	0.3333	0.5714	0.6000	0.4667	0.5333	9
3	0.8788	0.5286	0.1212	0.4714	0.8049	0.5148	0.6598	7
4	0.9697	0.8429	0.0303	0.1571	0.9429	0.7609	0.8519	1
5	0.0000	1.0000	1.0000	0.0000	0.3333	1.0000	0.6667	5
6	0.7879	0.1571	0.2121	0.8429	0.7021	0.3723	0.5372	8
7	0.9394	0.3429	0.0606	0.6571	0.8919	0.4320	0.6619	4
8	0.8485	0.6286	0.1515	0.3714	0.7675	0.5737	0.6706	3
9	0.9697	0.7000	0.0303	0.3000	0.9429	0.6250	0.7839	2

3.4.1 Effect of process parameters on GRG

The mean GRG response (Table 8) ranked austempering temperature as the most influential parameter, followed by Na_2SO_4 concentration, austempering time and K_2SO_4 concentration. Temperature had the largest delta (0.1500), with the optimum level being 320 °C, which produced a mean GRG of 0.7274, compared with 0.7058 at 260 °C and 0.5775 at 290 °C (Figure 3). The superior response at 320 °C may be associated with more favourable transformation conditions and phase development; however, this interpretation remains inferential because phase fractions were not quantitatively determined by techniques such as XRD or EBSD.

Na_2SO_4 had the second-largest influence (Δ = 0.1033), with 0% producing the highest mean GRG (0.7268), followed by 3% (0.6603) and 1.5% (0.6235). The non-monotonic response suggests that salt concentration does not continuously improve the combined tribological performance and may modify quenchant cooling characteristics and subsequent transformation behaviour (Aminu *et al.*, 2025).

Austempering time ranked third (Δ = 0.0982), with 45 min giving the highest mean GRG (0.7230), compared with 0.6248 and 0.6628 at 30 and 60 min, respectively. This intermediate optimum suggests a favourable transformation window within the investigated conditions. K_2SO_4 had the smallest delta (0.0855) but showed a progressive increase in mean GRG from 0.6199 at 0% to 0.6853 at 1.5% and 0.7055 at 3%, making 3% its optimum level.

Table 9: *Response for means (GRG vs K_2S0_4, Na_2SO_4, austempering time and austempering temperature)*

Level	K_2S0_4 (%)	Na_2SO_4 (%)	Austempering Time (min)	Austempering Temperature (^oC)
1	0.6199	**0.7268**	0.6248	0.7058
2	0.6853	0.6235	**0.7230**	0.5775
3	**0.7055**	0.6603	0.6628	**0.7274**
Delta	0.0855	0.1033	0.0982	0.1500
Rank	4	2	3	1

*Bold value signifies to show the level at which the optimum condition is achieved for each process parameter.

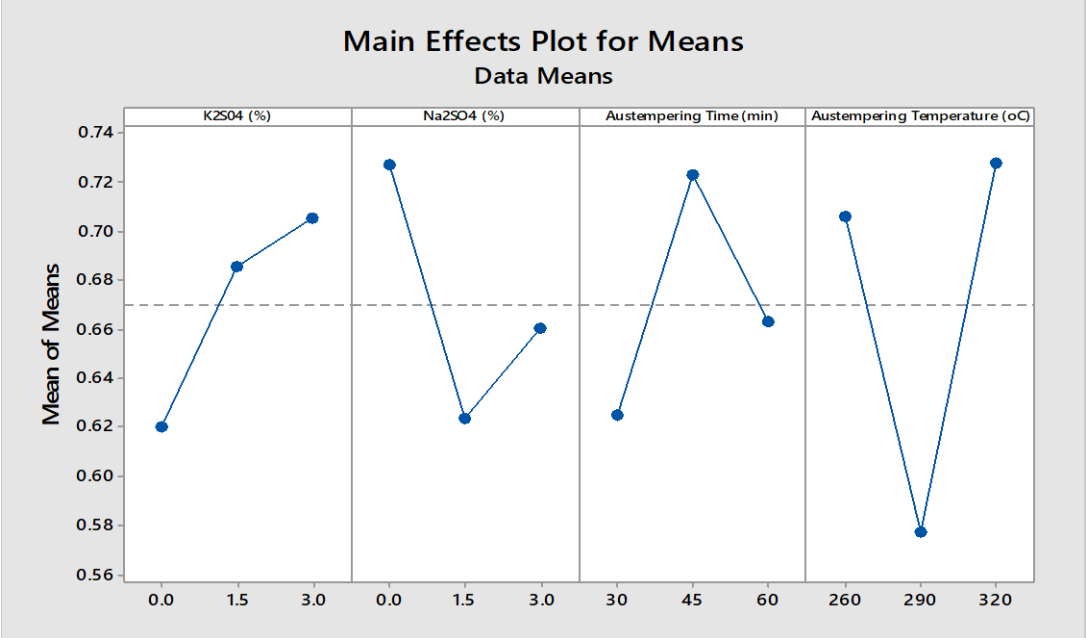

Figure 3: The main effect plots for means on GRG (Taguchi)

3.4.2 Predicted Optimum Condition

The best experimental condition and the predicted Taguchi optimum should be distinguished. Run 4 was the best of the nine tested conditions, with a GRG of 0.8519 at 1.5% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C. However, combining the optimum level of each factor from the GRG response (Table 9) gives the predicted condition 3% K_2SO_4 + 0% Na_2SO_4 + 45 min + 320 °C ($A_3B_1C_2D_3$).

Using the Taguchi additive model, the predicted GRG was 0.8721, approximately 2.37% higher than the highest experimentally observed GRG (0.8519). Because this combination was not included in the L9 array, the predicted improvement remains an unverified model estimate rather than demonstrated experimental improvement. Confirmation testing is therefore required to establish the predictive adequacy of the model.

Table 9: *Mean GRG for optimum levels*

Parameter	Optimum level	Mean GRG
K_2SO_4 concentration	3%	0.7055
Na_2SO_4 concentration	0%	0.7268
Austempering time	45 min	0.7230
Austempering temperature	320°C	0.7274

3.4.3 ANOVA for GRG

The pooled ANOVA (Table 10) identified austempering temperature as the largest contributor to GRG (47.74%), followed by Na_2SO_4 concentration (19.92%), while K_2SO_4 concentration and austempering time were pooled as error, accounting for 32.34%. This ranking agrees with the GRG response analysis, which also identified temperature as the most influential factor.

Although temperature had a higher F-value (2.952) than Na_2SO_4 (1.232), neither factor was statistically significant at the 5% level under the pooled-error model ($p = 0.163$ and 0.383, respectively). The relatively large pooled error and absence of replication limit the strength of statistical inference; therefore, these results should primarily be interpreted as estimates of relative parameter contribution within the investigated experimental range.

Table 10: *Pooled ANOVA for grey relational grade*

Factor	DOF	Sum of Squares (SS)	Mean Square (MS)	F-value	p-value	Contribution (%)
B: Na_2SO_4(%)	2	0.01645	0.00823	1.232	0.383	19.92
D: Austemp. temp(^oC)	2	0.03942	0.01971	2.952	0.163	47.74
Error (A + C pooled)	4	0.02671	0.00668	----	----	32.34
Total	8	0.08257	----	----	----	100.00

3.5 Microstructure–Property Correlation

SEM micrographs (Plates I – X) obtained at 1000× magnification revealed differences in the morphology, distribution and apparent refinement of the transformation products produced by the various heat treatment conditions. Phase identification from SEM morphology is qualitative; definitive identification and quantification, particularly of retained austenite, would require complementary techniques such as XRD or EBSD.

The normalized sample (Plate I) exhibited a relatively coarse ferrite–pearlite morphology, providing a reference for comparison with the austempered conditions and consistent with its comparatively poor wear resistance (Bhadeshia & Honeycombe, 2017). The austempered samples generally exhibited finer acicular transformation features (Plates II – X), morphologically consistent with bainitic transformation (Bhadeshia, 2015). Differences in feature size, uniformity and distribution were observed among the processing conditions, reflecting variations in transformation behaviour (Wang *et al.*, 2024a, 2024b).

Notably, Plate V (Run 4), which produced the highest experimental GRG (0.8519), exhibited comparatively refined and homogeneous transformation features. Such morphology may promote more uniform load distribution and resistance to localized plastic deformation during sliding, thereby contributing to its favourable combined wear and friction response. In contrast, relatively coarser or heterogeneous morphologies observed in Plates III, VI, VII and X may promote localized deformation and stress concentration, increasing susceptibility to wear damage (Bhadeshia & Honeycombe, 2017; Stachowiak & Batchelor, 2025).

Overall, the SEM observations qualitatively support the tribological results: better-performing conditions generally exhibited comparatively refined and homogeneous transformation morphologies, whereas less favourable responses were associated with coarser or less uniform features. However, this correlation should be regarded as qualitative because the study did not quantitatively determine phase fractions or retained-austenite stability.

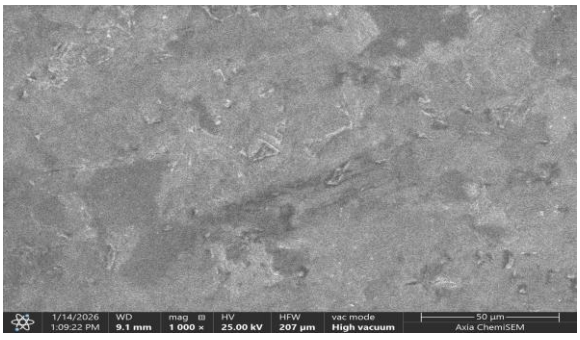

Plate I: SEM micrograph of normalized high-carbon steel at 1000×

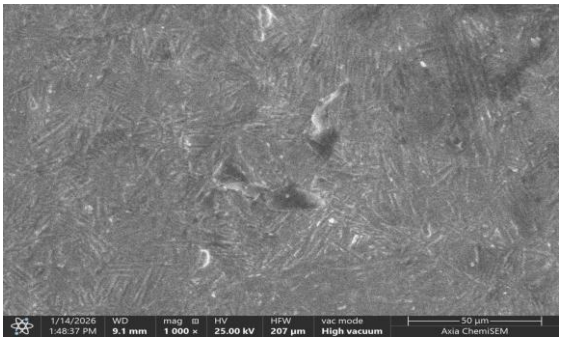

Plate II: SEM micrograph of austempered sample, Run 1, at 1000×

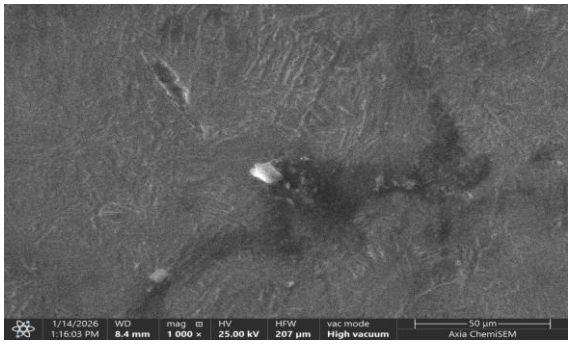

Plate III: SEM micrograph of austempered sample, Run 2, at 1000×

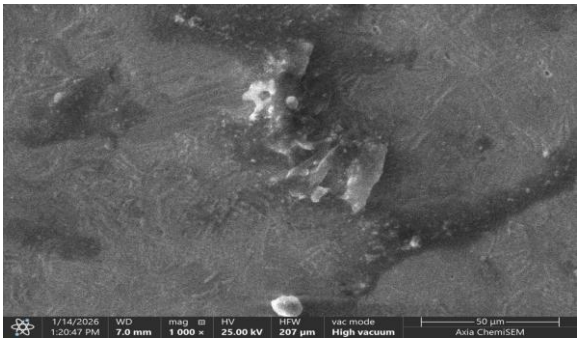

Plate IV: SEM micrograph of austempered sample, Run 3, at 1000×

Plate V: SEM micrograph of austempered sample, Run 4, at 1000×

Plate VI: SEM micrograph of austempered sample, Run 5, at 1000×

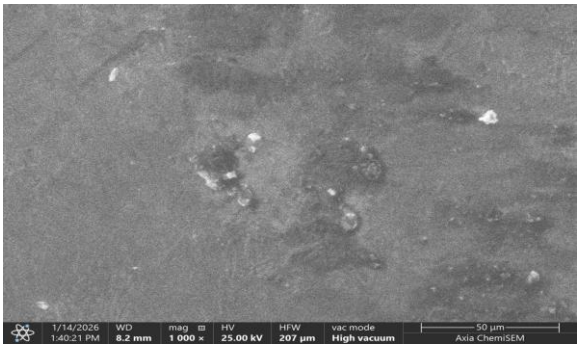

Plate VII: SEM micrograph of austempered sample, Run 6, at 1000×

Plate VIII: SEM micrograph of austempered sample, Run 7, at 1000×

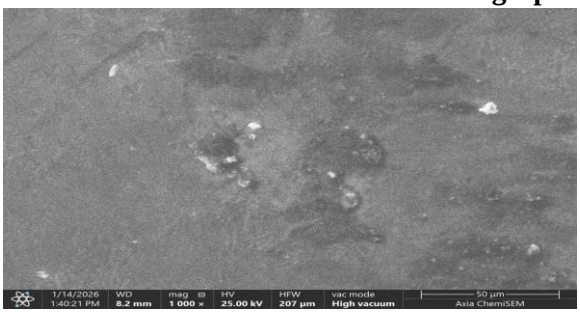

Plate IX: SEM micrograph of austempered sample, Run 8, at 1000×

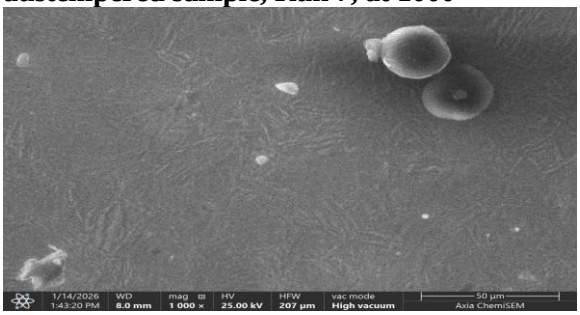

Plate X: SEM micrograph of austempered sample, Run 9, at 1000×

4. CONCLUSION

This study evaluated the tribological behaviour and multi-response optimization of austempered high-carbon steel using K_2SO_4- and Na_2SO_4-modified sesame oil. The principal conclusions are:

1. Austempering substantially improved tribological performance relative to the normalized condition, with the investigated sulfate-modified sesame-oil conditions generally producing lower wear rates and coefficients of friction under the specified dry-sliding conditions.
2. Single-response Taguchi optimization produced different parameter combinations. Minimum wear rate was associated with 1.5% K_2SO_4, 1.5% Na_2SO_4, 60 min and 290 °C, whereas minimum CoF corresponded to 0% K_2SO_4, 3% Na_2SO_4, 30 min and 290 °C, confirming the competing nature of the two tribological responses.
3. GRA provided a balanced multi-response solution. The highest experimentally observed GRG (0.8519) was obtained at 1.5% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C (Run 4). The Taguchi-GRA response analysis predicted 3% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C, with an estimated GRG of 0.8721. Since this combination was not included in the L9 array, experimental confirmation is required.
4. Austempering temperature was the largest contributor to GRG variation (47.74%), followed by Na_2SO_4 concentration (19.92%). However, neither factor was statistically significant at the 5% level under the pooled-error model; therefore, the contribution values should be interpreted as relative influences within the present L9 dataset.
5. SEM observations qualitatively supported the tribological trends, with better-performing conditions generally exhibiting comparatively refined and homogeneous transformation morphologies. Definitive phase identification and retained-austenite quantification would require complementary XRD or EBSD analysis.

5. LIMITATIONS AND FUTURE WORK

The study was limited to a single high-carbon steel, three levels of each sulfate concentration, three austempering temperatures and three holding times using an unreplicated L9 design. The 5-min tribological test duration, absence of independent replication and lack of confirmation testing limit extrapolation to long-term service performance. In addition, SEM provided qualitative rather than quantitative phase characterization.

Future work should prioritize replicated confirmation testing of the predicted condition (3% K_2SO_4, 0% Na_2SO_4, 45 min and 320 °C), followed by longer-duration tribological testing under varied loads and sliding speeds. XRD/EBSD and worn-surface SEM/EDS should be employed to clarify phase constitution and wear mechanisms. For industrial implementation, the thermal and suspension stability, quenchant reusability, additive availability, cost and scalability of the modified sesame-oil system should also be evaluated.

ABSTRACT

The use of Reclaimed Asphalt Pavement (RAP) in Hot Mix Asphalt (HMA) is as a result of the growing need for economical and environmentally friendly road construction solutions. When old asphalt is removed for resurfacing and reconstruction, RAP is created. Furthermore, the rise in plastic garbage in recent years has become a major ecological problem on a global scale. Therefore, this study explores the volumetric and Marshall properties of HMA containing High RAP proportion, Low-Density Polyethylene (LDPE) modified bitumen and Waste Engine Oil (WEO) as a rejuvenator. Preliminary physical property testing was conducted on the HMA constituent materials in accordance with the relevant standards. The Marshal mix design was employed to determine the optimum binder content of the control mix using virgin materials with varying bitumen content from 5% to 7% at 0.5% intervals. Furthermore, RAP in the varying proportion of 25% to 100% at an interval of 25% was introduced to replace the virgin coarse aggregates by weight (25%, 50%, 75%, and 100%) with LDPE Modification at varying replacement level from 4% to 12% at an interval of 4% by the weight of bitumen. A 15% of WEO by the weight of the optimum binder content was added to the mix as rejuvenator. Although some combinations containing 100% RAP exceeded the flow restrictions, the Marshall stability and flow values of the examined mixtures meet the requirement of >3.5 kN and 2-4mm respectively. Moreover, majority of the assessed volumetric properties of the mixes did not meet the established standards. These findings suggest that using high RAP contents, LDPE-modified bitumen and WEO has a potential to produce HMA with acceptable Marshall stability. However, in order to achieve satisfactory volumetric characteristics and complete compliance with specifications, there is need for further study to optimize the binder content, WEO dosage, LDPE concentration.

1.0 INTRODUCTION

Road infrastructures are important lifelines for modern societies, in Nigeria, socioeconomic developments are directly related to quality roads. According to FMWH (2013), the total national road network is approximately 200,000 km and only about 65,000km of the 200,000km are flexible pavements which represent about 33% of the entire road network. Flexible pavements are most commonly used for low to medium volume roads with significant usage also found in high volume interstate highways and airfield runways, taxiways and aprons subjected to heavy aircraft gear/wheel loads (Mohod and Kadam, 2016).

In recent years, however, growing environmental concerns have led many industrial and societal sectors to change their policies around waste management, resource use, and the efficiency of

production of goods and services. As we strive for a circular economy and sustainable resource use, it is becoming increasingly crucial to reuse and recycle non-renewable resources, as a result, the construction and maintenance of transportation infrastructure, in particular, is gradually adopting eco-friendly technology to reduce its ecological impact (Cheraghian et al., 2020)

In this context, the intensive extraction and processing of virgin materials for asphalt production significantly disrupt natural habitats and degrade ecological systems. Researchers have been investigating the possibility of finding suitable sustainable materials that can be used in replacement of conventional pavement materials. Arianto *et al.* (2019) reported recycling of the used pavement materials as a technique for pavement rehabilitation as it conserves energy and resource. Recycling and reusing of non-renewable materials are becoming increasingly imperative in order to move towards a circular and sustainable economy as well as a sustainable use of resources. In particular, the industry of construction and maintenance of transport infrastructures is gradually applying environmentally friendly solutions, aiming to reduce its ecological footprint (Rodrigues *et al.,* 2020).

Among the available sustainable approaches, most popular technique is recycling RAP back into hot mix asphalt (HMA). The addition of RAP to new asphalt mixtures made using different manufacturing processes, such as hot, warm, half-warm, and cold-mix asphalt, is one of the most popular recycling techniques in pavement construction and maintenance (Rodrigues *et al.*, 2020). Martinho *et al.* (2018) reported some potential benefits of using reclaimed asphalt such as reducing the quantity of demolition trash that is dumped in landfills, cutting down on energy consumption and emissions and lowering the need for more non-renewable raw materials. Additionally, it has been shown to reduce issues of waste disposal and the likelihood of cracking and rutting while increasing the stiffness and resistance of asphalt to deformation (Ozer *et al.,* 2009).

Despite these benefits, the introduction of RAP into a new asphalt mixture can create challenges because the aged RAP binder can significantly influence the properties of the resulting mixture, particularly when recycling involves high percentages. The incorporation of RAP as a constituent in the production of fresh asphalt mixtures causes some challenges having been the bitumen suffers short- and long-term ageing such as oxidation and volatilization of constituents as reported by Hunter *et al.* (2015) and Rodrigues *et al.* (2020).

To address these limitations, fresh bitumen or any other rejuvenating agent can be incorporated to partially recover the lost properties of the aged asphalt binder. To recover the desired properties of the aged binder, an appropriate amount of fresh bitumen or rejuvenator is added to a satisfactory level of performance. Consequently, the rejuvenator ability to reactivate the aged binder is of major importance to achieve adequate performance of the asphalt mixture (Rodrigues *et al.,* 2020).

Among the potential rejuvenating materials, Waste Engine Oil (WEO) is particularly relevant because enormous quantities are generated worldwide by cars, trucks, trains, airplanes, generators, industries, and other machinery (Khurshid *et al.,* 2021). Waste engine oil (WEO) has gained increasing attention as a potential rejuvenator for high-RAP asphalt mixtures due to its physicochemical resemblance to the maltene fraction of bitumen. WEO, rich in light hydrocarbons and aromatic fractions, can partially compensate for this depletion by restoring the maltene–asphaltene balance (Fathi *et al.,* 2026). Onuche *et al.* (2024) reported that Nigeria consumes about 700 million litres of lubricants annually from which about 80% WEO is generated with potential of production of 336 million litres per year of diesel like fuel. Therefore, effective management and beneficial reuse of this waste is of paramount importance in mitigating environmental pollution that may eventually endanger human health and ecosystem.

Additionally, polymer modification provides another approach for improving the performance of bituminous materials. Bitumen is known to degrade over time due to a number of factors, including volatilization and component oxidation. Polyethylene has been found to be one of the greatest polymer additives as it is the most commonly used plastic worldwide (Nizamuddin *et al.,* 2021). Simultaneously, the increasing generation of plastic waste presents a significant environmental challenge. Ezeudu *et al.* (2024) reported an estimated figure of about 27.3 million tonnes of municipal solid waste currently generated in Nigeria's urban cities per annum about 11.2 million tonnes is collected of which about 1.1 million tonnes is plastic.

Beyond these environmental considerations, the use of suitable modifier can also improve the performance and economic sustainability of bituminous mixtures. Bitumen, a binder made from refined

crude oil, is one of its most crucial components. Environmental harm results from bitumen production's carbon dioxide emissions (Sharma *et al.,* 2022). Nevertheless, although several commercial modifiers can improve bituminous performance, the cost-benefit ratio of bitumen blends' is decreased when they are used. Therefore, the availability of alternative modifiers that can improve bitumen's qualities without increasing the cost of bitumen mixes or decreasing their cost-benefit ratio is crucial (Shuaibu *et al.,* 2021).

More specifically, bituminous materials are widely used in road construction around the world. These hydrocarbons can be found in nature or as a byproduct of distilling crude oil. The two types of bituminous materials used in highway construction are tars and asphalts (Syrmanova *et al.,* 2017). Modified bitumen and the regeneration of old bitumen not only help with the safe disposal of RAP waste but also reduce the consumption of limited and non-renewable resources, which makes them more desirable in terms of global sustainability. According to several publications, 15% WEO should be used while producing HMA (Mamun and Al-Abdul Wahhab, 2018; Khan *et al*., 2021).

Despite these individual applications, previous studies had investigated RAP recycling, LDPE modification, Waste Cooking oil (WCO) (Rodrigues *et al.,* 2020) and Waste Engine Oil rejuvenation (WEO) (Maharaj and Maharaj, 2015) largely as separate approaches. However, there remains a need to evaluate their combined application in high-RAP HMA, particularly to determine suitable RAP–LDPE combinations while using WEO to rejuvenate the aged RAP binder. Therefore, the present study examines the potential applications of RAP–LDPE combinations with Waste Engine Oil (WEO) as a rejuvenating agent in high RAP HMA.

2.0 MATERIALS AND METHODS

2.1 Materials

The materials used in this study comprised 60/70 penetration-grade bitumen, low-density polyethylene (LDPE), waste engine oil (WEO), virgin coarse and fine aggregates, mineral filler and reclaimed asphalt pavement (RAP).

2.1.1 Bitumen

60/70 penetration grade bitumen was utilized in the production of the Hot Mix Asphalt. The bitumen was sourced from one of the operational locations of Julius Berger Nigeria Plc construction company located along Kaduna-Zaria Road.

2.1.2 Low-Density Polyethylene (LDPE)

The LDPE flakes with a density of 0.91 to 0.93 g/cm³ and melting point of about 100-125ºC was utilized to modify the bitumen. The flakes were sourced from open dumps in Samaru area. They were washed, dried and shredded to produce the required size for the bitumen modification.

2.1.3 Waste Engine Oil (WEO)

The Waste Engine Oil (WEO) utilized in the study is the conventional used engine oil sourced from mechanic workshop in Samaru, Zaria Kaduna state.

2.1.4 Mineral Aggregates

Coarse and Fine Aggregates were obtained from a nearby quarry in Zango, Zaria, Kaduna state, Nigeria. Sieve Analysis was carried out on the aggregates to determine their particle size distributions. The particles retained on 4.75mm and 0.075mm were used as Coarse and Fine aggregates respectively in the production of the HMA.

2.1.5 Mineral Filler

Quarry dust obtained from a nearby Zango quarry in Zaria was used as the mineral filler. Sieve Analysis was carried out to determine the particle distribution of the quarry dust. The particles that passed through a 0.075 mm sieve was used in the production of the HMA.

2.1.6 Reclaimed Asphalt Pavement (RAP)

The RAP utilized in the research was obtained from one of the operational locations of Julius Berger Nigeria Plc construction company stockpiled by the roadside along Zaria-Kaduna Road in Dumbin Dutse. It was milled to achieve the required particle sizes of the RAP, the particles retained on 4.75mm sieve was utilized. The RAP was used as a partial to complete replacement for virgin coarse aggregate in the production of the HMA.

2.2.0 Characterization of the Constituent Materials

The constituent materials were characterized through laboratory testing to determine their physical properties and establish their suitability for asphalt mixture production. The laboratory tests were conducted at the Department of Civil Engineering Ahmadu Bello University, in accordance with the applicable standards.

2.2.1 Bitumen

The bitumen was characterized by conducting specific gravity, flash and fire point, ductility, softening point, and penetration tests in accordance with ASTM D70, ASTM D92, ASTM D113, ASTM D36, and ASTM D5, respectively.

2.2.2 Waste engine oil (WEO)

WEO is a dark brown or black liquid with varying properties depending upon type and utilization. The temperature determines its state, which is usually liquid and lighter than water (Mehmood *et al.,* 2024). Based on the previous studies of DeDene. (2011), metals such as lead, zinc, calcium, and magnesium were found in the used engine oil. Consequently, the WEO was filtered to remove the unwanted solid particles without carrying out any treatment on it. It was used as a rejuvenating agent to restore or soften the aged binder contained in the RAP. A WEO content equivalent to 15% by weight of the optimum binder content was incorporated into the asphalt mixture

2.2.3 LDPE-Modified Bitumen Preparation

LDPE is a thermoplastic polymer widely available from post-consumer plastic waste. When incorporated into asphalt binder, it forms a dispersed polymer-rich phase that improves stiffness and elastic recovery (Ling *et al.,* 2019; Fathi *et al.,* 2026). Because LDPE has a melting temperature of approximately 105–120°C, which is lower than the blending temperature of bitumen, it was incorporated using the wet-mixing technique (Ahmad and Ahmad, 2022). Prior to modification, the LDPE was cleaned, shredded into small pieces, and dissolved in kerosene on a heating pan at a controlled temperature to facilitate blending. The required quantity of conventional bitumen was gradually heated to 170 ± 5°C and maintained at this temperature throughout the process. Predetermined LDPE contents of 4%, 8%, and 12% by weight of the optimum binder content were then gradually added to the heated bitumen under continuous mechanical agitation. The mixture was maintained at 170 ± 5°C and mixed continuously for 60 minutes to promote the softening, dispersion, and uniform distribution of LDPE within the bitumen matrix, while avoiding excessive heating. A 15% waste engine oil (WEO), by weight of optimum binder content, was also added as a rejuvenator for the aged binder in the reclaimed asphalt pavement (RAP). The resulting homogeneous LDPE-modified binders were subsequently used to prepare asphalt mixtures containing the specified proportions of virgin aggregate and RAP.

2.2.4 Mineral aggregates

The virgin aggregates, both coarse and fine aggregates, were characterized through particle-size distribution, specific gravity, aggregate impact value (AIV), aggregate crushing value (ACV) and water absorption tests, conducted in accordance with, ASTM C136, ASTM C127, ASTM C535, ASTM C535, and ASTM C127, respectively.

2.2.5 Mineral Filler

The mineral filler was characterized through particle-size distribution and specific gravity tests, conducted in accordance with, ASTM C136, and ASTM C127 respectively.

2.2.6 Reclaimed Asphalt Pavement (RAP)

The RAP was characterized using sieve analysis, specific gravity, aggregate impact value, aggregate crushing value and water absorption tests. These tests were conducted in accordance with ASTM C136, ASTM C127, ASTM C535, ASTM C535 and ASTM C127 respectively.

2.2.7 Marshall Mix Design

The Marshall mix-design procedure, in accordance with ASTM D6927, was used to determine the optimum binder content (OBC) of the control asphalt mixture designed for heavy-traffic conditions. Control specimens comprising virgin aggregates and conventional bitumen were prepared at binder contents of 5-7% at 0.5% increments. Marshall stability, flow, bulk density, air voids (VIM), voids in mineral aggregate (VMA), and voids filled with bitumen (VFB) were evaluated. The OBC was selected based on the binder contents corresponding to maximum stability, maximum bulk density, and the specified air-void requirement; consequently, an OBC of 6.5% was obtained for the control mixture.

Subsequently, reclaimed asphalt pavement (RAP) was incorporated at replacement levels of 25-100% at an interval of 25% while LDPE was added at 4-12% at an interval of 4% by weight of bitumen. A full-factorial experimental design was developed using Design-Expert software version 13 to assess the combined effects of RAP and LDPE contents on the Marshall and volumetric properties of the asphalt mixtures. The design comprised 36 experimental runs. For each mixture, the constituent materials were thoroughly blended and compacted using 75 Marshall blows on each face of the specimen, in accordance with the requirements for a heavy-traffic wearing course.

3.0 RESULTS AND DISCUSSIONS

3.1 Bitumen

The results of the physical property tests, presented in Table 1, indicate that the bitumen is 60/70 penetration grade and has a specific gravity of 0.98. All the results of the carried-out tests fell within the specified limits of the relevant standards with the exception of softening point result in which there is an observed slight deviation from the standard which might have been due to human error when conduction the test. These results confirm the suitability of the bitumen for use in the production of Hot Mix Asphalt (HMA).

Table 1: Tests and Code Limits on Bitumen

Tests	**Results**	**Specifications**	**Code**
Fire test (^{0}C)	355	Min. 232	ASTM D92
Ductility at 25 ^{0}C, cm	110	Min. 100	ASTM D113
Softening point (^{0}C)	*57.5	48-56	ASTM D36
Penetration at 25^{0}C (0.1mm)	64	60-70	ASTM D5
Specific gravity test at 25^{0}C	0.98	0.97-1.02	ASTM D70
Flash test (^{0}C)	325	Min. 232	ASTM D92

*Asterisk indicates a slight deviation in softening point result from the code specification

3.2 Mineral Aggregates

The results presented in Tables 2 and 3 show that the coarse aggregate recorded an ACV of 23.10%, an AIV of 25.97%, and a specific gravity of 2.85, while the fine aggregate had a specific gravity of 2.64. The obtained results satisfied the requirements specified by the relevant standards for mineral aggregates, indicating that the virgin aggregates were suitable for use in the production of the HMA.

Table 2: Tests and Code Limits on Coarse Aggregates

Tests	Results	Limitations	Code
Sieve analysis	Cu>1<3, Cc<1		ASTM C136
Specific gravity	2.85	Max. 3	ASTM C127
Aggregate impact value (%)	25.97	Max. 30	ASTM C535
Aggregate crushing value (%)	23.10	Max. 30	ASTM C535
Absorption test (%)	0.4	Max. 5	ASTM C 127

Table 3: Tests and Code Limits on Fine Aggregates

Tests	Results	Limitations	Code
Specific gravity	2.64	2.50-3.00	ASTM C127
Sieve analysis	Cu>3, Cc>1<3		ASTM C136

3.3 Reclaimed Asphalt Pavement (RAP)

Table 4 displays the results of the physical characteristics tests conducted on Reclaimed Asphalt (RAP). The reclaimed asphalt's specific gravity, ACV, and AIV are 2.56, 26.00, and 23.00, respectively. The RAP is suitable for use in asphalt mixtures because they fall within the specified ranges in ASTM Standards.

Table 4: Tests and Code Limits on RAP

Tests	Results	Limitations	Code
Specific gravity	2.56	3max	ASTM C127
Aggregate impact value (%)	26.00	30max	ASTM C535
Aggregate crushing value (%)	23.00	30max	ASTM C535
Absorption test (%)	0.40	0.5max	ASTM C127

3.4 Combined Aggregate Curve

The centre curve displays the mix derived from the findings of the particle size distribution test conducted on the mineral aggregates utilized in this investigation, while the upper and lower curves are as specified in the applicable code for use in asphalt. This implies that the mixed aggregate will have a strong interlocking and an appropriate packing density to support loads and withstand deformation as supported by (Shuaibu *et al.* 2024). The results of the combined particle size analysis, as displayed in Figure 1, indicate that the aggregates are suitable for use in HMA since the test results fell between the upper and lower boundary limits (FMWH, 2016).

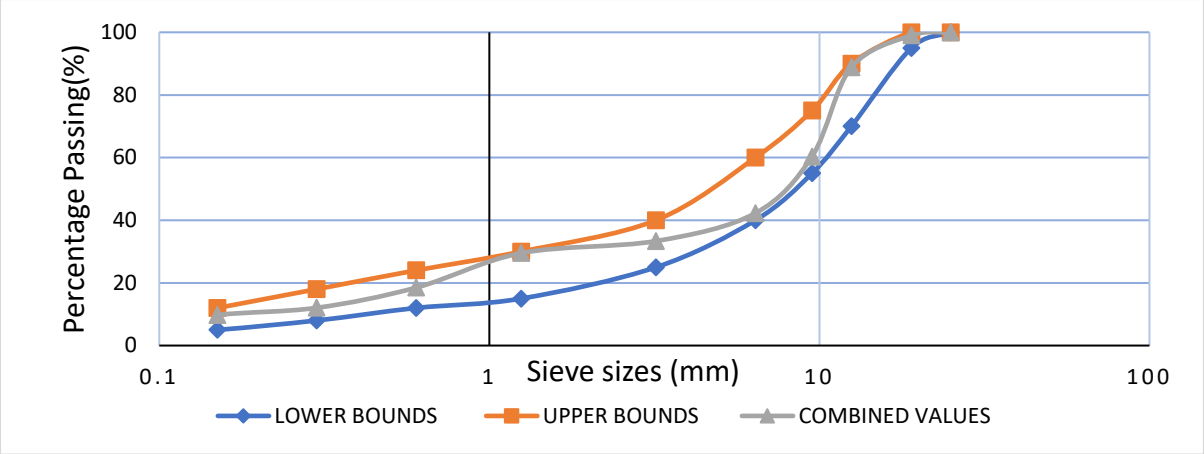

Figure 1: Combined curve for mineral aggregates

3.5 Marshall Mix Design - Optimum Bitumen Content

The asphalt contents having the maximum value of bulk density, Marshall Stability and median air void are selected. The bitumen content at median numerical values for approximately 7% air void, maximum stability and maximum bulk density are 6.5%, 6% and 7% respectively. The optimum bitumen content of 6.5% was determined by taking the average value of the selected properties in accordance with the Nigerian general specification code for roads and bridges which satisfies the requirements for surface course of 5-8%.

$$\text{OBC (\%)} = \frac{Maximun\ Stability(\%BC)+Maximum\ bulk\ density(\%BC)+Median\ VA(\%BC)}{3}$$

$$= \frac{6.0+7.0+6.5}{3} = 6.5\%$$

Table 5: Marshall Property Test carried out on HMA samples

Bitumen Content (%)	Stability (kN)	Flow (mm)	Bulk Density (g/cm^3)	Quotient (kN/mm)	VMA (%)	VFB (%)	VA (%)
5.0	4.90	4.90	2.08	1.00	21.06	52.52	10.00
5.5	6.40	4.60	2.13	1.39	21.10	53.46	9.82
6.0	7.60	3.70	2.15	2.05	20.05	59.50	8.12
6.5	6.60	3.90	2.10	1.69	19.74	63.12	7.28
7.0	5.90	3.20	2.21	1.84	21.26	59.78	8.55

3.6 Analysis of the Effect of LDPE and RAP to Marshall and Volumetric Parameters

The results of the Marshall and volumetric Analysis of sample with varying RAP and LDPE contents are presented in the figures below.

3.6.1 Stability

Stability is the maximum load needed to cause failure of a specimen upon application of load. The stability of the LDPE-modified asphalt mix with respect to the amount of RAP and LDPE wastes is depicted in Figure 2. The chart peaks at 8.28kN stability represents 50% RAP and 12% LDPE waste. Continuously, until it reached 50% RAP content, the stability of the modified asphalt mix rose in step with the RAP level; after that, stability started to decline at higher bitumen content. This decrease in

stability revealed that increasing bitumen content creates too thick film on the aggregate particles, resulting in loss of inter-particle friction and this leads to insufficient stability in pavements (Genet *et al.,* 2021). However, as a saturation point was reached at 50% RAP, stability started to decline. Previous research indicates that the stability of the mix increases with the quantity of LDPE in HMA until a certain point, beyond which it begins to decrease as the amount of plastic grows (Akinpelu *et al.,* 2013). Although the peak stability was recorded at 50% and 12% LDPE modification, all the values recorded at different RAP contents and LDPE modifications exceeded the Nigerian minimum limits of 3.5kN.

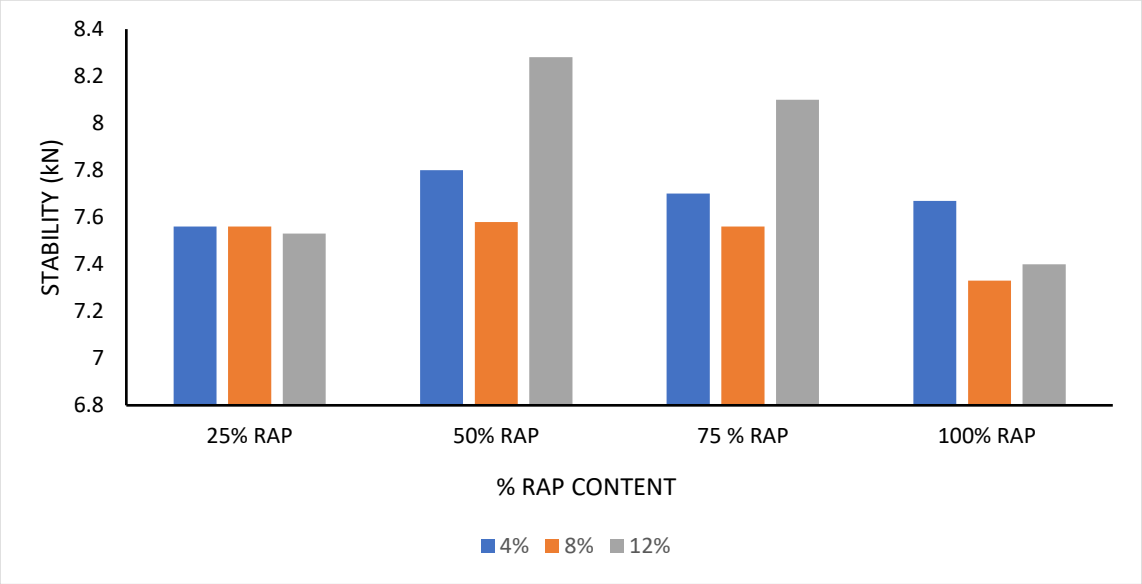

Figure 2: Relationship between the stability and the RAP content at different LDPE modifications.

3.6.2 Flow

The relationship between the flow in the asphalt mix sample and the RAP/LDPE waste concentration is shown in Figure 3. There is observed increase in the flow of the LDPE-modified bitumen at lower LDPE waste content and continuously increased until it reached a maximum value of 3.56mm, then it started decreasing at higher LDPE/RAP wastes content. The decrease in flow of the marshal mix as the waste LDPE content increase also shows that the increase in resistance to rutting. Higher flow value shows higher flexibility while lower flow value shows higher rigidity (Jassim *et al.,* 2014; Kotresh *et al.,* 2016; Genet *et al.,* 2021). As observed from the chart, the optimal flow of 3.56 mm is achieved with 50% RAP and 8% LDPE waste. The outcome of the flow is between 2-4mm, falling within the FMWH general parameters' range. This illustrates how well LDPE reduces flow, enhancing the capacity of the asphalt to support loads. A higher flow value denotes more flexibility, whereas a lower flow value denotes more stiffness (Genet *et al.,* 2021).

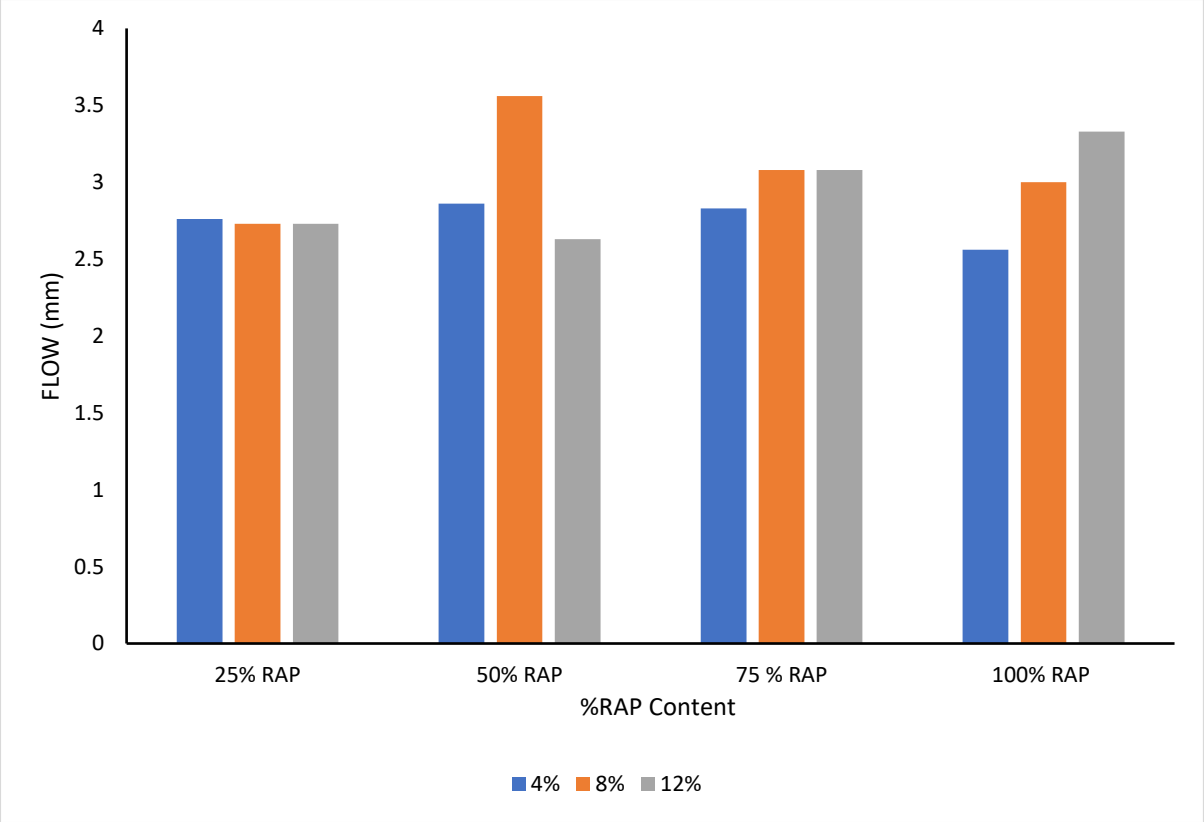

Figure 3: The Relationship between the flow and the RAP content at different LDPE modifications

3.6.3 Marshell Quotient

Figure 4 shows the relationship between the RAP/LDPE waste contents and the asphalt marshall qoutient. The overall stiffness and viscosity of the asphalt mixture reduced as the bitumen concentration rose, which caused the quotient to decline as the RAP percentage rose. At 4% LDPE waste and 100% RAP, the quotient peaks at 2.99KN/mm. This result is in line with another study's conclusions (Kotresh *et al.,* 2016).

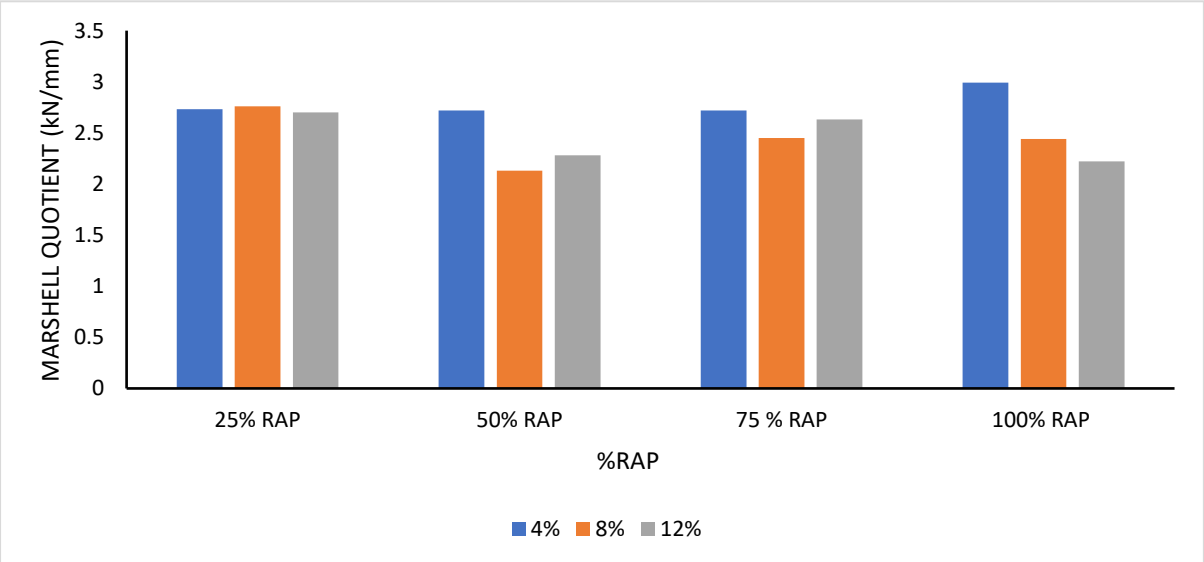

Figure 4: The Relationship between the Quotient and the RAP content at different LDPE modifications

3.6.4 Bulk Density

The relationship between Bulk Density and RAP at various LDPE modifier contents is shown in Figure 5. The addition of material having a lower specific gravity than the base material results in a drop in the bulk density of the compacted mixes as the RAP content rises; in other words, the increase in LDPE content causes the decrease. The variation in the density values from 2.22-2.25 g/cm^3 shows minimal variation confirming stable compaction behavior which is in line with the study conducted by (Fadhil et al., 2026).

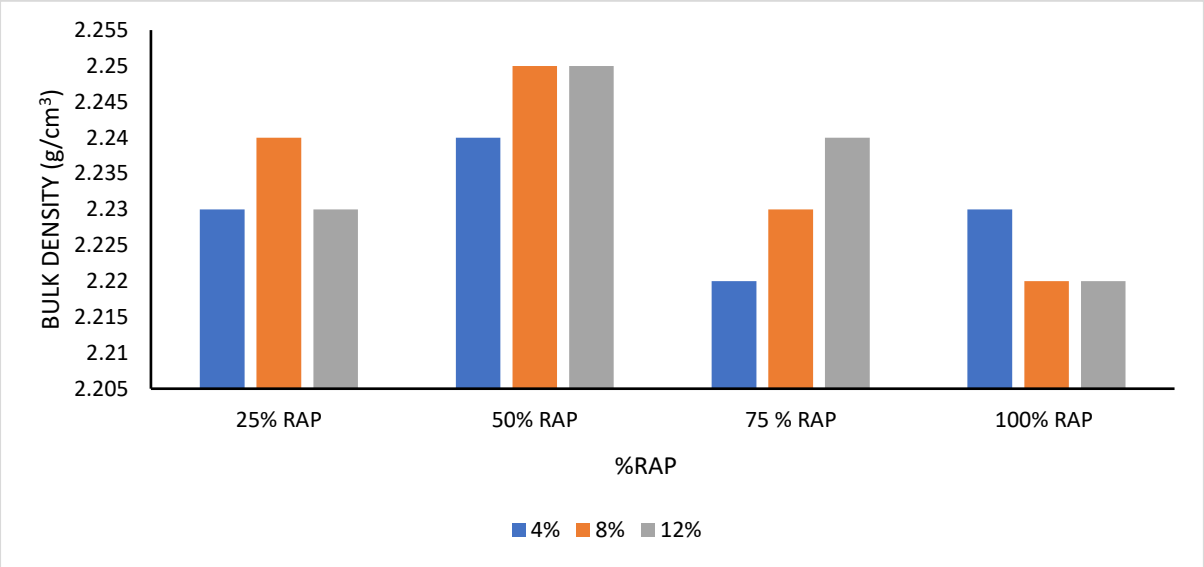

Figure 5: Relationship between Bulk Density and RAP at different LDPE modifier contents.

3.6.5 Voids in Mineral Aggregate

The void in the mineral aggregate (VMA) is defined by the intermolecular spaces between the aggregate particles in compacted paving mixtures that includes the air voids and the effective asphalt content (Genet et al, 2021). The correlation between VMA and RAP at varying LDPE modifier levels (25, 50%, 75%, and 100%) of RAP is depicted in Figure 6. The number of voids that can be filled with asphalt binder is indicated by the presence of voids in mineral aggregates with a numerical value of 22.2% void in mineral aggregate. The highest VMA was achieved at 75% RAP and 4% LDPE waste content. According to the applicable usage standards for asphalt mix, this result falls within the ideal range for VMA. The gaps between the particles have been successfully filled in and partially sealed by the LDPE.

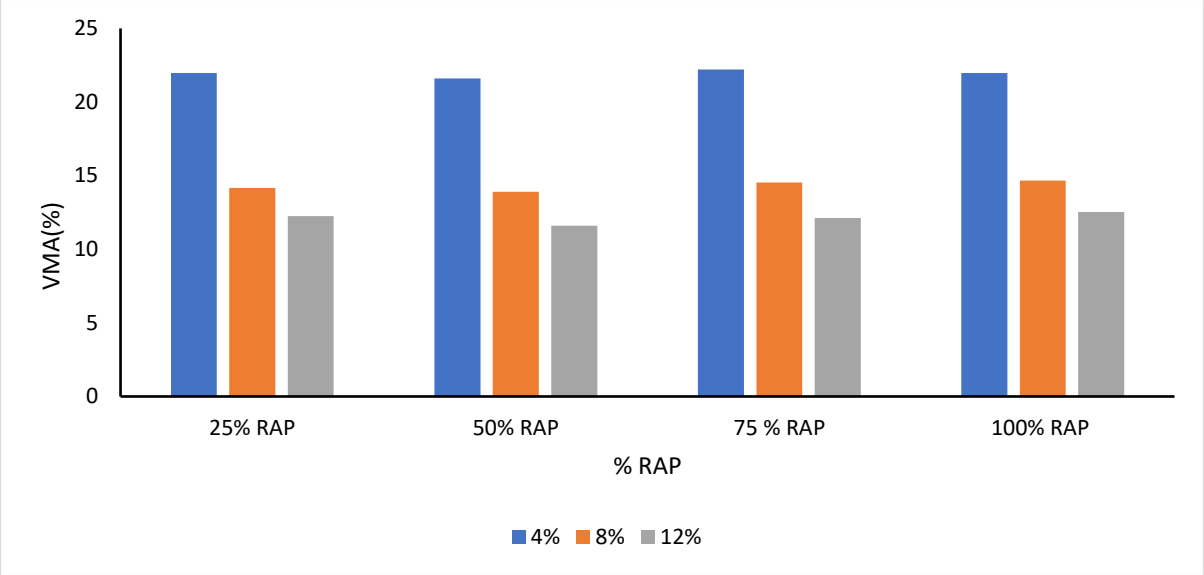

Figure 6: The relationship between VMA and RAP at different LDPE modifier content

3.6.6 Voids Filled with Bitumen

Figure 7 illustrates the link between VFB and RAP at different LDPE modifier contents. The findings indicated that when the RAP and LDPE contents increase, the VFB value decreases. The chart indicates that the ideal bitumen-filled void was found at 50% RAP and 12% LDPE waste content, which is equivalent to 53% VFB. The VFB values of the modified mix are higher than those of the control mix. The observed reduction at 100% RAP further suggests that the influence of LPDE waste becomes more significant as the proportion of aged RAP materials increases**.** The reduction in VFB at higher RAP and LDPE contents may be associated with changes in binder rheology and aggregate-binder interaction, which could eventually influence aggregate packing, compaction and air-void development. The maximum VFB is 53%, which is less than the 75-85% required value of the Nigerian general standard for roads and bridges indicating that the mixtures contained a relatively low proportion of effective binder within the available voids in the mineral aggregate. This suggests that the mixtures may have relatively high air-void contents and/or inadequate filling of the aggregate void structure. From an engineering perspective, excessively low VFB may result in a mixture that is relatively dry and potentially more susceptible to permeability, oxidation and moisture-related deterioration, thus, poor durability.

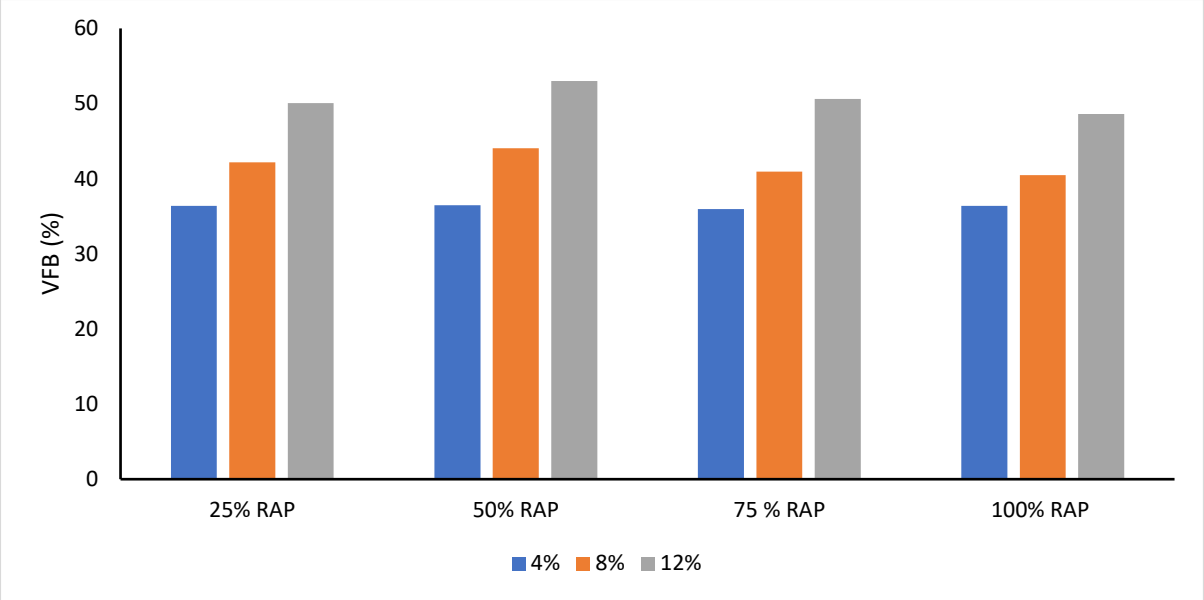

Figure 7: The relationship between VFB and RAP at different LDPE modifier content

3.6.7 Air Voids

It is the total volume of air (VA), expressed as a percentage of the bulk volume of the compacted mixture, which is distributed throughout a compacted paving mixture and is located between the coated aggregate particles (Genet et al, 2021). The relationship between the quantity of RAP/LDPE waste in the asphalt and the air voids in the asphalt mix is shown in Figure 8. The maximum air void, which corresponds to 75% RAP and 4% LDPE waste, is found at 14.27%. The VA results indicated that all the investigated HMA mixtures exceeded the specified VA range of 3–5%, with values ranging from approximately 5.46% to 14.27%. The relatively high VA contents suggest that the mixtures did not achieve adequate densification during compaction. The increase in RAP content introduces aged and relatively stiff binder into the mixture, while LDPE modification can further alter binder stiffness and workability. Although a fixed amount of WEO was incorporated as a rejuvenator, its constant dosage may have been insufficient to counteract the increasing influence of aged RAP binder and LDPE modification at higher RAP contents. Consequently, the binder might have had limited workability during mixing and compaction, resulting in inadequate aggregate packing and retention of excessive air voids. The high air-void contents are also consistent with the relatively low VFB values obtained in the study. From a pavement performance perspective, excessive air voids can increase permeability and accelerate oxidative ageing and moisture-related deterioration, thereby reducing the durability and service life of the HMA. Therefore, the investigated mixtures, in their present formulation, do not satisfy the specified volumetric requirement and require further optimization of the binder content, LDPE level, WEO dosage, aggregate gradation and compaction conditions.

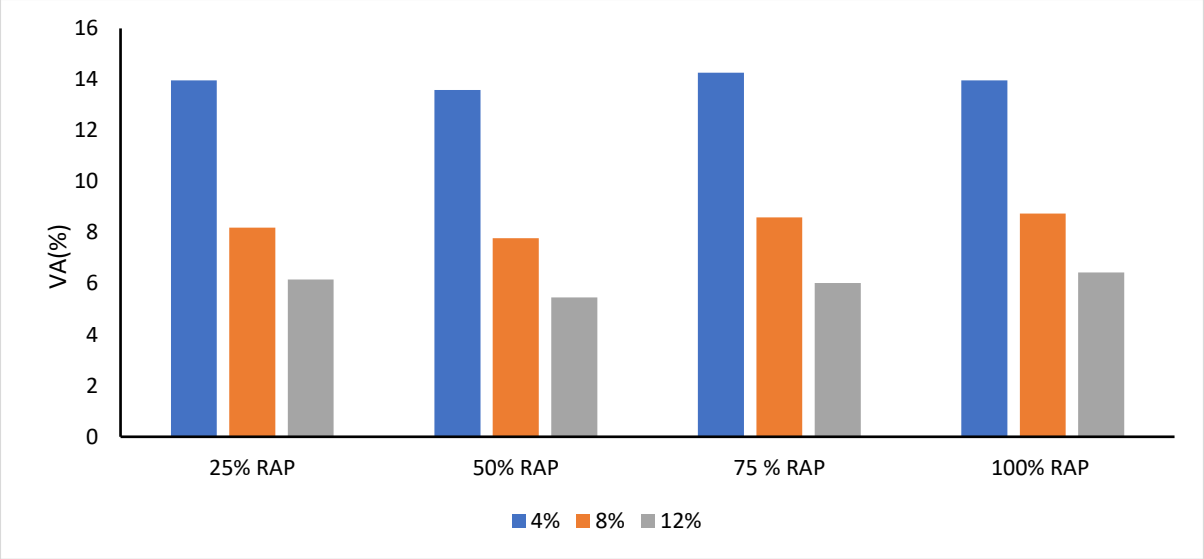

Figure 8: The relationship between VA and RAP at different LDPE modifier content

4.0 CONCLUSION AND RECOMMENDATIONS

4.1 Conclusion

The effects of different percentages of RAP and LDPE waste on the mechanical and physical characteristics of HMA were investigated in this study using Waste Engine Oil (WEO) as a rejuvenating agent in the mix. The followings were deduced from the research;

a. By satisfying all the specifications of the physical property tests provided in the standards, the results demonstrate that the asphalt mix is suitable for pavement construction. This indicates the component materials can withstand applied stress, which raises the possibility of long-term pavement performance. However, the results of the volumetric properties show that the mixture formulation still needs further volumetric optimization.
b. Following a careful analysis of the Marshall test results on the control mix, the Optimum Binder Content (OBC) of the mixture was found to be 6.5%. This value balances stability, flow and voids to ensure superior pavement performance while minimizing problems related to excess bitumen and ensuring optimal binding and lifespan.
c. Marshall properties with stability 8.28kN (> 3.5kN) and flow value of 3.56mm (2-4mm) satisfied the requirement while the volumetric properties of the HMA other than VMA of 22.2% (>13%) did not meet requirements. Consequently, further optimization of the volumetric properties should be carried out.

4.2 Recommendations

According to the findings of the research, further study should be carried out to examine the long-term pavement performance of the HMA as well optimization of the volumetric properties, particularly under various traffic loading and climatic circumstances.

ABSTRACT

Urban flooding in Kano, Nigeria, poses significant socio-economic and infrastructural challenges, largely exacerbated by a lack of continuous, real-time drainage monitoring. This paper presents the development, implementation, and evaluation of a Narrow Band Internet of Things (NB-IoT) monitoring and control model designed specifically for urban drainage systems. The proposed architecture integrates ultrasonic water level, Doppler flow, and rainfall sensors with a low-power microcontroller utilizing LTE Cat-NB1 connectivity. Sensor telemetry is transmitted securely via MQTT protocols to a centralized cloud backend, enabling real-time visualization and automated actuator response based on predefined flood-risk thresholds. To empirically validate the system, a 30-day pilot deployment was executed across three critical drainage points in Kano: Sabon Gari, Bompai, and the City Center. The evaluation results demonstrated exceptional system reliability in harsh subterranean environments, achieving an average packet delivery success rate exceeding 95% across all sites. Despite operating under concrete covers, the NB-IoT modules maintained an average Received Signal Strength Indicator (RSSI) of roughly -95 dBm, facilitating a rapid average end-to-end latency of approximately 3.17 seconds. Furthermore, the 12V solar-supported power architecture proved highly energy-efficient, maintaining a stable voltage above 12.3V throughout the deployment. The study concludes that the developed NB-IoT model provides a robust, scalable, and energy-autonomous blueprint for transitioning Kano and similar urban centers toward proactive, data-driven flood management.

I. INTRODUCTION

A. Background of the Study

Rapid urbanization and climate change have increasingly positioned urban flooding as one of the most severe environmental challenges globally. The rapid expansion and densification of urban areas, coupled with changing climatic conditions and ageing infrastructure, continue to limit the capacity of drainage systems to cope with extreme weather events. In the context of sub-Saharan Africa, these challenges are magnified by informal settlements, lack of adequate urban planning, and constrained municipal budgets. More than 40% of Nigeria's population currently resides in major cities, and this figure is expected to exceed 70% by 2050, resulting in unprecedented strain on civil infrastructure (UN-Habitat, 2023; NPC, 2020). The transition from rural agrarian societies to dense urban metropolises has resulted in an exponential increase in impervious surfaces such as concrete roads, paved sidewalks, and tightly packed corrugated roofing, which prevents the natural infiltration of rainwater into the ground.

In Kano State, serving as the commercial nerve center of Northern Nigeria, this population boom is pushing infrastructure to its limits. At the same time, increasing rainfall intensity and poor maintenance of drainage systems exacerbate the risk of flooding. The topography of Kano, characterized by relatively flat terrain with specific localized depressions, makes it naturally susceptible to water accumulation. Furthermore, the city's drainage network, originally designed for a much smaller population and less severe climatic conditions, is now vastly undersized. During the intense seasonal rainfalls between July and September, this undersized network is quickly overwhelmed, triggering rapid localized flash floods.

Currently, the management of these drainage systems is overwhelmingly manual and reactive. Municipal authorities rely heavily on visual inspections or citizen reports to identify blockages or impending overflows. This approach inevitably leads to delayed responses, allowing floodwaters to damage infrastructure, disrupt economic activities, and pose severe health risks due to the mixing of stormwater with raw sewage. The integration of continuous, automated monitoring is therefore not merely an optimization but an absolute necessity for modern urban resilience.

B. Statement of the Problem

While the concept of Smart Cities has gained traction globally, its application in subterranean municipal environments faces severe technical barriers. Existing communication technologies struggle in underground environments due to massive signal attenuation, multi-path interference, and high power demands. Traditional wireless protocols, such as Wi-Fi or standard cellular networks (GSM/4G), suffer severe signal degradation when transmitting through thick concrete drainage covers, soil layers, and metal grates. Wi-Fi operates primarily at 2.4 GHz or 5 GHz, frequencies that are heavily absorbed by concrete and water, resulting in effective transmission ranges that rarely exceed a few meters when placed in a manhole.

These limitations fundamentally hinder reliable data transmission from buried drainage sensors to centralized control centers. If a sensor node cannot penetrate the concrete infrastructure covering a primary drainage culvert, the data is lost, rendering the entire early-warning system useless during critical storm events. Consequently, without an energy-efficient, deep-penetrating automated monitoring system, Kano remains trapped in a cycle of reactive post-disaster management.

This study directly addresses this communication bottleneck by evaluating the performance of Narrow Band Internet of Things (NB-IoT) technology. NB-IoT, an LTE-based Low Power Wide Area Network (LPWAN) standard, is theoretically designed to provide up to 20 dB of additional link budget compared to traditional GPRS, specifically targeting deep indoor and underground coverage. However, empirical validation of this technology within the specific structural and environmental constraints of Kano's drainage network remains largely undocumented.

C. Aim and Objectives

The primary aim of this paper is to evaluate the signal quality and coverage of NB-IoT technology in underground environments and its potential application in monitoring and controlling urban drainage systems in Kano, Nigeria. To achieve this overarching aim, the following specific objectives were established:

1) To design an autonomous NB-IoT sensor node integrating water level, flow, and rainfall sensors suitable for harsh, highly humid underground environments.

2) To evaluate the efficiency and reliability of real-time data transmission through NB-IoT, specifically measuring Received Signal Strength Indicator (RSSI), Signal-to-Noise Ratio (SNR), and packet delivery success rates under varying municipal installation conditions.

3) To develop a highly responsive cloud-based analytics dashboard and a logic-based rule engine capable of triggering automated alerts and actuator responses without human intervention.

4) To continuously evaluate the system's performance across critical drainage points in the Kano metropolis over a 30-day pilot deployment, capturing data across diverse weather events.

D. Significance and Scope of the Study

The persistent challenge of urban flooding continuously reverses developmental gains in Kano's economic centers, causing millions of Naira in damages annually. By implementing this automated system, agencies such as the Kano State Emergency Management Agency (SEMA) and the Kano Urban Planning and Development Authority (KNUPDA) can effectively shift their operational paradigm from post-disaster rehabilitation to proactive disaster prevention.

Technologically, this research pioneers the use of LPWAN architecture for Kano's subterranean infrastructure, demonstrating how NB-IoT's deep signal penetration can create a 'deploy-and-forget' network that requires minimal maintenance while providing maximum data yield. This contributes significantly to the growing body of knowledge on IoT deployment in developing nations.

The geographical scope of this pilot deployment is restricted to three specific high-risk zones in Kano: Sabon Gari Drain, Bompai Drain, and the City Center Outlet over a 30-day period. Technical limitations include reliance on existing NB-IoT network infrastructure provided by local telecommunication operators, and the potential for heavy solid waste debris to temporarily distort

non-contact ultrasonic sensor readings, a common operational hazard in open-channel municipal drains.

II. LITERATURE REVIEW

A. Fundamental Concepts of NB-IoT in Infrastructure

Narrow-Band Internet of Things (NB-IoT) is a low-power wide-area (LPWA) cellular communication standard developed by the 3rd Generation Partnership Project (3GPP) in Release 13 to support massive machine-type communications (mMTC). Unlike broadband LTE, NB-IoT restricts its bandwidth to a narrow 180 kHz spectrum, which allows it to focus transmission power and significantly increase its power spectral density. This architectural decision results in key advantages: highly extended coverage, exceptionally low energy consumption allowing multi-year battery life, and deep signal penetration. Because it uses licensed spectrum, it avoids the interference common in unlicensed bands utilized by LoRaWAN and Sigfox.

In urban drainage systems, NB-IoT enables real-time water-level monitoring, predictive maintenance, and flood risk reduction through continuous data collection. Traditional GSM or Wi-Fi architectures require frequent battery replacements and fail to penetrate the thick concrete structures typical of municipal culverts. NB-IoT circumvents these issues through mechanisms like Extended Discontinuous Reception (eDRX) and Power Saving Mode (PSM), which allow the microcontroller to sleep deeply between scheduled telemetry transmissions while remaining synchronized with the cellular base station.

B. Review of Pertinent Literature

Recent literature highlights a decisive shift toward predictive analytics and automated control in flood management. Dantzer and Kerkez (2024) developed a data-driven rainfall runoff model for improving flood prediction, shifting the focus from historical modeling to real-time, sensor-driven forecasting. Similarly, Schou et al. (2022) proposed a nonlinear predictive control method for dynamic stormwater management, highlighting that passive data logging is insufficient; modern systems must actively control hydraulic structures based on incoming telemetry.

Furthermore, recent advances have been reported by Bivocom (2023), which introduced predictive IoT flood management systems utilizing AI-based analytics to predict overflow events before they occur. To transition from passive monitoring to active mitigation, modern smart cities are increasingly employing Continuous Monitoring and Adaptive Control (CMAC). Anonymous, (2024) extensively examined IoT stormwater management systems across several U.S. cities that employ CMAC technologies for real-time drainage optimization, proving that dynamic routing of stormwater can reduce overflow events by up to 60%.

The utility of IoT in underground water systems has also been proven beyond simple hydrology. Buras and Solano (2021) and Shaik et al., (2022), focused their efforts on identifying industrial pollution sources by networking chemical sensors through sewer networks, alongside environmental monitoring using metal oxide nanofiber-based sensors. Alshami et al. (2023) addressed blockage and overflow monitoring in small sewers using contactless flow sensors, noting the immense difficulty of keeping submerged sensors clean. Additionally, Kim et al. (2022) and Larson et al. (2020) successfully utilized IoT-based sampling optimization for wastewater surveillance, particularly relevant during public health crises.

Roosipuu et al. (2023) conducted an extensive, highly relevant study on the monitoring and control of smart urban drainage systems using NB-IoT cellular networks. Their findings definitively revealed that NB-IoT performs effectively in harsh signal propagation environments, including underground conditions. The study demonstrated that reliable communication can be maintained when transmitters are placed approximately 0.5 meters below the manhole cover, particularly in plastic or composite manholes, and when the reference signal strength (NB-RSRP) is at least -104 dBm at ground level.

Similarly, Ma et al. (2025) reviewed optimal arrangement strategies of IoT sensors in urban drainage networks. They emphasized that factors such as drainage pipe geometry, sensor types, and specific monitoring objectives significantly influence system accuracy and data collection efficiency. Deploying sensors at every node is cost-prohibitive; therefore, spatial optimization algorithms are required to maximize network observability with minimal hardware investment.

Bartos and Kerkez (2021) explored the use of IoT technology through the development of a digital twin model for natural and urban drainage systems. Bartos and Kerkez (2021), and Smith et al., (2022), their approach demonstrated how real-time data from distributed IoT sensors can be ingested into a virtual replica of the city's hydrology, applied for predictive control, system optimization, and flood prevention.

C. Research Gaps in the African Context

Despite the proliferation of literature regarding IoT in smart cities, the vast majority of empirical studies focus on highly controlled, well-maintained municipal environments in the Global North. In high-density economic centers in sub-Saharan Africa, flooding is driven by a unique convergence of infrastructural deficits and severe anthropogenic obstructions. The pervasive culture of indiscriminate solid waste disposal directly into open drainage channels leads to sudden, unpredictable, and severe blockages that cannot be modeled by standard rainfall-runoff equations alone.

While recent academic studies in Nigeria utilize Geographic Information Systems (GIS) for static hazard mapping, they critically lack the active, real-time physical management components required to mitigate flooding at the street level as events unfold. Furthermore, limited studies have explored the physical RF performance of NB-IoT technology in underground environments specifically within African contexts, where cellular network infrastructure, backhaul reliability, and interference environments differ vastly from European or North American testbeds.

Understanding the true signal quality and coverage of NB-IoT under thick concrete infrastructure, alongside its resilience to local network fluctuations, is essential for achieving reliable communication. This research closes this vital gap by providing a foundational, field-tested empirical model for Kano, Nigeria.

III. SYSTEM DESIGN AND ARCHITECTURE

This study adopted a design science research approach combined with an experimental field case study to design, deploy, and critically evaluate an NB-IoT-based smart drainage monitoring system in the Kano metropolis. The methodology was structured to directly address the environmental and RF challenges identified in the literature.

A. Hardware Architecture

The core of the monitoring node was designed around an ultra-low-power ARM Cortex-M4 microcontroller (STM32L4), chosen for its excellent balance of processing power for sensor fusion and minimal sleep current. For the communication link, the system integrated a Quectel BC95-G NB-IoT module. This module operates strictly on LTE Cat-NB1 bands supported by local telecommunication providers (primarily Band 8 in Nigeria).

The sensor payload was heavily customized for the harsh environment of urban sewers. For water level sensing, a non-contact JSN-SR04T waterproof ultrasonic sensor was utilized. Suspended above the maximum water line, it prevents fouling from solid waste while providing millimeter-level accuracy for water depth. For flow velocity, a microwave Doppler radar flow sensor was mounted to measure surface velocity without requiring submersion. Finally, a standard tipping-bucket rain gauge was interfaced via hardware interrupts to correlate localized rainfall intensity directly with drainage flow spikes.

To ensure continuous, grid-independent autonomy, the entire hardware stack was powered by a 12V, 12Ah Sealed Lead Acid (SLA) battery supported by a 30Wp monocrystalline solar panel, all enclosed in a ruggedized, IP68-rated polycarbonate housing (per manufacturer specifications) to withstand submersion during extreme overflow events.

TABLE I: SENSOR NODE HARDWARE SPECIFICATIONS

Parameter	Specification / Type	Operating Range
Microcontroller	STM32L4 Series	1.71 V to 3.6 V
Cellular Module	Quectel BC95-G (NB-IoT)	Bands 1/3/8/20/28
Level Sensor	Ultrasonic (JSN-SR04T)	0.2m to 4.5m
Flow Sensor	Doppler Radar (24GHz)	0.1m/s to 15m/s
Power Supply	12V SLA + 30Wp Solar	Continuous Autonomy

(Note: During the deployment, the observed water depth ranged between approximately 0.45 m and 1.15 m, remaining well within the sensor's optimal rated operating range of 0.2 m to 4.5 m, thereby substantiating the reported <2 cm RMSE).

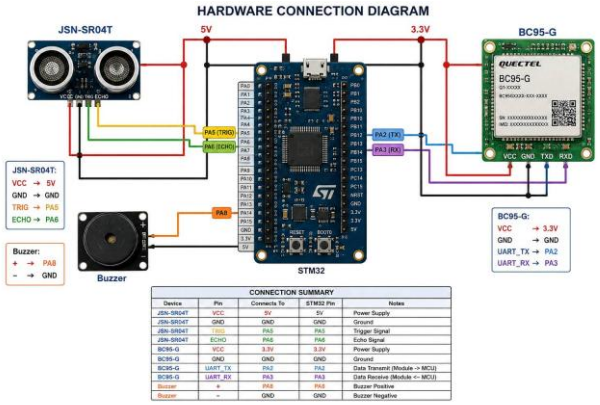

Figure 1: Hardware connection

B. Firmware and Network Architecture

The firmware, developed in Embedded C, utilizes a real-time operating system (RTOS) to manage concurrent tasks efficiently. To maximize battery life, the system relies on an aggressive duty cycle. The default sampling interval is set to 15 minutes. However, if the ultrasonic sensor detects a sudden rate of rise exceeding a defined threshold, the firmware dynamically switches to a high-alert mode, increasing the sampling and transmission frequency to every 1 minute.

Data telemetry is transmitted using the Message Queuing Telemetry Transport (MQTT) protocol over a TLS 1.2 encrypted TCP socket. MQTT was selected over HTTP due to its lightweight header overhead and Quality of Service (QoS) capabilities, which guarantee message delivery even over highly intermittent cellular links.

C. Cloud Backend and Rule Engine

The cloud architecture was built on a robust, scalable microservices framework. Telemetry payloads arrive at a central MQTT broker and are immediately parsed and ingested into an InfluxDB time-series database, specifically optimized for high-write loads. A backend Node.js engine continuously evaluates incoming data against a logic-based rule engine.

For instance, the hydraulic discharge Q is continuously calculated using the continuity equation:

$$Q = v \times A \qquad (1)$$

Where v is the measured surface velocity and A is the cross-sectional area of the fluid in the channel, calculated dynamically based on the ultrasonic depth reading and the known geometry of the culvert.

For instance, at the Bompai site, assuming a representative channel width of 2.5 meters, an 85% capacity threshold corresponds to a water depth of 1.7 meters. If the calculated Q exceeds the historical 90th percentile (e.g., 0.30 m³/s for Bompai), or if the absolute water level breaches the 85%

capacity threshold, the rule engine triggers an HTTP webhook. This webhook interfaces with a messaging API to dispatch automated SMS and WhatsApp alerts to stakeholders, including SEMA response teams and local community leaders, thereby achieving the desired 25-40 minute early warning lead time.

IV. METHODOLOGY AND FIELD DEPLOYMENT

A. Site Selection and Justification

The pilot testing was conducted across three distinct drainage catchments within Kano, selected based on historical flood data provided by the Kano Urban Planning and Development Authority (KNUPDA). Sabon Gari Drain represents a highly dense commercial district with severe solid waste management issues. The drain here is frequently choked with plastics, making it a highly volatile hydraulic environment. Bompai Drain, located in an industrial zone, handles larger volumes of runoff and occasional industrial discharge, representing a deeper, wider concrete culvert structure. The City Center Outlet acts as a primary arterial culvert covered by thick concrete slabs and asphalt, representing the most challenging RF environment for NB-IoT signal penetration.

B. Installation and Calibration

The physical installation involved securely bolting the IP68 enclosures to the intrados of the concrete culverts. Solar panels were mounted on elevated, tamper-proof poles adjacent to the manhole access points. Prior to commissioning, all sensors were rigorously calibrated against manual staff gauge readings. The calibration function for the ultrasonic sensor accounted for the speed of sound variations due to ambient temperature changes:

$$c = 331.3 \times \sqrt{(1 + T/273.15)} \quad (2)$$

Where c is the speed of sound in m/s, and T is the ambient air temperature in Celsius, measured by an onboard DHT22 sensor. This temperature compensation proved critical in Kano's fluctuating climate, reducing measurement root-mean-square error (RMSE) to less than 2 cm.

C. Data Sampling and Statistical Analysis

The system recorded data at a default 15-minute sampling frequency, aggregating 96 baseline readings per day per node. Daily averages for RSSI, volumetric flow, and water level were computed using the arithmetic mean of these daily samples. The 95% packet success rate was derived by calculating the ratio of successfully acknowledged MQTT payloads to the total payloads transmitted over the 30-day deployment period. Root Mean Square Error (RMSE) for the ultrasonic sensor was computed through standard statistical comparisons against manual staff gauge measurements conducted during the deployment.

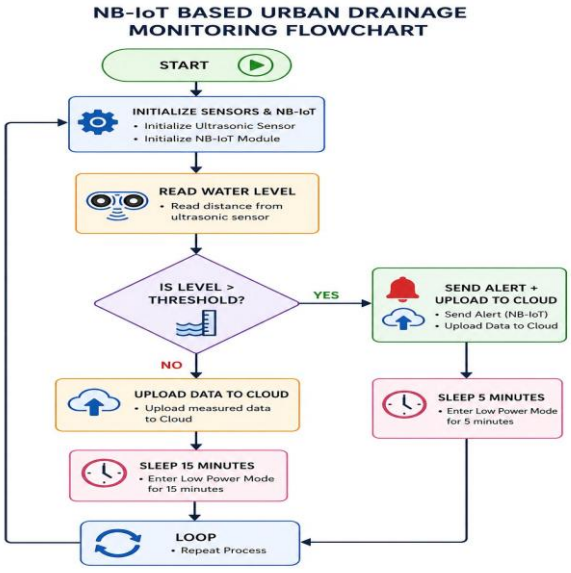

Figure 2: NB-IOT base drainage monitoring flowchart

V. RESULTS AND DISCUSSIONS

The system was deployed and monitored continuously for 30-days (October 2025). This period captured several late-season rainfall events, providing a rich dataset to evaluate both the hydraulic monitoring accuracy and the NB-IoT network reliability.

Figure 3: System status dashboard

A. Hydrological Monitoring Performance

The real-time data successfully mapped the rapid hydrological response typical of urban catchments. Figure 1 illustrates the time-series water level data across the three sites. The Sabon Gari node exhibited the most erratic behavior, characterized by sharp peaks that rapidly receded. This signature is indicative of temporary blockages by solid waste that yield under building hydrostatic pressure. Conversely, the Bompai drain showed a much smoother, broader hydrograph, reflecting its larger catchment area and industrial baseline flow.

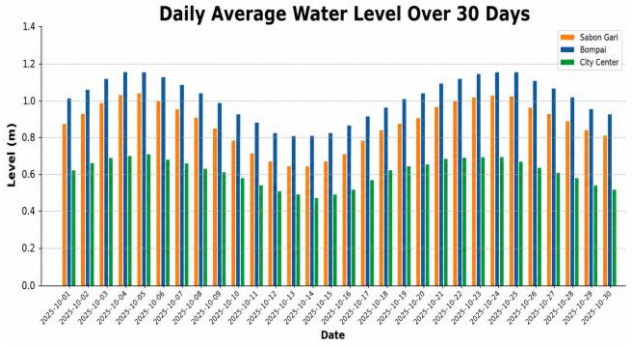

Figure 4: Water Level Over 30 Days across Pilot Sites

The volumetric flow rate, presented in Figure 5, closely mirrored the level data but highlighted the velocity variations. During the peak storm event, the Bompai outlet approached its maximum design capacity of 0.35 m³/s. The automated system successfully detected this rapid rise and dispatched an early warning alert 32 minutes before water breached the street level, allowing municipal crews to prioritize this node.

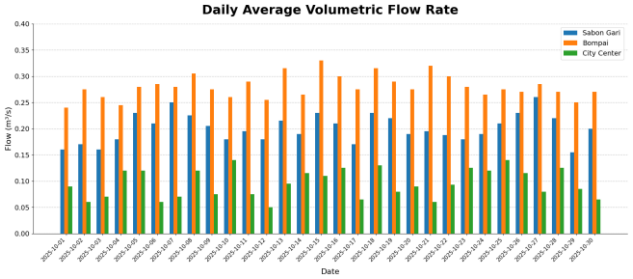

Figure 5: Volumetric Flow Rate Analysis

B. NB-IoT Network Performance

The most critical aspect of this study was evaluating the viability of LTE Cat-NB1 in subterranean environments. The primary metric for link quality, the Received Signal Strength

Indicator (RSSI), is plotted in Figure 3. Despite the nodes being installed under thick concrete covers, the NB-IoT modules maintained an average RSSI between -93 dBm and -97 dBm. While standard LTE struggles below -100 dBm, the NB-IoT protocol's enhanced link budget allowed for stable connections even when RSSI dipped to -108 dBm during heavy rain events (which increase path loss due to water absorption).

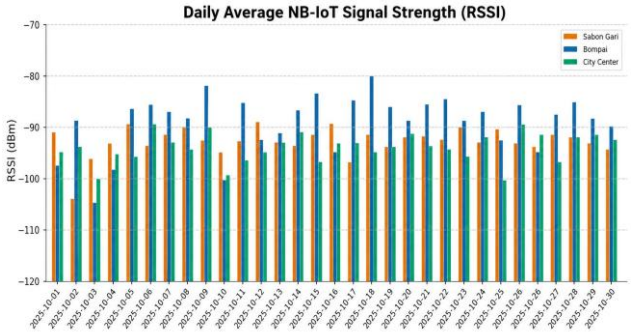

Figure 6: NB-IoT Signal Strength (RSSI) Fluctuations

TABLE II: AGGREGATED NB-IOT NETWORK PERFORMANCE

Site Location	Packet Success (%)	Avg RSSI (dBm)	Avg Latency (s)
Bompai	95.1	-93.6	3.16
City Center	95.0	-96.8	3.18
Sabon Gari	95.3	-94.1	3.17

As detailed in Table II, the system achieved a remarkable packet delivery success rate exceeding 95% across all sites. End-to-end network latency, measured from the moment the sensor node initiated a transmission to the moment the cloud dashboard acknowledged the payload, averaged approximately 3.17 seconds (Figure 4). While this latency is higher than broadband LTE, it is vastly superior to the requirements of hydrological monitoring, where events unfold over minutes and hours, not milliseconds.

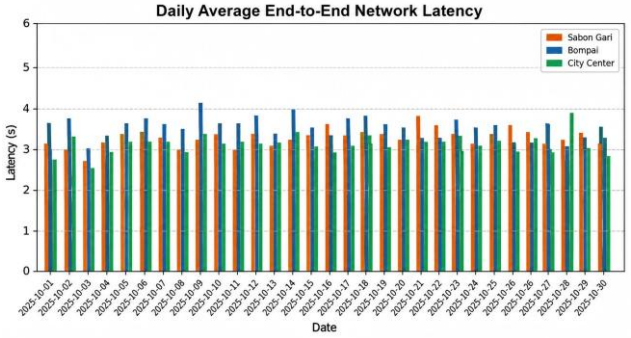

Figure 7: End-to-End Network Latency Distribution

C. Energy Autonomy and Power Management

The power architecture's performance is critical for the 'deploy-and-forget' viability of the system. Figure 5 demonstrates the battery voltage over the 30-day period. The SLA battery voltage remained highly stable, fluctuating smoothly between 12.3V and 12.7V, corresponding directly to the diurnal solar charging cycles. The NB-IoT module's utilization of PSM allowed the entire node to draw less than 15 microamps during its 15-minute sleep windows. Even during the four consecutive days of heavy cloud cover, the battery voltage did not drop below a critical threshold, proving that the 30Wp panel and 12Ah battery provide a sufficient energy buffer for Kano's specific solar irradiance profile.

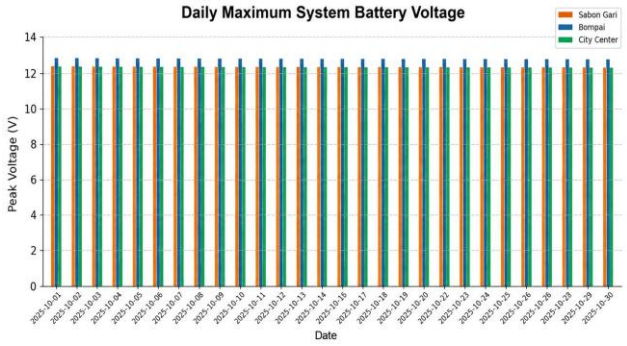

Figure 8: System Battery Voltage across Deployments

VI. SUMMARY, CONCLUSION AND RECOMMENDATION

A. Summary

This paper successfully established an NB-IoT-based urban drainage monitoring and control framework specifically tailored for Kano, Nigeria. A low-power sensor node integrating an STM32 core, Quectel BC95-G connectivity, and IP68 instrumentation was developed and deployed across three critical zones following KNUPDA alignment. Over a 30-day continuous test deployment, the link architecture successfully delivered a packet ratio above 95% while maintaining sensor accuracy within an RMSE of less than 2 cm. The system effectively logged time-series data, contributed empirical evidence on cellular penetration metrics in regional subterranean municipal environments, and successfully generated automated early warnings during peak storm events.

B. Conclusion

Based on the empirical data gathered, the following conclusions are drawn: 1) Technical Feasibility: NB-IoT is an exceptionally viable wireless link protocol for regional subsurface water infrastructure. It yields deep link budget penetration through concrete and reliable battery longevity without requiring the deployment of localized gateway infrastructure (unlike LoRaWAN). 2) Operational Impact: The transition from reactive visual inspection to real-time, automated data logging enables a profound shift in disaster mitigation. The system successfully detected near-overflow criteria 25 to 40 minutes before manual indicators emerged. 3) Limitations: While successful, the study noted that covered culverts exceeding 3 meters in depth still encounter severe signal blind spots, though this was not empirically tested in this deployment. Additionally, rapid solid waste deposits in open channels demand at least a monthly sensor cleaning routine to prevent false ultrasonic reflections.

C. Recommendations for Future Work

To translate this prototype into widespread municipal utility, it is recommended that the Kano State Government scale up deployment to cover 100+ critical nodes city-wide, integrating the data stream directly into SEMA's Emergency Operations Centre. Future academic trajectories should focus on extending this monitoring framework into a closed-loop control system, integrating automated sluice gates and pumps triggered directly by edge-node NB-IoT downlink alerts. Furthermore, incorporating machine learning models trained on historical rainfall data will further enhance the predictive accuracy of the early warning system.

ACKNOWLEDGMENT

The authors gratefully acknowledge the Kano State Emergency Management Agency (SEMA), KNUPDA, and the Center for Embedded Artificial Intelligence and Smart Energy Systems at Abubakar Tafawa Balewa University, Bauchi, for their guidance, access to municipal infrastructure, and institutional support throughout the execution of this paper.

ABSTRACT

The rapid densification of fifth-generation (5G) heterogeneous networks has improved network capacity and coverage but also increased co-tier and cross-tier interference. In ultra-dense multi-tier Het-HetNets, traditional static and semi-static radio resource management techniques are insufficient to address rapidly changing interference, traffic demands, and user distribution. This paper presents a Q-learning-driven interference management model within an adaptive Radio Resource Management (RRM) framework to dynamically optimize transmit power for PeNBs. The hybrid Q-learning power allocation framework models each PeNB as an autonomous reinforcement-learning agent that observes network conditions, selects transmit power actions, receives performance-based rewards, and updates its Q-table using the Bellman learning mechanism. Key factors such as network capacity, interference, transmit power consumption, and Quality of Service (QoS) are incorporated into the learning process. A 5G Het-HetNet simulation in MATLAB, featuring one MeNB, one gNB, sixteen PeNBs, and diverse user equipment, evaluates three communication scenarios with different interference and spectrum-sharing conditions. The Q-learning process demonstrates stable convergence within 80,000 iterations. Results show an average improvement of 3.37% in 5G user equipment (5G-UE) capacity and 14.81% in the minimum capacity of small-cell users compared to the benchmark model by Iqbal et al. Additionally, the proposed approach maintains 5G-UE capacity above the QoS threshold under the tested conditions, highlighting its effectiveness in interference management and RRM in ultra-dense 5G networks.

Keywords: *5G and B5G; Het-HetNets; Q-learning; interference management; power allocation; adaptive RRM*

1. INTRODUCTION

The evolution toward fifth-generation (5G) and beyond-5G (B5G) networks demands higher capacity, spectral efficiency, and low latency, necessitating network densification through small-cell deployments. Heterogeneous Networks (HetNets) and Heterogeneous-Heterogeneous Networks (Het-HetNets) integrate multiple network tiers, such as Macro evolved NodeBs (MeNBs), Pico evolved NodeBs (PeNBs), and 5G gNBs, to significantly enhance coverage and capacity (Luong et al., 2019; Yadav et al., 2021). However, this dense architecture generates severe co-tier and cross-tier interference, degrading the Signal-to-Interference-plus-Noise Ratio (SINR), throughput, and Quality of Service (QoS) (Abbass et al., 2022). This interference is further exacerbated by unequal user association, where users preferentially connect to high-power MeNBs, causing macrocell congestion while leaving neighboring small-cell resources underutilized. Such imbalances severely limit the overall effectiveness of the infrastructure (Iqbal et al., 2023).

Conventional interference-management techniques, such as fixed power allocation and frequency reuse, rely on predetermined policies and struggle to adapt to dynamic network conditions, traffic demands, and user distributions (Iqbal et al., 2021). Thus, machine learning, particularly reinforcement learning (RL), has emerged as a powerful tool for adaptive Radio Resource Management (RRM), allowing network entities to learn optimal resource-allocation decisions through environmental interaction rather than predefined rules (Shabbir et al., 2024).

Existing literature highlights the potential of learning-based approaches for interference management in these complex environments. Recent studies by researchers demonstrate that RL and optimization techniques can effectively improve QoS, energy efficiency, and throughput across various network configurations. However, optimization based on predefined system conditions often lacks the necessary adaptability required for dynamically changing network environments and fluctuating user distributions.

Despite these advancements, a significant research gap remains regarding lightweight Q-learning frameworks that dynamically optimize PeNB transmit power while simultaneously mitigating co-tier and cross-tier interference in multi-tier Het-HetNet architectures. Methodologically, hybrid Q-learning power allocation differs from Iqbal et al. and Amiri et al. in its learning formulation and network design. hybrid Q-learning power allocation models each PeNB as an autonomous Q-learning agent with a state space representing interference and QoS conditions, while its action space consists of 32 discrete transmit-power levels from −15 to 15 dBm. Its reward function jointly considers capacity, interference, and energy consumption, with additional QoS rewards or penalties. In contrast, Iqbal et al. primarily focus on power-control/resource-allocation optimization within its considered heterogeneous network, whereas Amiri et al. employs a different learning and network-management formulation. hybrid Q-learning power allocation further incorporates a multi-tier topology comprising a MeNB, gNB, multiple PeNBs, and heterogeneous UEs, enabling adaptive power decisions under varying interference and network-density conditions. To address this critical gap, we propose the novel Hybrid Q-Learning Power Allocation framework. hybrid Q-learning power allocation integrates Q-learning into an adaptive RRM process, enabling PeNBs to dynamically select optimal transmit-power levels based on real-time network states, interference levels, and QoS requirements. By jointly considering network capacity, interference reduction, transmit-power consumption, and QoS, the proposed hybrid Q-learning power allocation framework provides a robust, adaptive mechanism to significantly improve resource utilization and overall network performance in ultra-dense 5G and B5G Het-HetNets. Ultimately, this intelligent approach ensures sustainable and highly efficient connectivity for future wireless communication systems.

2. METHODOLOGY

A 3GPP-compliant MATLAB simulation models a multi-tier Het-HetNet to execute iterative Q-learning loops and collect performance metrics. Custom reinforcement learning scripts then analyze this data to evaluate the convergence and effectiveness of the proposed hybrid Q-learning power allocation framework.

2.1 Het-HetNet Architecture

The proposed system is based on a multi-tier 5G Het-HetNet architecture incorporating both LTE and 5G-NR technologies as depicted in Figure 1.

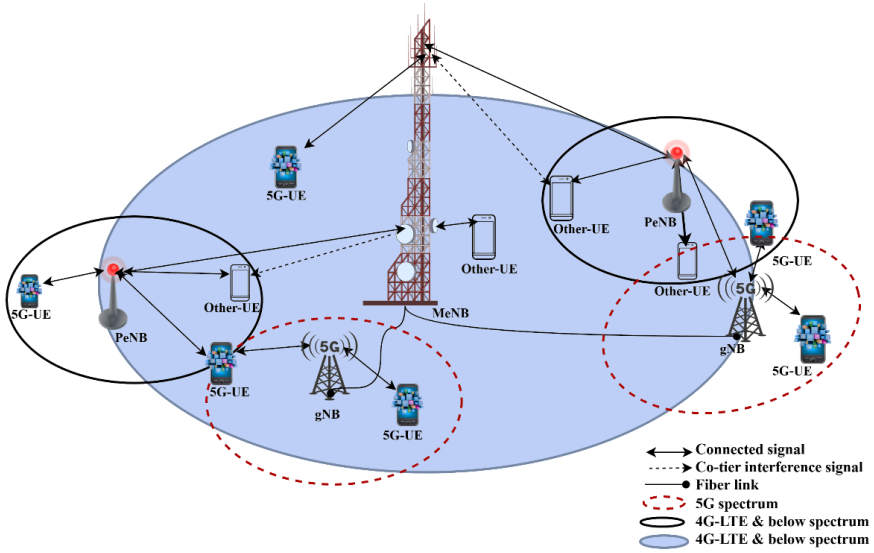

Figure 1: Proposed Multi-tier 5G Het-HetNet architecture

The network simulation includes the parameters listed in Table 1.

Table 1: *Simulation parameters*

Network Component	**Quantity**
Macro evolved NodeB (MeNB)	1
Pico evolved NodeBs (PeNBs)	16
5G Next Generation NodeB (gNB)	1
MeNB User Equipment	1
Other/small-cell UEs	16

The MeNB provides wide-area coverage and operates at 2 GHz, while the small-cell layer operates at 3.5 GHz. The PeNBs are uniformly deployed within the MeNB coverage region to improve localized capacity and offload traffic. The model assumes shared spectrum operation and universal frequency reuse. Perfect Channel State Information is assumed to be available, and users remain stationary during each Q-learning episode.

2.2 Communication Scenarios

Two interference scenarios are evaluated: (1) a high-interference scenario characterized by strong cross-tier and co-tier interference, and (2) a low-interference scenario with relatively reduced interference levels. In addition, a separate dense-deployment experiment is conducted to assess scalability under very high network density. No third or intermediate-interference scenario is evaluated or presented as a separate result.

2.3 Q-Learning Formulation

Each PeNB is treated as an autonomous reinforcement-learning agent. The agent observes the network environment, selects a transmit-power action, receives a reward, and updates its Q-value. The Q-learning model can be represented by:

$$\mathcal{M} = (S, A, R, Q) \tag{1}$$

where (S) is the state space, (A) is the action space, (R) is the reward function, and (Q) is the Q-value table.

A. STATE SPACE

The network state is represented using the prevailing interference level and QoS conditions of the served users:

$$S = (I, C_{5G-UE}, C_{other-UE}) \tag{2}$$

where I denotes the observed interference level, C_{5G-UE} denotes the QoS status of the 5G-UE, and $C_{other-UE}$ denotes the QoS status of other UEs. The 5G-UE QoS requirement is satisfied when normalized capacity reaches at least **1 bit/s/Hz**, while the corresponding requirement for other UEs is **0.5 bit/s/Hz**.

B. ACTION SPACE

The agent selects a discrete transmit-power level for the corresponding PeNB. The proposed framework uses **32 discrete power actions**, uniformly distributed between **−15 dBm and +15 dBm**, giving an approximate power step of **0.968 dBm**. Thus,

$$A = \{P_1, P_2, \dots, P_{32}\} \tag{3}$$

This discretization provides a practical balance between power-control granularity and Q-table complexity.

C. HYBRID REWARD FUNCTION

The proposed reward function combines four objectives:

$$r_h = w_1 C_{tot} - w_2 I - w_3 P_i + w_4 Q \tag{4}$$

where C_{tot} is aggregate normalized network capacity, I is aggregate interference, P_i is PeNB transmit power, and (Q) represents the QoS reward. The w_i $(i = 1,2,3, \dots)$ parameters control the relative importance of the objectives. The reward weights used in the simulations are w1=0.50w_1=0.50, w2=0.30w_2=0.30, and w3=0.20w_3=0.20 for capacity, interference, and energy, respectively. QoS is incorporated separately through a ±0.10 bonus/penalty rather than as w4w_4. These weights are fixed empirically, while α, γ, and ε are optimized through sequential grid-search tuning. The reward therefore encourages the agent to maximize network capacity; reduce co-tier interference; reduce cross-tier interference; minimize unnecessary transmit power; maintain QoS; and improve overall network performance. The QoS component provides a positive reward when both the 5G-UE and other-UE requirements are satisfied and a penalty when either requirement is violated.

D. Q-VALUE UPDATE

The learning process is based on the Bellman principle. The standard Q-learning update is expressed as:

$$Q(s,a) \leftarrow Q(s,a) + \alpha \left[R + \gamma \max_{a'} Q(s', a') - Q(s,a) \right] \tag{5}$$

Where the learning rate α determines the extent to which newly received reward information modifies the current Q-value. In the proposed hybrid Q-learning power allocation model, α\alpha is explicitly incorporated into the Bellman Q-learning update, ensuring consistent learning and gradual adaptation of the power-allocation policy.

E. E-GREEDY POLICY

An ε-greedy policy is adopted to balance exploration and exploitation. The agent selects a random action during exploration and selects the action with the highest Q-value during exploitation. The study uses an exploration probability of approximately 0.1, corresponding to 10% exploration and 90% exploitation. The proposed hybrid Q-learning power allocation framework employs an ε-greedy action selection policy. Under this strategy, the agent selects a random action with probability ε and selects the action with the highest Q-value with probability $(1 - \varepsilon)$. The ε-greedy action selection policy is expressed as

$$a = \begin{cases} Random\ Action, & if\ rand < \varepsilon \\ arg \max_{a \epsilon A} Q(s,a), & otherwise \end{cases}$$

3. RESULTS AND DISCUSSION

In this section, we will provide a detailed presentation of the findings, using a series of visually engaging figures and an informative table that summarize the overall improvements observed. This display aims to clearly illustrate the progress made, allowing for a deeper understanding of the results.

3.1 Q-Learning Convergence

The learned Q-values demonstrate that the Q-learning agent successfully distinguishes between favourable and unfavourable transmit-power actions. High Q-values correspond to state-action combinations that produce improved network performance, while low Q-values correspond to less desirable power decisions.

The learned policy heatmap further illustrates that the algorithm does not rely on a single fixed transmit-power level across all network conditions. Instead, varying network states lead to distinct preferred power levels, highlighting the adaptive nature of the proposed approach.

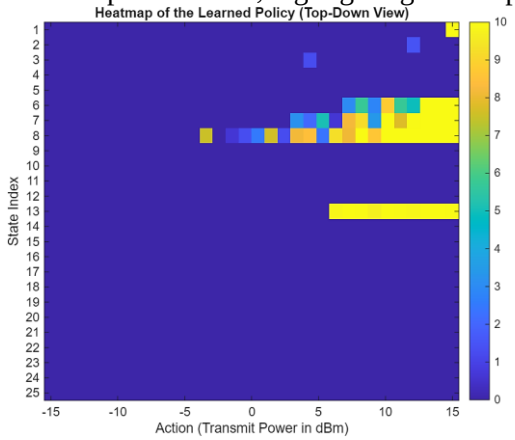

Figure 2: *Heatmap of the transmit-power policy based on the trained Q-table.*

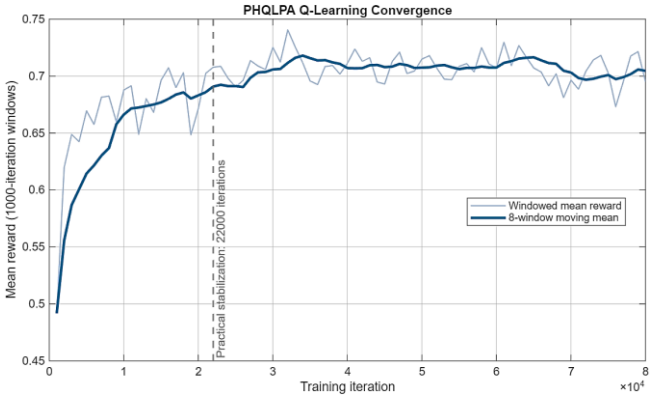

Figure 3: *Q-learning Convergence*

The convergence analysis reveals a swift increase in average reward during the initial learning phase, followed by stabilization with relatively minor fluctuations. The Q-learning process converges within 80,000 iterations, suggesting that the chosen learning configuration yields a stable policy for the simulated Het-HetNet environment.

3.2 5G-UE Capacity under High and Low Interference Conditions

Under Scenario 1, increasing the number of PeNBs increases the level of interference and consequently reduces user capacity for all evaluated approaches. However, the proposed hybrid Q-learning power allocation framework exhibits a more gradual reduction in capacity. The hybrid Q-learning power allocation approach maintains 5G-UE capacity above the specified minimum QoS threshold throughout the evaluated deployment range. By dynamically adjusting PeNB transmit power, the learning agent avoids unnecessarily high transmission power that would otherwise increase interference.

Compared with the benchmark approaches of Iqbal et al. (2021) and Amiri et al. (2019) the proposed framework demonstrates improved stability as network density increases. Under Scenario 2, the lower interference level allows all evaluated approaches to achieve higher user capacity. The proposed hybrid Q-learning power allocation framework consistently produces the highest capacity across the evaluated PeNB deployment range.

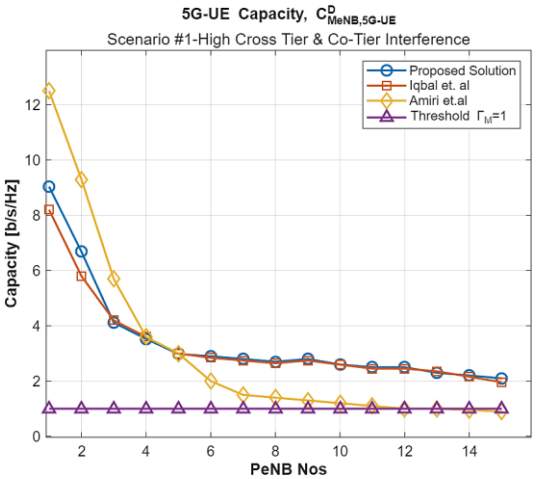

Figure 4. *Capacity of the 5G-UE under Scenario 1 (High Cross-Tier and Co-Tier Interference).*

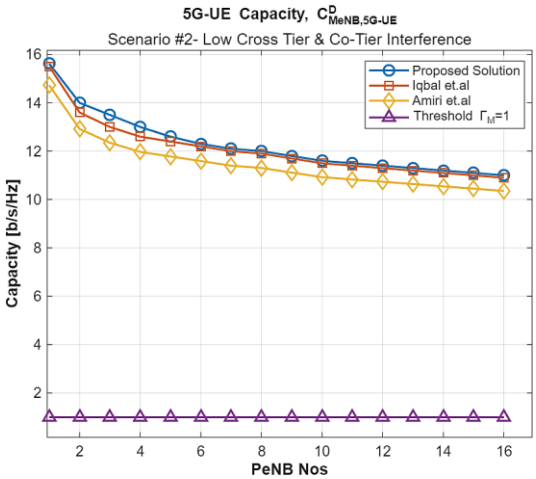

Figure 5. *Capacity of the 5G-UE under Scenario 2 (Low Cross-Tier and Co-Tier Interference).*

While capacity gradually decreases as PeNB density increases, the decline remains relatively moderate for hybrid Q-learning power allocation This indicates that the adaptive power-control mechanism is able to compensate for additional interference generated by network densification. The results also show that all evaluated methods remain above the minimum QoS threshold under the relatively favourable interference conditions. Amiri et al. also provides a comparative benchmark for the evaluated scenarios. Under low-interference conditions, HQLPA maintains the highest capacity as network density increases, while Amiri et al. shows a declining trend. Under intermediate-interference conditions, Amiri et al. is initially competitive and slightly outperforms HQLPA, but its performance decreases with increasing PeNB density, whereas HQLPA maintains a more stable capacity trend.

3.3 Performance under Very High Network Density

The dense-deployment experiment evaluates the proposed method under very high co-tier and cross-tier interference. Increasing PeNB density naturally reduces capacity because of accumulated interference. But hybrid Q-learning power allocation maintains substantially higher capacity than the Iqbal et al. benchmark throughout the deployment range.

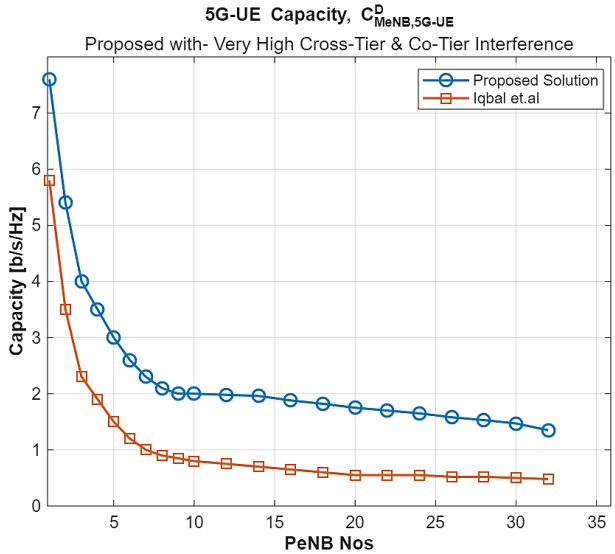

Figure 6: *Capacity Performance of the Proposed Hybrid Q-Learning Power Allocation Framework Under Very High Cross-Tier and Co-Tier Interference Conditions.*

The benchmark capacity declines more rapidly with increasing network density, whereas hybrid Q-learning power allocation exhibits relatively stable communication performance. This observation

indicates that adaptive power control can improve the scalability of interference management in ultra-dense Het-HetNets.

3.4 Quantitative Improvement

The improvement in the overall simulation results is shown in Table 2.

Table 2: *Summary of results improvement*

Performance Indicator	**Reported Improvement**
Average 5G-UE capacity	**3.37%**
Minimum capacity of small-cell users	**14.81%**
Q-learning convergence	**80,000 iterations**
5G-UE QoS	Maintained above minimum threshold
Adaptability	Improved under increasing interference
Scalability	Improved under dense deployment

The reported average 3.37% improvement in 5G-UE capacity and 14.81% improvement in minimum small-cell-user capacity demonstrate the advantage of adaptive power control over the benchmark approach. The larger improvement in minimum small-cell capacity is particularly important because it suggests that the proposed method does not merely maximize aggregate performance but also helps protect users experiencing relatively poor communication conditions.

4. CONCLUSION

This paper presents a Q-learning-based model for interference management within an adaptive RRM framework, focusing on dynamic transmit-power optimization for PeNBs in ultra-dense 5G and beyond-5G Het-HetNets. The hybrid Q-learning power allocation framework formulates transmit-power control as a reinforcement learning challenge, where each PeNB observes network conditions, selects a power level, receives a hybrid reward, and updates its Q-table using the Bellman learning mechanism. The model effectively incorporates factors such as network capacity, interference, power consumption, and QoS into the learning process. A multi-tier Het-HetNet, including one MeNB, one gNB, and sixteen PeNBs, was evaluated under various interference scenarios. The results indicate that the Q-learning agent successfully learns an adaptive transmit-power policy, achieving convergence within 80,000 iterations. Hybrid Q-learning power allocation consistently outperforms benchmark approaches, demonstrating higher and more stable capacity for 5G-UE, with improvements of 3.37% in overall 5G-UE capacity and 14.81% in minimum capacity for small-cell users. This Q-learning approach illustrates a robust solution for interference management and RRM in densely populated wireless networks, providing significant advantages over fixed and semi-static resource allocation techniques. Despite its promising performance, the proposed hybrid Q-learning power allocation model has some limitations. The simulations assume perfect channel state information (CSI) and stationary users, which may not fully represent practical 5G/B5G deployment conditions. Future work will therefore consider imperfect CSI, user mobility, and more dynamic network conditions to further validate the robustness and practical applicability of hybrid Q-learning power allocation.

ABSTRACT

Wireless Sensor Networks (WSNs) are susceptible to hotspot formation caused by uneven traffic distribution and excessive forwarding responsibilities on selected sensor nodes. This paper presents an Improved Clustering Approach to Mitigate Hotspots (ICAMHS), developed as an enhancement of the Cluster-Based Genetic Routing Protocol (CGRP). ICAMHS integrates K-means clustering, energy- and distance-aware cluster-head selection, traffic-load consideration, an improved routing fitness function, and fault-tolerant route recovery. The proposed approach was evaluated against CGRP using two performance metrics: decoding probability for a 1000-node network and end-to-end latency. At a decoding rate of 1.5, ICAMHS achieved a decoding probability of 0.35, compared with 0.10 for CGRP, representing a 250% relative improvement. At a decoding rate of 3.0, ICAMHS achieved 1.00 compared with 0.98 for CGRP, representing a 2.04% relative improvement. For latency, ICAMHS achieved 998 ms at 1000 nodes compared with 1000 ms for CGRP, representing a 0.20% reduction. The results indicate that ICAMHS improves decoding performance while maintaining comparable latency under the evaluated simulation conditions. The evaluation is limited to decoding probability and latency; energy consumption, network lifetime, scalability, computational overhead, and repeated-run statistical analysis are left for future work.

Keywords: *Wireless Sensor Networks; hotspot mitigation; ICAMHS; clustering; CH selection*

1. INTRODUCTION

Wireless Sensor Networks (WSNs) consist of distributed sensor nodes that collect environmental information and transmit data to a base station (BS). They are widely used in monitoring and automation applications. However, limited energy and communication resources make efficient clustering and routing essential for reliable operation (Patil & Kohle, 2024).

A major challenge in clustered WSNs is hotspot formation, where some nodes experience disproportionately high communication and forwarding loads. CHs close to the BS may aggregate their own data while relaying traffic from other clusters, resulting in increased communication burden and faster resource depletion (Lonkar et al., 2026). Clustering reduces communication overhead by grouping nodes under CHs, which collect, aggregate, and forward data to the BS. Genetic Algorithms (GAs) have also been applied to WSN routing to optimise routing configurations based on predefined fitness criteria (Khalaf et al., 2022).

CGRP combines clustering with GA-based route optimisation to improve routing performance (Patil & Kohle, 2024). However, its CH selection may not sufficiently consider existing traffic loads, potentially increasing hotspot formation. To address this limitation, this study proposes ICAMHS,

which extends CGRP through traffic-aware CH selection, improved routing fitness, and fault-tolerant route recovery. The evaluation is limited to decoding probability for N=1000 and latency under identical simulation conditions. The proposed approach is also relevant to the conference theme of Nigeria's Growth for Sustainable Development because reliable WSNs can support distributed sensing applications such as rural environmental monitoring, agricultural monitoring, and infrastructure condition monitoring. Reducing hotspot formation can improve the reliability and operational efficiency of such sensing systems, aligning the work with the Intelligent Systems, Automation and Control Engineering sub-theme.

2. RELATED WORK

Recent studies have addressed hotspot formation and energy imbalance in WSNs through intelligent clustering, load balancing, and adaptive routing. These approaches have reported improvements in energy efficiency, network lifetime, routing performance, and CH selection. However, computational complexity, scalability, dynamic adaptation, and balanced traffic distribution remain areas requiring further investigation.

Table 1: Summary of Recent Clustering and Routing Approaches in WSNs

Study	Approach	Main Contribution	Limitation / Gap
Somula et al. (2024)	Osprey optimization-based CH selection	Improves packet delivery and network lifetime through optimized CH selection	Limited adaptaton to dense and heterogeneous networks
Mabunga and Dela Cruz (2024)	Wild Geese Optimization-based clustering and routing	Optimizes CH selection and routing using multiple network parameters	Computational cost and scalability require further consideration
Patil and Kohle (2024)	Cluster-Based Genetic Routing Protocol (CGRP)	Combines clustering, energy/distance-based CH selection, and GA-based routing optimization	Limited consideration of traffic-load concentration and hotspot-aware CH selection
Soltani et al. (2025)	Multi-agent reinforcement-learning routing	Adapts routing using energy, hop count, hotspot proximity, and neighbourhood information	Re-clustering overhead and CH depletion remain challenges
Prince et al. (2025)	Multilevel clustering and prediction-based routing	Uses clustering and prediction to reduce hotspot effects	Centralized clustering and CH-management overhead remain concerns
Peter et al. (2026)	Density-aware clustering with Voronoi partitioning	Addresses dense WSNs using density, link quality, and dynamic reclustering	Computational complexity, delay, and implementation cost remain concerns
Ramesh et al. (2026)	Hybrid ML-based CH selection and routing	Integrates machine learning and optimization to improve network lifetime	Integrated adaptive clustering and routing may increase computational complexity
Baslem et al. (2026)	Hotspot-aware load-balanced clustering and routing	Combines energy-aware clustering, load balancing, and fault-tolerant routing	Computational cost and real-world deployment require further evaluation
Proposed ICAMHS	K-means and load-aware CH selection with improved routing fitness	Combines energy, distance, traffic load, energy-balanced routing, and fault-tolerant recovery	Further evaluation of energy consumption, network lifetime, scalability, and computational overhead is required

The reviewed studies demonstrate that energy-aware clustering, intelligent CH selection, load balancing, and adaptive routing can improve WSN performance. However, the integration of traffic-aware CH selection, energy-balanced routing, and fault-tolerant recovery remains insufficiently addressed. In particular, CGRP primarily considers residual energy and distance in CH selection, leaving traffic-load concentration insufficiently addressed (Patil & Kohle, 2024). Therefore, ICAMHS extends CGRP by incorporating traffic load into CH selection, an energy-imbalance factor into routing fitness, and fault-tolerant route recovery. The comparison in Table 1 also highlights differences in the mechanisms used to address hotspot formation. Somula et al. (2024) focus on optimisation-based CH selection and report gains in packet delivery and network lifetime, but their approach has limited adaptation to dense and heterogeneous networks. Mabunga and Dela Cruz (2024) jointly optimise clustering and routing using multiple network parameters, although computational cost and scalability remain concerns. Soltani et al. (2025) introduce multi-agent reinforcement learning for routing using energy, hop count, hotspot proximity, and neighbourhood information, but re-clustering overhead and CH depletion remain challenges. Peter et al. (2026) address dense WSNs through density, link quality, and dynamic reclustering, while Ramesh et al. (2026) combine machine learning with optimisation for CH selection and routing; both approaches may increase computational complexity. These studies indicate that hotspot mitigation can benefit from adaptive decision-making, but they do not directly combine the specific traffic-aware CH selection, energy-balanced routing fitness, and fault-tolerant recovery used in ICAMHS. ICAMHS therefore targets this combination while retaining a relatively simple K-means-based clustering structure.

3. PROPOSED ICAMHS PROTOCOL

3.1 Network Model

The proposed model assumes a homogeneous sensor network in which sensor nodes are randomly distributed within the network area, the BS remains fixed, and all nodes have equal initial energy. The nodes communicate through cluster heads. K-means clustering is used to partition the network into clusters, after which suitable CHs are selected using energy, distance, and traffic-load information. This homogeneous assumption is consistent with the simulation configuration used in the present study. Although ICAMHS is motivated by hotspot problems also reported in heterogeneous WSNs, its current evaluation does not model heterogeneous initial energies or heterogeneous node capabilities. Consequently, applicability to heterogeneous WSNs should be regarded as a limitation requiring further validation. The simulation configuration adopted from the source study uses a 1000 m² network area, 50 J initial node energy, 30 m transmission range, 10 m sensing range, 60 kbps bandwidth, 50 packets/s transmission rate, 1000-bit data packets, and a 200-time-unit operating period (Patil & Kohle, 2024).

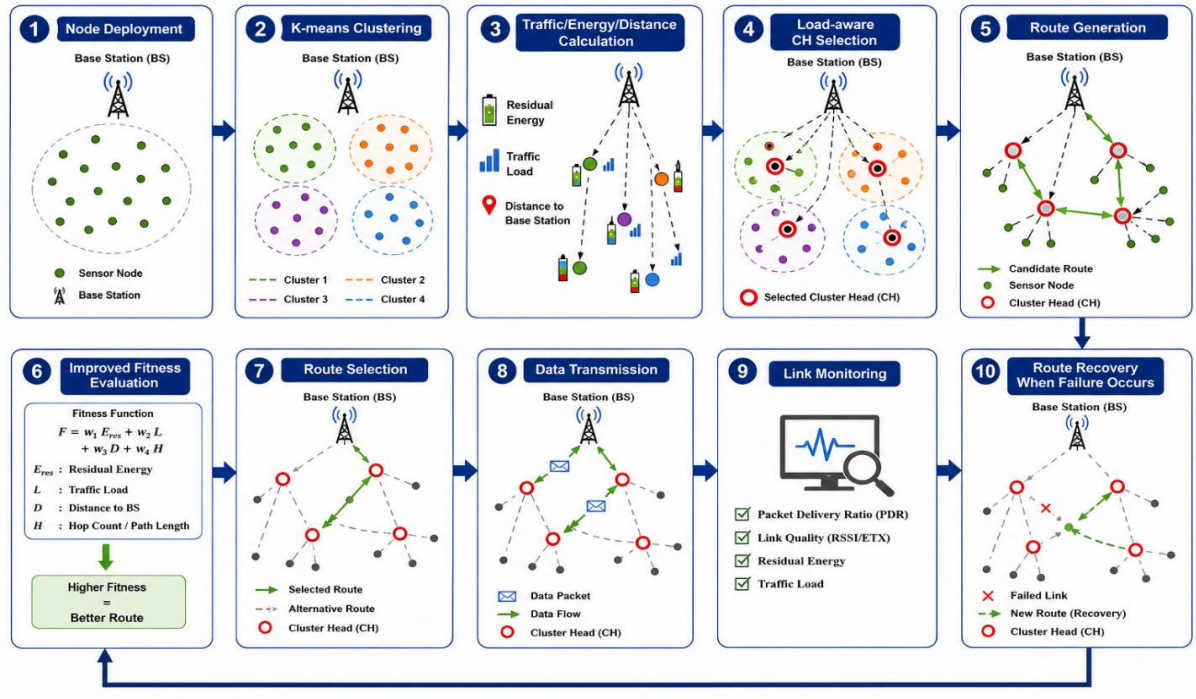

Figure 1: Conceptual Architecture of the Proposed ICAMHS Protocol

Figure 1 summarises the ten operational steps of ICAMHS. First, sensor nodes are deployed around a fixed base station (BS). Second, K-means clustering partitions the nodes according to their spatial positions. Third, residual energy, traffic load, and distance information are calculated for candidate CHs. Fourth, the load-aware CH-selection metric combines these factors to select a CH for each cluster. Fifth, candidate routes are generated between CHs and the BS. Sixth, the improved fitness function evaluates candidate routes using energy balance and routing-related criteria. Seventh, the route with the highest fitness is selected. Eighth, sensed data are transmitted along the selected route. Ninth, links are monitored using packet delivery ratio (PDR), link quality represented by RSSI/ETX, residual energy, and traffic load. Tenth, when a link becomes unacceptable, the failed link is detected and an alternative route is established through the fault-tolerant recovery mechanism.

3.2 Enhanced Cluster Formation

ICAMHS employs the K-means algorithm to group sensor nodes according to their spatial positions. For each cluster, the cluster centre is calculated as the arithmetic mean of the coordinates of all nodes assigned to that cluster. The cluster centre is given by (Guo et al., 2025).

$$C_j = \left(\frac{1}{n_j} \sum_{i=1}^{n_j} x_{i,} \;\; \frac{1}{n_j} \sum_{i=1}^{n_j} y_i \right) \tag{1}$$

Where (C_j) represent the centre of cluster (j), (n_j) is the number of sensor nodes belonging to cluster (j), and (x_i) and (y_i) are the x- and y-coordinates of node (i).

The K-means clustering objective can additionally be expressed as

$$J = \sum_{j=1}^{k} \sum_{\mathrm{i} \in C_j} \| \, X_i = C_j \, \|^2 \tag{2}$$

where K is the number of clusters, $X_i = (x_i, y_i)$ is the position vector of node i, and (C_j) is the centre of cluster j.

The objective of K-means is to minimise the total squared Euclidean distance between sensor nodes and their corresponding cluster centres. This arrangement reduces unnecessary communication distances and provides a spatial basis for subsequent CH selection.

3.3 Load-Aware Cluster-Head Selection

The principal modification introduced by ICAMHS is the incorporation of traffic load into CH selection. Conventional CH selection based primarily on residual energy and distance may repeatedly assign CH responsibilities to nodes that already carry substantial communication traffic. To address this limitation, ICAMHS introduces a load-balancing factor defined as (Baslem et al., 2026)

$$L_b = \frac{1}{1 + \alpha T_i} \tag{3}$$

Where (T_i) represents the traffic load handled by node (i), and (α) is a positive tuning parameter that controls the influence of traffic load on CH selection.

The inverse formulation ensures that the load factor decreases as the traffic handled by a node increases. Thus, a node carrying a high traffic load receives a lower preference for additional CH responsibilities.

A normalized distance factor can be defined as (Mabunga & Dela Cruz, 2024)

$$D_i = 1 - \frac{d_{iC_j}}{d_{max}} \tag{4}$$

where $d_{iC_j}$is the Euclidean distance between node i and the centre of cluster j, while d_{max} is the maximum reference distance used for normalization.

The residual-energy factor is expressed as

$$E_i = \frac{E_i^{res}}{E_{max}} \tag{5}$$

where E_i^{res} is the residual energy of node i, and E_{max} is the maximum or initial node energy.

The three factors can then be combined into the proposed CH-selection metric:

$$CH_i = w_E \, E_i + w_D \, D_i + w_L \, L_i \tag{6}$$

$$\text{Subject to} \quad w_E + w_D + w_L = 1 \tag{7}$$

where $w_E . w_D$ and w_L are the weighting coefficients assigned to residual energy, distance, and traffic load, respectively.

The cluster-head node is selected according to

$$CH_i^* = arg \max_{i \in C_j} CH_i \tag{8}$$

where CH_i^* represents the selected CH for cluster j.

This formulation gives preference to nodes with higher residual energy, shorter distance to the cluster centre, and lower traffic load. Consequently, CH responsibilities can be distributed more evenly across the network, thereby reducing the likelihood of hotspot formation.

3.4 Improved Fitness Function

The improved fitness function introduces an energy-imbalance penalty based on the maximum energy consumed by nodes participating in a candidate route. A suitable formulation is to first calculate the energy consumed by node i during a routing operation as (Guo et al., 2025)

$$E_i^{cons} = E_i^{init} - E_i^{res} \tag{9}$$

where E_i^{init} and E_i^{res} denote the initial and residual energy of node i, respectively.

The maximum energy consumption among nodes participating in a candidate route is then

$$E_{max}^{cons} = \max_{i \in R} E_i^{cons} \tag{10}$$

where R represents the set of nodes participating in the candidate routing solution.

A normalized energy-imbalance penalty can be expressed as

$$P_E = \frac{E_{max}^{cons}}{\sum_{\in \mathbf{R}} E_i^{cons} + \varepsilon} \tag{11}$$

where ε is a small positive constant introduced to avoid division by zero.

The improved ICAMHS fitness function can then be represented generally as (Patil & Kohle, 2024)

$$F_{ICAMHS} = F_{CGRP} - \lambda_E P_E \tag{12}$$

where F_{CGRP} is the original CGRP fitness value, PE is the maximum-energy-consumption penalty, and λE controls the influence of the energy-imbalance penalty.

ICAMHS modifies the original CGRP fitness function by incorporating an energy-imbalance penalty based on the maximum energy consumed by participating nodes. The purpose of this penalty is to discourage routing solutions that concentrate excessive communication responsibilities on a small number of nodes. Therefore, the GA is encouraged to select routing configurations that provide a more balanced distribution of energy consumption and reduce the likelihood of hotspot formation.

3.5 Fault-Tolerant Routing

Q_{IJ} Link quality Q_ij is used as a general link-quality measure in the fault-detection condition; RSSI is therefore treated as one possible measurement contributing to Q_ij rather than as a separate variable in the link-failure equation. A link-failure indicator between node i and neighbouring node j is defined as

$$F_{ij} = \begin{cases} 1. & Q_{IJ} < Q_{th} \\ 0, & Q_{IJ} \geq Q_{th} \end{cases} \tag{13}$$

where $F_{ij} = 1$ indicates a failed or unacceptable link, $F_{ij} = 0$ indicates an acceptable link, Q_{IJ} represents the link quality between nodes i and j, and Q_{th} is the minimum acceptable link-quality threshold.

When a link failure is detected, node i broadcasts an LREQ message to its neighbouring nodes. Each responding neighbour provides information regarding its residual energy, distance to the destination, and link quality.

The alternative-next-hop score can be defined as

$$S_i = w_E \frac{E_J}{E_{mx}} + w_D \left(1 - \frac{d_{\,i}D}{d_{max}}\right) + w_Q \frac{Q_{iJ}}{Q_{max}} \tag{14}$$

where E_{ires} is the residual energy of neighbouring node j, E_{mx} is the maximum or initial node energy, $d_{\,i}D$ is the distance between node j and the destination D, d_{max} is the maximum reference distance, $Q_{iJ}$is the link quality between nodes i and j, Q_{max} is the maximum reference link-quality value, and wE, wD, and wQ are weighting coefficients.

The alternative next hop is then selected as

$$J^* = arg \max_{i \in N_i} S_{ij} \quad (15)$$

where N_i represents the set of eligible neighbouring nodes of node i, and j$*$ is the neighbour with the highest link score.

This mechanism allows ICAMHS to dynamically establish an alternative communication path when the primary route becomes unavailable.

4. SIMULATION SETUP

4.1 Simulation Parameters

The simulation parameters for developing the Improved Clustering Approach to Mitigate Hotspots (ICAMHS) in WSNs are presented in Table 3.1. These values are used to evaluate the performance of the developed model.

Table 2: Simulation parameters and its values

S/N	Parameter	Default Value
1	Transmission range	30 m
2	Sensing Range	10 m
3	Initial Energy	50 J
4	Node deployment	Random
5	Nodes Bandwidth	60kbps
6	Network area	1000 Sq.m
7	Transmission Rate	50 p/s
8	Packet size	1000 bits
9	Simulation duration	200-time units

4.2 Simulation Environment

The ICAMHS model was implemented using MATLAB. The principal simulation parameters were adopted from Patil and Kohle (2024), including a 30 m transmission range, 10 m sensing range, 50 J initial energy, 60 kbps bandwidth, 1000 m² network area, 50 packets/s transmission rate, 1000-bit packet size, and a 200-time-unit operating period. The CGRP baseline was independently re-simulated in MATLAB under the same network assumptions and parameter settings to provide a direct comparison. The node positions, traffic conditions, and simulation parameters were kept identical for ICAMHS and CGRP.

.

5. RESULTS AND DISCUSSION

5.1 Decoding Probability

Figure 2 shows the decoding probability of CGRP and ICAMHS for a network of 1,000 sensor nodes. ICAMHS consistently achieves a higher decoding probability than CGRP across the evaluated decoding rates. The improvement is more pronounced at lower decoding rates and decreases as both protocols approach a decoding probability of 1.00.

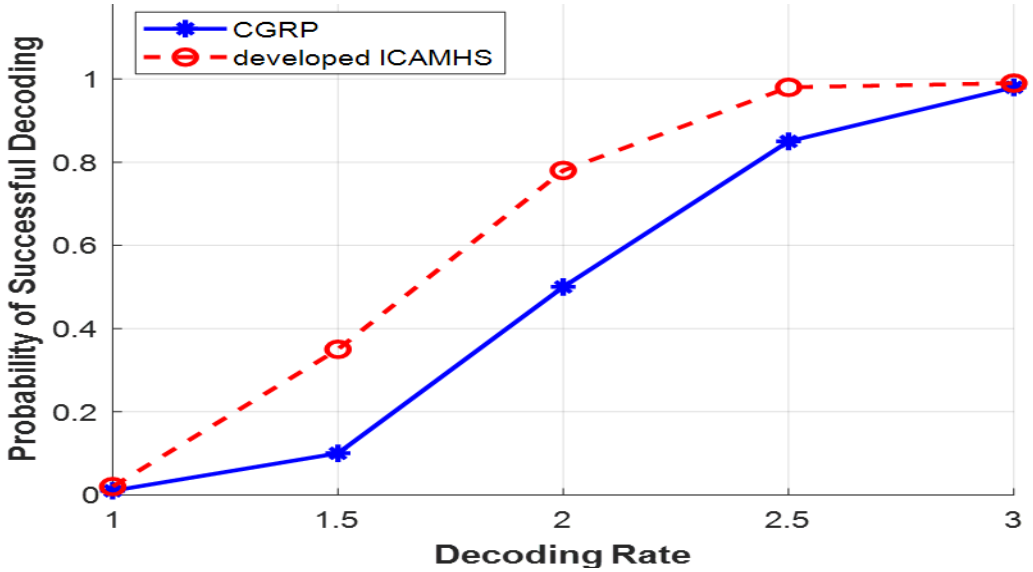

Figure 2: Decoding Probability versus Decoding Rate

At a decoding rate of 1.5, the decoding probability increases from 0.10 for CGRP to 0.35 for ICAMHS, representing a 250% relative improvement. At a decoding rate of 3.0, the improvement is 2.04%. These results indicate that the traffic-aware cluster-head selection and modified routing fitness function improve communication reliability, particularly at lower decoding rates. The numerical results are summarized in Table 3.

Table 3: Decoding Probability Comparison for N=1000

Decoding Rate	CGRP	ICAMHS	Improvement (%)
1.0	0.00	0.00	0.00
1.5	0.10	0.35	250.00
2.0	0.50	0.78	56.00
2.5	0.85	0.98	15.29
3.0	0.98	1.00	2.04

The improved performance can be attributed to the traffic-aware CH-selection mechanism and the modified routing fitness function. By reducing the probability of assigning additional forwarding responsibility to heavily loaded nodes, ICAMHS provides a more balanced communication structure and improves the likelihood of successful data delivery.

5.2 Latency Performance

Figure 3 presents the latency performance as the number of sensor nodes increases. ICAMHS maintains slightly lower latency than CGRP across the evaluated network sizes. The small difference indicates that the additional traffic-aware mechanisms do not introduce a substantial latency penalty under the simulated conditions.

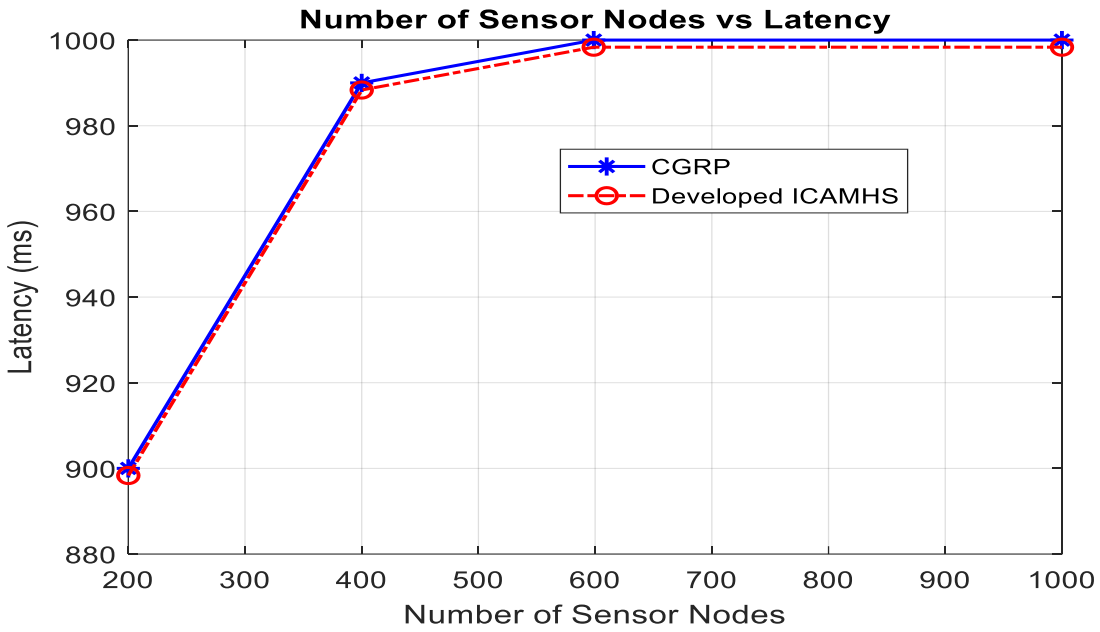

Figure 3: Latency Comparison of CGRP and ICAMHS

At 200 nodes, latency decreases from 900 ms for CGRP to 899 ms for ICAMHS, corresponding to a 0.11% reduction. At 400 nodes, the reduction is 0.20%. For 600–1000 nodes, ICAMHS maintains a latency of 998 ms compared with 1000 ms for CGRP, giving a 0.20% reduction. The detailed results are presented in Table 4.

Table 4: Latency Comparison between CGRP and ICAMHS

Number of Nodes	CGRP (ms)	ICAMHS (ms)	Reduction (%)
200	900	899	0.11
400	990	988	0.20
60	1000	998	0.20
800	1000	998	0.20
1000	1000	998	0.20

The results indicate that the additional processing associated with traffic-aware CH selection and routing optimisation does not produce a substantial latency penalty under the simulated conditions. The main performance advantage of ICAMHS is therefore the improvement in decoding probability rather than a major reduction in latency.

5.3 Comparative Discussion

The two performance metrics provide complementary evidence of ICAMHS performance. ICAMHS achieves higher decoding probability than CGRP across the evaluated decoding rates, with the highest relative improvement of 250.00% at a decoding rate of 1.5. For latency, the improvement is small. At 1000 nodes, ICAMHS reduces latency from 1000 ms to 998 ms, representing a 0.20% reduction. Thus, the main advantage of ICAMHS is improved decoding performance while maintaining comparable latency.

The improved decoding performance is consistent with the load-aware CH-selection strategy, which considers traffic load alongside residual energy and distance. This reduces the likelihood of assigning additional communication responsibilities to heavily loaded nodes. The improved routing fitness further promotes more balanced routing decisions. Overall, ICAMHS improves decoding performance without significantly affecting latency under the evaluated simulation conditions.

6. CONCLUSION

This paper presented ICAMHS, an improved clustering and routing approach for hotspot mitigation in large-scale Wireless Sensor Networks. The approach extends CGRP by incorporating traffic-aware cluster-head selection, an energy-imbalance factor in the routing fitness function, and fault-tolerant route recovery. The evaluation showed that ICAMHS achieved a decoding probability of 0.35 at a decoding rate of 1.5, compared with 0.10 for CGRP, representing a 250.00% relative improvement. At a decoding rate of 3.0, ICAMHS achieved 1.00 compared with 0.98 for CGRP, representing a 2.04% relative improvement. For latency, ICAMHS achieved 998 ms at 1000 nodes compared with 1000 ms for CGRP, representing a 0.20% reduction.

These results indicate that ICAMHS improves decoding performance while maintaining latency comparable to CGRP under the evaluated simulation conditions. The study has several limitations. The evaluation uses a homogeneous network model, considers only decoding probability and latency, and is based on a single simulation run without confidence intervals or statistical significance testing. Energy consumption, network lifetime, scalability beyond the evaluated network sizes, and computational overhead were not quantitatively evaluated. Future work will therefore include repeated simulation trials with statistical analysis, direct evaluation of energy consumption and network lifetime, scalability tests for larger networks, evaluation under heterogeneous node conditions, computational-overhead analysis, and validation using real sensor-network hardware.

ABSTRACT

As the number of wireless devices and services grows exponentially, the Radio Frequency (RF) spectrum is becoming increasingly a scarce resource. Again, the current fixed spectrum-licensing policy has made the RF spectrum underutilized. Cognitive Radio (CR) seeks to provide solution to address the imbalance between spectrum scarcity and spectrum underutilisation by allowing cognitive users, called Secondary Users (SUs), to share the spectrum with the licensed users called Primary Users (PUs) in a manner that the PUs do not suffer harmful interference. This work is aimed at mitigating underlay cognitive intra-network interference with a view to enhancing the effective sum capacity of the SUs. The PU is protected through Interference Temperature (IT) model. Interference Alignment (IA) scheme under the IT constraints is developed for mitigating the mutual interference among the SUs. A closed form expression for the sum capacity of three-user underlay cognitive channel is derived. Applying the ergodic IA with IT constraints enhances the sum capacity of the SUs thereby achieving 23.54% and 24.77% gain in the channel sum capacity under maximum and average IT limits respectively. This gain is with respect to time-division scheme at signal-to-noise-ratio of 19dB. By utilizing the long delay time associated with ergodic IA to send more bits in time-division scheme, 3.0094 bps/Hz and 3.1741 bps/Hz gains in spectral efficiency were achieved under maximum and average IT limits over a full time-division scheme at SNR of 19dB.

Keywords: *Cognitive Radio; Interference Alignment; Underlay; Spectral Efficiency; SNR*

1. INTRODUCTION

The rapid growth of wireless broadband, multimedia, mobile computing, and emerging wireless services has resulted in an increasing demand for radio-frequency spectrum. At the same time, conventional fixed spectrum allocation has resulted in significant underutilization of portions of the licensed spectrum. Out of the imbalance between scarcity of preferred spectrum and underutilisation was born the idea of Cognitive Radio (CR) to improve spectrum utilization (Mitola, 2009). CR uses advanced radio and signal processing technology along with novel spectrum allocation policies to share the spectrum as a Secondary User (SU) in a manner that the Primary (licensed) Users (PUs) are as unaffected as possible. CR provides a means of improving spectrum utilization by allowing unlicensed or SUs to opportunistically access spectrum assigned to PUs, subject to appropriate interference constraints (Xu *et. al.*, 2025).

Three principal spectrum-sharing paradigms are commonly considered in cognitive radio networks: interweave, overlay, and underlay as illustrated in figure 1.

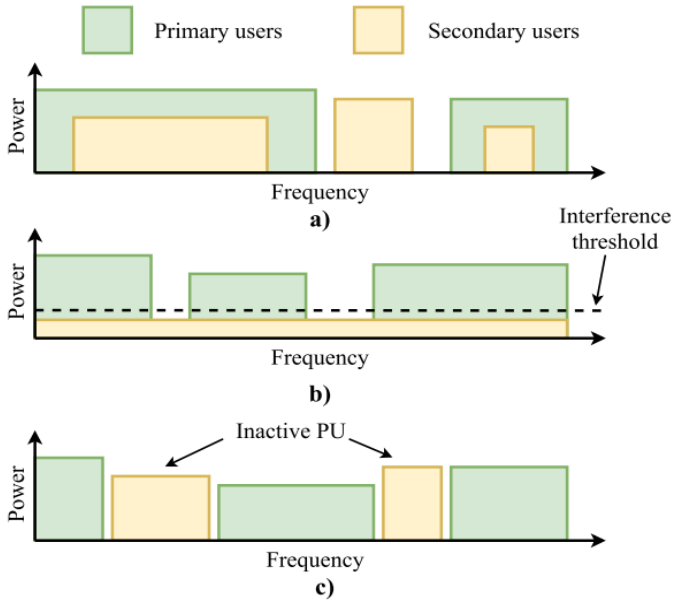

Figure 1: Spectrum sharing in CR. a) overlay, b) underlay, c) interweave (Briones *et. al.*, 2020)

In the underlay paradigm, an SU is allowed to transmit concurrently with a PU provided that the interference received by the PU remains below a prescribed threshold. The interference-temperature (IT) concept provides a convenient means of specifying this interference constraint (Yau *et. al.*, 2025).

Although the underlay approach allows simultaneous transmission, the requirement to protect the PU imposes a restriction on the transmit power of the SUs. The problem becomes significant when multiple SUs share the spectrum. In addition to SU-to-PU interference, there is mutual SU-to-SU interference. Consequently, a reduction in SU transmit power does not by itself solve the interference problem; rather, the mutual interference may become a dominant limitation on the achievable secondary-network capacity (Yang, *et. al*., 2024).

Interference Alignment (IA) is a transmission strategy that combines transmitter precoding and receiver interference suppression to achieve optimal network degrees of freedom. The idea of IA has challenged most of conventional wisdom about the sum capacity limit of wireless channels (Abdulkadir *et. al.*, 2024). IA is an interference-management technique that exploits the dimensions of a time-varying interference channel to arrange interfering signals in a manner that permits their suppression at the intended receivers. Ergodic Interference Alignment (EIA) uses appropriately selected channel realizations to align and cancel interfering signals. The work of Yau *et. al.*, (2025) evaluated the ergodic capacity of multiple underlay cognitive users under maximum interference constraints. This paper investigates interference mitigation of multiple underlay SUs using ergodic interference alignment under interference-temperature constraints with the following novel contributions:

i. Modelling the interference in a 3-SU underlay cognitive-radio in the presence of a single PU.
ii. Incorporating EIA is into the underlay system for mitigating interference among the SUs while satisfying both maximum and average IT constraints.
iii. Obtaining a closed-form sum-capacity expressions for the three-user system.
iv. Evaluating the performance of EIA against an equal time-division benchmark
v. Utilizing the EIA to send delay insensitive bits for significant spectral efficiency gains.

2. METHODOLOGY

A spectrum sharing model is considered as illustrated in Figure 2 where three Secondary Users (SUs) underlay their transmissions in the same narrow-band frequency as the Primary User (PU). The IT metric is used as measure of the interference power. The channel coefficient between transmitter j to receiver i is denoted as hij. All the channel coefficients are assumed to be independent and identically distributed (i.i.d) random variable following Rayleigh distribution (Ren *et. al.*, 2026).

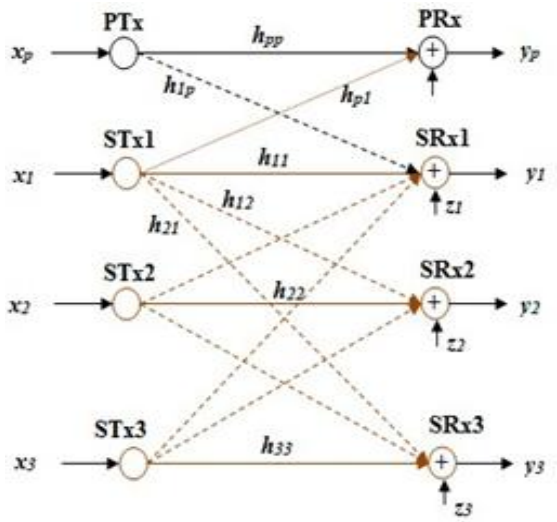

Figure 2: System Model: 3 SUs Coexisting with a Single PU

The received signal at the primary receiver, y_p, is a noisy linear combination of the signals from the intended primary transmitter and unintended secondary transmitters which can be modelled as:

$$y_p = h_{pp}x_p + \sum_{k=1}^{3} h_{pk}x_k + z_p \tag{1}$$

where:

h_{pp} and h_{pk} are the channel coefficient between the PU transmitter and PU receiver and the channel coefficient between the kth SU transmitter and the PU receiver respectively; x_p and x_k are the signals transmitted by the PU transmitter and the kth SU transmitter respectively; z_p is an additive white Gaussian noise with zero mean and unit variance at the primary receiver.

Similarly, the channel model for the jth SU receiver is as follows

$$y_j = h_{jp}x_p + \sum_{k=1}^{3} h_{jk}\, x_k + z_p \tag{2}$$

where, $j = 1, 2, 3$

For a given bandwidth, B, the SU determines its transmit power, P, subject to interference constraint given by.

$$P \leq \frac{k.B(T_L - T_I)}{L} \tag{3}$$

Thus,

$$E[|x_k|^2] = P \leq \frac{k.B(T_L - T_I)}{L} \tag{4}$$

Equation (4) ensures that the total power in the terms $\sum_{k=1}^{3} h_{pk}x_k$ of equation (1) do not cause harmful interference to the PU receiver.

2.1 ERGODIC INTERFERENCE ALIGNMENT UNDER IT CONSTRAINTS

For a time varying interference channel, the achievable capacity per user, C_{SU_EIA}, using ergodic interference alignment is given by

$$C_{SU_EIA} = \frac{1}{2}E[\log(1 + 2|h_{kk}|^2 P)] \tag{5}$$

where, P is the transmit power of the user.

The sum capacity achieved for fully connected 3 underlay CR users under the IT constraints is formulated as follows:

A. ERGODIC IA UNDER MAXIMUM IT LIMITS

The sum capacity, C_{Σ}^{EIA}, achieved for a fully connected 3-users is solution to the following optimization problem.

$$C_{\Sigma}^{EIA} = \max_{P \geq 0} \frac{3}{2} \mathrm{E}[\log(1 + 2 g_{ss} P)] \tag{6}$$

Subject to

$$\sum_{k=1}^{3} g_{pk} \, P \; \leq \; kBT_L \tag{7}$$

The optimal power, P^*, is just given by

$$P^* = \frac{kBT_L}{\sum_{k=1}^{3} g_{pk}} \tag{8}$$

Putting equation (8) into equation (6) gives

$$C_{\Sigma}^{EIA} = \max_{P \geq 0} \frac{3}{2} \mathrm{E}\left[\log\left(1 + 2 \frac{g_{ss}}{\sum_{k=1}^{3} g_{pk}} \psi\right)\right] \tag{9}$$

$$C_{\Sigma}^{EIA} = 1.44 \times \frac{24\psi^3 \log 2\psi - 36\psi^3 + 24\psi^2 - 3\psi}{2(2\psi - 1)^3} \tag{10}$$

B. ERGODIC IA UNDER AVERAGE IT CONSTRAINT

The sum capacity, C_{Σ}^{EIA}, achieved is solution to the following optimization problem.

$$C_{\Sigma}^{EIA} = \max_{P_{su} \geq 0} \frac{3}{2} \mathrm{E}[\log(1 + 2 g_{ss} P)] \tag{11}$$

Subject to

$$\mathrm{E}\left[\sum_{k=1}^{3} g_{pk} \, P\right] \; \leq \; kBT_L \tag{12}$$

The optimal power, P^*, is obtain using Lagrange method as

$$P^* = \left(\frac{1}{\lambda \sum_{k=1}^{3} g_{pk}} - \frac{1}{2 g_{ss}}\right)^{+} \tag{13}$$

Hence, the sum capacity, C_{Σ}^{EIA}, in bpcu is obtained as

$$C_{\Sigma}^{EIA} = 1.44 \left[\frac{3}{2} \log(1 + \gamma(\psi)) - \frac{3\gamma(\psi)(2 + 3\gamma(\psi))}{4(1 + \gamma(\psi))^2} + \frac{3\gamma(\psi)^3 \log 2}{2(1 + \gamma(\psi))^3}\right] \tag{14}$$

2.2 UTILIZING THE EXPECTED DELAY OF ERGODIC ALIGNMENT

A major drawback of ergodic alignment scheme is a very long delay incurred to attain half the interference-free rate. This limits the scheme to applications where high rates are far more valuable than low delays. Thus, the spectral efficiency of the ergodic alignment becomes very low due to the long delay time during which the users have to stay quite waiting for the realization of the complimentary channel matrix. To better the spectral efficiency of the proposed ergodic IA under IT constraints, the waiting time (expected delay) can be exploited by the SUs for sending delay-sensitive messages. The spectral efficiency gain is obtained as follows.

Let τ be the expected delay time slots between the two transmissions to achieve ergodic alignment. If the SUs utilize the expected delay time slots in a time-division scheme, the spectral efficiency is given by

$$\eta_{EIA} = 2 \times \frac{3}{2} \mathrm{E}[\log(1 + 2g_{ss}P^*)] + \tau \times \mathrm{E}[\log(1 + g_{ss}P^*)] \quad (15)$$

For a full time-division SUs, the spectral efficiency, η is

$$\eta = (2 + \tau)\mathrm{E}[\log(1 + g_{ss}P^*)] \quad (16)$$

Subtracting equation (16) from equation (15), the gain in spectral efficiency, η', is obtained as

$$\eta' = 3\mathrm{E}[\log(1 + 2g_{ss}P^*)] - 2\mathrm{E}[\log(1 + g_{ss}P^*)] \quad (17)$$

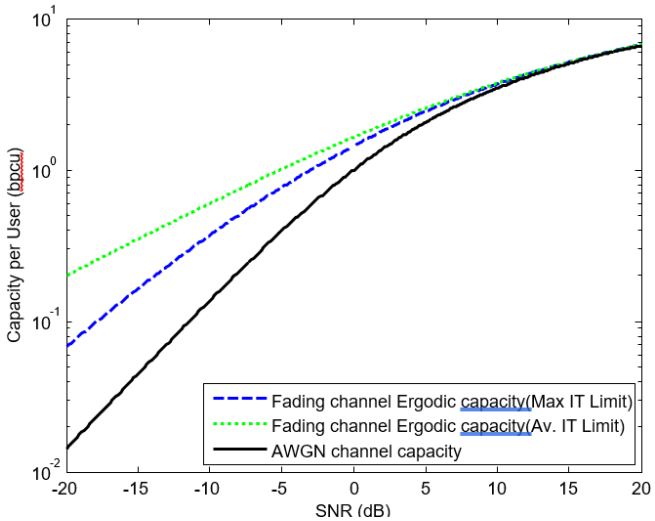
3. RESULTS AND DISCUSSION

This section describes the performance of the proposed ergodic interference-alignment (EIA) scheme was evaluated for the 3-SU underlay cognitive-radio system. Table 1 shows the simulation parameters.

Table 1: Simulation Parameters

S/N	Parameter	Value/Setting
1	Boltzmann constant (K)	1.38×10^{-23}J/K
2	Background IT	290 K
3	SNR range, ψ	0 – 20 dB
4	Channel model	i.i.d Rayleigh fading
5	Channel knowledge	Perfect CSI
6	Channel bandwidth , B	Normalised
7	SU time allocation	1/3
8	EIA time factor	½

Comparison of the sum capacities of the SUs under maximum IT limit and average IT limit for the same SNR in done in Figure 3. The capacities in the former case are generally lower than those of the latter which results due to the more restrictive nature of the maximum (as opposed to the average) IT constraint.



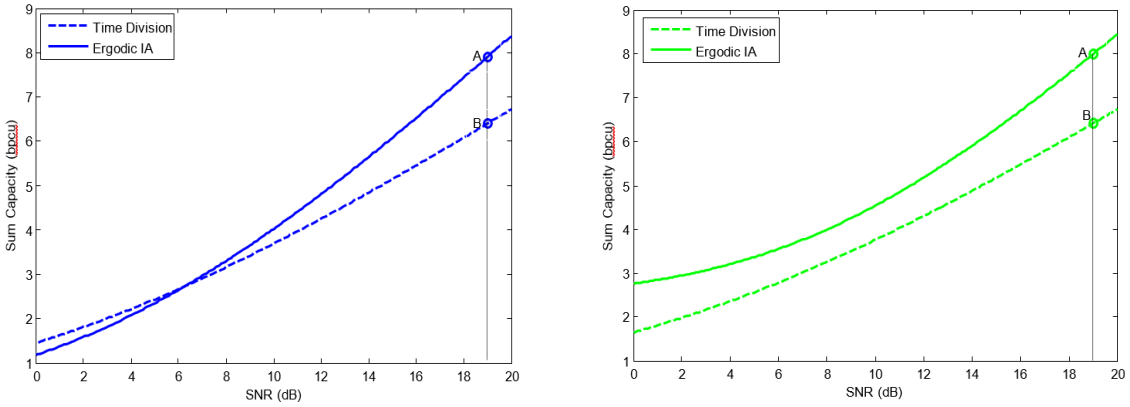


Figure 3: Sum Capacity through Time Division

A. ACHIEVABLE SUM CAPACITY THROUGH EIA UNDER IT LIMITS

Figures 4 (a) and (b) show the sum capacity achieved through ergodic IA under maximum and average interference temperature limits using equations (10) and (14). For all values of SNR under average IT limit, the achievable sum capacity through ergodic IA is higher than that obtained through time-division. But in the case of Max. IT limit below 6.2dB, the capacity achieved through ergodic IA is below that of time-division. This due to the more restrictive nature of the maximum (as opposed to the average) IT constraint.

(a) under Maximum IT Limits (b) under Average IT Limits

Figure 4: Sum Capacity

The typical values of SNR of UWB (an underlay communication) applications are around 19 dB (Nelson *et. al.*, 2025). Thus, the performance of the developed model is evaluated at 19 dB under maximum and average IT limits as follows:

Maximum IT Limit

The sum capacities achieved through the developed ergodic IA under IT limits and the time division scheme are given by the coordinates A(19 dB, 7.8968 bpcu) and B(19 dB, 6.3921 bpcu) respectively in Figure 4 (a).

The capacity gain = 7.8968−6.3921=1.5047 bpcu

The capacity gain

$$= \frac{1.5047}{6.3921} \times 100\ \% = 23.54\ \%$$

Average IT Limit

The sum capacities achieved through the developed ergodic IA under IT limits and the time division scheme are given by the coordinates A(19 dB, 7.9943 bpcu) and B(19 dB, 6.4073 bpcu) respectively in Figure 4 (b).

The capacity gain = 7.9943−6.4073=1.5870 bpcu

$$= \frac{1.5870}{6.4073} \times 100\ \% = 24.77\ \%$$

The capacity gain

Comparison of the achievable capacity under IT constraints with that of the time-division scheme is shown in Figure 5. It also gives an upper bound to the capacity which corresponds to capacity achievable by non-interfering cognitive users.

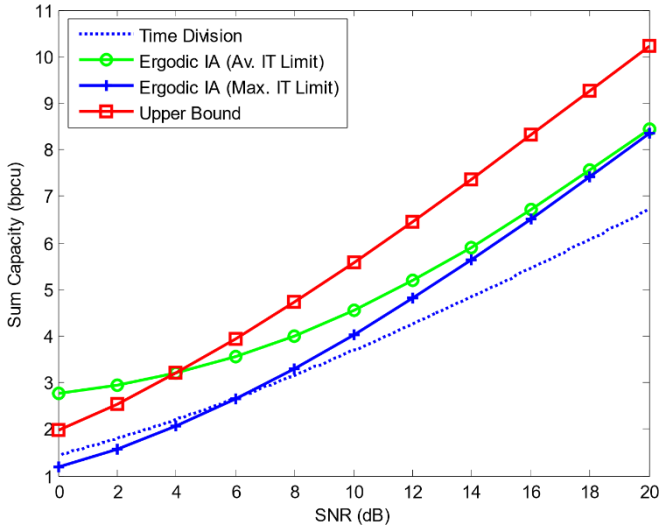

Figure 5: Sum Capacity Comparison

B. SPECTRAL EFFICIENCY GAIN

Spectral efficiency gain was achieved through exploiting the long delay necessary for the ergodic alignment. By utilizing the waiting time slot to send delay insensitive bits in time division scheme, 3.0094 bps/Hz and 3.1741 bps/Hz gains in spectral efficiency were achieved under maximum and average IT limits over a full time-division scheme at SNR of 19dB.

4. CONCLUSION

This research work proposed to mitigate the mutual interference among multiple Secondary Users (SUs) in underlay cognitive radio network aimed at enhancing the sum capacity the SU. Mitigating interference and improving spectrum efficiency are essential for rapid and sustainable growth of telecommunications industry in Nigeria. Ergodic interference alignment scheme under the IT constraints is developed for mitigating the mutual interference among the SUs. To provide a benchmark to gauge the performance of the developed model, the sum capacity through time-division scheme is first obtained. A closed form expression for the sum capacity of three-user underlay cognitive channel is derived. The ergodic IA has a major drawback of a very long delay in order to achieve half the interference-free rate. This was utilized to send delay insensitive bits which give significant percentage improvements of 23.54% and 24.77% in the channel sum capacity under maximum and average IT limits respectively. Since the network sum capacity with EIA increases linearly with the number of users, successful implementation of IA for higher number of SUs will render the capacity of wireless channels interference unlimited. A Rayleigh fading environment is assumed to demonstrate the performance of the developed model. For further work, more generalized fading distributions such as Nakagami-m and α- μ distributions could be considered so that the model can be adapted to suit different environment.

ABSTRACT

Accurate wireless localisation in Non-Line-of-Sight (NLOS) environments remains challenging because multipath propagation, signal blockage, and environmental obstructions introduce severe measurement errors. Conventional Least Squares (LS) estimators are particularly vulnerable to NLOS-induced outliers because their quadratic loss function assigns disproportionately large weights to large residuals. This study proposes a robust hybrid Time of Arrival-Received Signal Strength (TOA-RSS) localisation framework that combines Second-Order Cone Programming (SOCP) with the Huber loss function to mitigate the influence of NLOS-corrupted measurements. The nonconvex Euclidean-distance localisation problem is transformed into a convex SOCP formulation through epigraph reformulation, while the piecewise-convex Huber penalty limits the contribution of large residuals. Monte Carlo simulations covering a comprehensive range of LOS/NLOS anchor configurations demonstrate the effectiveness of the proposed estimator. Under the most severe scenario, involving 0 LOS and 10 NLOS anchors, SOCP+Huber reduced position RMSE by up to 43.4% compared with conventional LS and 23.1% compared with non-robust SOCP. Cumulative distribution analysis further showed that 75–78% of localisation estimates were within 5 m of the true position, compared with approximately 70% for LS. The improvement was most pronounced under severe NLOS conditions, while performance remained competitive under LOS-dominant scenarios, confirming effective outlier suppression. The robustness was achieved with a modest computational increase, from $O(n^{3.5})$ for the standard SOCP to $O(n^{4.5})$, remaining substantially lower than the $O(n^6)$ complexity associated with semidefinite-programming alternatives.

Keywords: *wireless localisation; TOA/RSS; NLOS mitigation; second-order cone programming; and Huber loss*

I. INTRODUCTION

Accurate position estimation is a core requirement in modern wireless systems, spanning 5G infrastructure, IoT sensor networks, indoor navigation, autonomous robotics, and smart building management (Pan et al., 2022; Olejniczak et al., 2024; Pei et al., 2024). As these applications increases, the demand for reliable localisation in challenging real-world environments has intensified (Maduranga et al., 2023). Among widely used positioning techniques, time of arrival (TOA) estimates range by measuring signal propagation delay, achieving centimetre- to decimetre-level accuracy under ideal conditions (Kaune et al., 2011; Shui et al., 2025). Received signal strength (RSS) is used to estimate distance from received signal power via a path-loss model (Yaro et al., 2024; Li et al., 2023). Exploiting the complementary characteristics of both through sensor fusion has been recognised as a promising direction (Wang et al., 2022; Mukhopadhyay et al., 2022).

In dense or indoor environments, multipath propagation introduces a systematic positive bias into TOA estimates because the received signal may travel along indirect paths that are longer than the direct LOS path. For RSS measurements, NLOS propagation produces additional attenuation and shadowing that are not completely represented by the nominal path-loss model, resulting in significant ranging errors. Unlike zero-mean measurement noise, NLOS-induced errors contain a systematic bias component and therefore cannot generally be eliminated simply by averaging repeated measurements. Consequently, even a limited number of NLOS-corrupted links can introduce substantial position offsets in conventional least-squares localisation because large biased residuals can exert a

disproportionate influence on the estimated position (Wang et al., 2014; Wang et al., 2023; Charles et al., 2026).

Most hybrid TOA-RSS frameworks rely on a squared-error (L2) loss, which is optimal under Gaussian noise but highly sensitive to heavy-tailed outliers in severe NLOS conditions because large residuals are amplified quadratically (Huber, 1964). The Huber loss (Huber, 1964) addresses this by applying quadratic penalisation for small residuals and linear penalisation beyond a threshold δ, thereby limiting outlier influence. When embedded in a second-order cone programming (SOCP) framework, it preserves the convex optimisation structure and avoids dependence on initialisation heuristics (Kumar et al., 2015; Xiong et al., 2021), while δ provides a tunable robustness–efficiency trade-off (Mohanty et al., 2023). The combination of SOCP-based hybrid TOA–RSS localisation with Huber loss has received limited attention, motivating this work.

The remainder of this paper is organised as follows. Section II reviews related work. Section III presents the system model, the TOA and RSS measurement equations under NLOS conditions, and the proposed SOCP formulation with the Huber loss function. Section IV describes the simulation setup and presents the numerical results. Section V concludes the paper.

II. RELATED WORK

Early NLOS mitigation methods relied on statistical identification, classifying links as LOS or NLOS using features such as measurement variance, channel impulse response characteristics, or deviation-based statistics, then discarding or down-weighting NLOS links prior to position estimation (Olejniczak et al., 2024; Yang et al., 2023; Yaro et al., 2024). These methods perform well when LOS and NLOS distributions are clearly separable, but can deteriorate in indoor environments where the distributions overlap (Qin & Luo, 2024). A deeper limitation is that classification is decoupled from estimation, so classification errors cannot be corrected downstream.

Convex optimisation offers a more principled alternative. Semidefinite programming (SDP) incorporates robustness directly into the estimator via positive semidefinite matrix constraints (Ma et al., 2022; Shamsian & Behnia, 2025), but its computational complexity can make it impractical at large scale. SOCP provides a lower-complexity convex alternative while retaining strong modelling expressiveness (Kumar et al., 2015), and convex-relaxation approaches have demonstrated good empirical performance under NLOS conditions without requiring precise knowledge of the error distribution (Wang et al., 2014; Xiong et al., 2021).

Hybrid TOA-RSS fusion exploits the complementary physical characteristics of the two measurement mechanisms, propagation delay bias and shadow fading, to improve robustness. Recent work has leveraged this through semidefinite relaxation (Katwe et al., 2020), majorisation–minimisation without prior NLOS bias knowledge (Panwar et al., 2022), and Huber-based robust formulations with convex relaxation (Xiong et al., 2023).

Learning-based approaches have also shown strong results for NLOS identification, signal denoising, and intelligent localisation in 5G and massive-MIMO-related settings (Liu et al., 2022; Zhang et al., 2024; Li et al., 2020), but they generally require representative training data and can be sensitive to environmental changes. Model-based optimisation methods require no training data and provide interpretable optimisation structures, making them attractive where predictable behaviour is important (Mohanty et al., 2023).

The combination of SOCP-based hybrid TOA-RSS localisation with a Huber loss has received limited attention in the published literature. Most existing robust SOCP localisation work focuses on either TOA or RSS alone, and hybrid frameworks that consider both models have largely retained squared-error objectives.

III. SYSTEM MODEL

A. Measurement and Hybrid Observation Model

Consider a two-dimensional localization scenario with an unknown target position

$$x = [x, y]^T$$

1

and (N) anchors located at known positions

$$a_i = [x_i, y_i]^T, \quad i = 1,2, \dots, N \tag{2}$$

The TOA-based distance measurement is given by

$$d_i^{\mathrm{TOA}} = \|x - a_i\| + \epsilon_i^{\mathrm{TOA}} \tag{3}$$

where ($\epsilon_i^{\mathrm{TOA}}$) represents measurement noise and NLOS bias.

The RSS measurement follows the log-distance path loss model:

$$P_i = P_0 - 10n \log_{10}(\|\boldsymbol{x} - \boldsymbol{a_i}\|) + \epsilon_i^{\mathrm{RSS}} \tag{4}$$

where (P_0) is the reference power and (n) is the path loss exponent.

The RSS-based distance estimate is obtained as

$$d_i^{\mathrm{RSS}} = 10^{\frac{P_0 - P_i}{10n}} \tag{5}$$

To combine TOA and RSS measurements, a combined distance estimate ($\widehat{d_\iota}$) is defined.

$$\widehat{d_\iota} = d_i^{\mathrm{TOA}} + d_i^{\mathrm{RSS}} \tag{6}$$

The residual error is expressed as

$$r_i = \|\boldsymbol{x} - \boldsymbol{a_i}\| - \widehat{d_\iota} \tag{7}$$

The localisation problem becomes an optimisation problem that minimises the residuals across all anchors. A conventional least-squares formulation based on the residual in (7) is given as:

$$\min_x \sum_{i=1}^{N} \left(\|\boldsymbol{x} - \boldsymbol{a_i}\| - \widehat{d_\iota}\right)^2 \tag{8}$$

$$\min_x \sum_{i=1}^{N} (r_i)^2 \tag{9}$$

Minimisation using the traditional least-squares method can result in large localisation errors under NLOS conditions because large residuals are penalised quadratically. Hence, the Huber loss is introduced to reduce the influence of NLOS-induced outliers.

B. Huber Loss Function

To mitigate the effect of NLOS-induced outliers, the Huber loss function is employed. The Huber loss is given as:

$$\phi(r_i) = \begin{cases} \frac{1}{2} r^2 & |r_i| \le \delta \\ \delta |r_i| - \frac{1}{2}\delta^2 & |r_i| > \delta \end{cases} \tag{10}$$

where δ is the predefined Huber threshold that determines the transition from quadratic to linear penalisation. Residuals with magnitude not exceeding δ are treated approximately as Gaussian perturbations, whereas larger residuals receive a linear penalty and therefore have bounded influence on the estimate (Huber, 1964).

The objective function becomes:

$$\min_x \sum_{i=1}^{N} \phi(r_i)$$

subject to:

$$r_i = \|\boldsymbol{x} - \boldsymbol{a_i}\| - \widehat{d_\iota} \tag{11}$$

C. SOCP CONVEX RELAXATION

The original hybrid localisation problem is inherently nonlinear and non-convex because of the Euclidean norm in the distance expression. Hence, the problem is transformed into a convex SOCP formulation. This requires the introduction of auxiliary variables to enable convex reformulation. Introduce auxiliary variables such that:

$$t_i \ge \|\boldsymbol{x} - \boldsymbol{a_i}\| \tag{12}$$

This converts the equality constraint into an inequality, which is essential for convex relaxation.

Thus, the residual becomes:

$$r_i = t_i - \widehat{d}_\iota \quad (13)$$

The constraint in (12) can be written in standard SOCP form:

$$\|\boldsymbol{x} - \boldsymbol{a_i}\| \leq t_i. \quad (14)$$

Equation (14) is a second-order cone constraint and is therefore convex. Combining the robust objective and the cone constraints produces the complete SOCP–Huber relaxation. The resulting programme can be solved to global optimality with respect to the relaxed convex formulation transformations, the complete SOCP formulation becomes:

$$\min_x \sum_{i=1}^{N} \phi(r_i)$$

subject to:

$$\|\boldsymbol{x} - \boldsymbol{a_i}\| \leq t_i, \quad i = 1, \ldots, N, \quad (15)$$

$$r_i = t_i - \widehat{d}_\iota \quad (16)$$

D. Performance Metric

Root mean square error (RMSE) is used as the principal accuracy metric because it measures the Euclidean position error accumulated over the Monte Carlo trials. Mathematically, RMSE is expressed as:

$$RMSE = \sqrt{\frac{\sum_{i=1}^{N}(x_i - x_o)^2 + (y_i - y_o)^2}{N}} \quad (17)$$

where:

N is the number of observations,

x_i, y_i are the estimated coordinates for the ith position, and

x_o, y_o are the actual coordinates of the true position.

IV. SIMULATION RESULTS AND DISCUSSION

This section presents the simulation setup and parameters, followed by the localisation performance results of the proposed scheme.

Table 1: Simulation Parameters

Parameter	Value / Range	Units
Simulation Area	100 × 100	m²
Number of Anchors (N)	10	—
Number of Targets	1	—
TOA noise std. dev. (σ_{TOA})	0.5 – 3.0	m
RSS path-loss exponent (η)	2.0	—
Reference Distance (d_0)	1.0	m
Reference RSS (P_0)	−30	dBm
RSS shadow-fading std. (σ_{RSS})	4 – 8	dB
NLOS Bias (b_i)	0 – 5	m
NLOS Probability (P_{NLOS})	0 – 1	—
Huber Threshold (δ)	1.5 σ	m / dB
Monte Carlo runs	500	—

The simulation considered a two-dimensional 100×100 m² localisation region containing one target node and $N = 10$ anchors. Five propagation scenarios were investigated to evaluate estimator robustness as the environment transitions from severe NLOS to pure LOS conditions. These scenarios consisted of 0 LOS/10 NLOS, 3 LOS/7 NLOS, 5 LOS/5 NLOS, 7 LOS/3 NLOS, and 10 LOS/0 NLOS anchors, corresponding to realised NLOS fractions of 1.0, 0.7, 0.5, 0.3, and 0.0, respectively.

For each Monte Carlo trial, the prescribed number of NLOS anchors was selected from the available anchors, while all remaining links were treated as LOS. LOS measurements contained only the specified measurement noise, with the NLOS bias set to $b_i = 0$. For each designated NLOS link, an additional positive ranging bias within the interval $0 \leq b_i \leq 5m$ was introduced in addition to the nominal measurement noise. Thus, the number of corrupted links was explicitly controlled for each scenario rather than being determined solely from a Bernoulli NLOS probability. This procedure ensured that all five LOS/NLOS configurations contained exactly the required number of corrupted measurements.

A total of 500 independent Monte Carlo trials was performed for each configuration. Within an individual trial, identical measurement realisations, anchor geometry and LOS/NLOS assignments were supplied to the LS, SOCP and SOCP–Huber estimators so that differences in localisation performance resulted from the estimation method rather than from different measurement conditions. The resulting position errors were subsequently used to calculate RMSE and the empirical cumulative distribution function.

Results and Discussion

The results presented in Figures 1 and 2 demonstrate the localisation performance and robustness of Least Squares (LS), SOCP, and the proposed SOCP–Huber method under varying LOS/NLOS conditions.

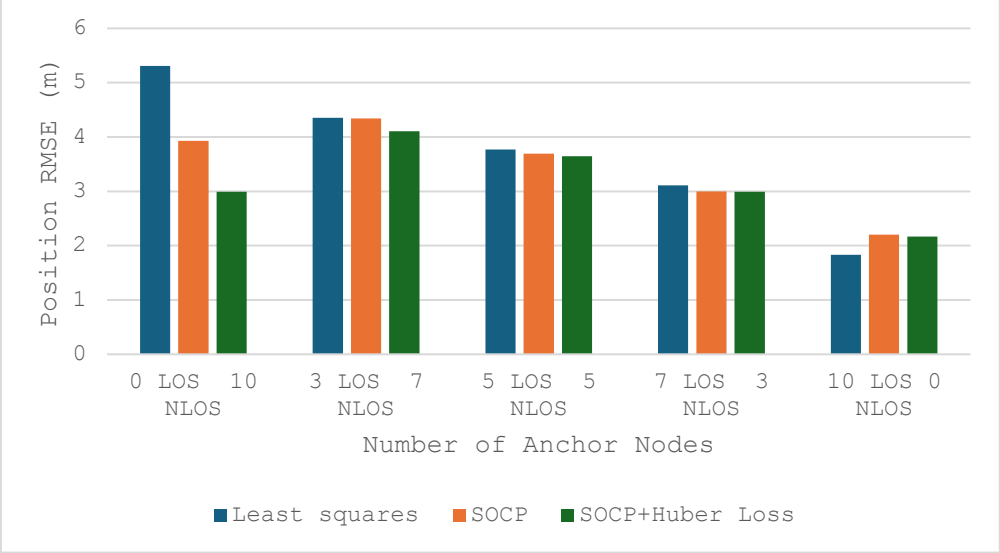

Figure 1: Position RMSE comparison of Least Squares, SOCP, and SOCP–Huber methods.

From the RMSE analysis in Figure 1, it is evident that localisation accuracy improves as the number of LOS anchors increases and the number of NLOS anchors decreases. Under the severe NLOS scenario of 0 LOS and 10 NLOS anchors, the Least Squares method recorded the highest localisation error of approximately 5.3 m, while SOCP achieved about 3.9 m and the proposed SOCP–Huber method attained the lowest RMSE of approximately 3.0 m. This corresponds to an improvement of nearly 43.4% over Least Squares and approximately 23.1% over conventional SOCP. The improvement is attributable to the behaviour of the Huber loss function, which suppresses the influence of large NLOS residuals that typically dominate quadratic-error minimisation approaches. As the propagation environment gradually transitions towards LOS-dominant conditions, the localisation errors of all methods decrease. For instance, under the 10 LOS and 0 NLOS configuration, the localisation RMSE reduced to approximately 1.8 m, 2.2 m, and 2.1 m for Least Squares, SOCP, and SOCP–Huber, respectively. This indicates that the advantage of robust optimisation becomes most significant in severe NLOS environments where measurement outliers are pronounced.

Table 2: Key RMSE Values Reported in Figure 1

LOS/NLOS configuration	LS RMSE (m)	SOCP RMSE (m)	SOCP–Huber RMSE (m)
0 LOS / 10 NLOS	5.3	3.9	3.0
10 LOS / 0 NLOS	1.8	2.2	2.1

Under the pure-LOS configuration of 10 LOS and 0 NLOS anchors, LS achieved an RMSE of approximately 1.8 m, compared with 2.2 m for conventional SOCP and 2.1 m for SOCP–Huber. The slightly better performance of LS in this clean propagation regime can be explained by both statistical efficiency and the relaxation mechanism employed in the SOCP formulation. In the original localisation problem, the estimated geometric distance is constrained by the equality $d_i = \| x - a_i \|$, whereas the convex reformulation replaces this equality with the second-order cone constraint $\| x - a_i \| 2 \leq t_i$. Although this constraint is expected to approach equality when the relaxation is tight, small inconsistencies among the noisy TOA–RSS range measurements may result in $t_i > \| x - a_i \|$ for some anchors. In such cases, the auxiliary variable can partially absorb measurement perturbations without requiring an equivalent change in the target position, thereby introducing a small relaxation gap between the fitted range and the physical geometric distance. This additional degree of freedom may cause a modest localisation penalty relative to direct LS estimation when measurements are predominantly LOS and approximately Gaussian. In contrast, LS directly minimises the squared geometric-range residuals and is therefore statistically efficient under such conditions. The 0.4 m difference between LS and SOCP observed in the pure-LOS case is consequently attributable to the trade-off introduced by convex relaxation rather than to a failure of the SOCP estimator. As NLOS contamination increases, however, the robustness provided by the convex formulation and particularly the Huber penalty outweighs this small clean-data efficiency loss.

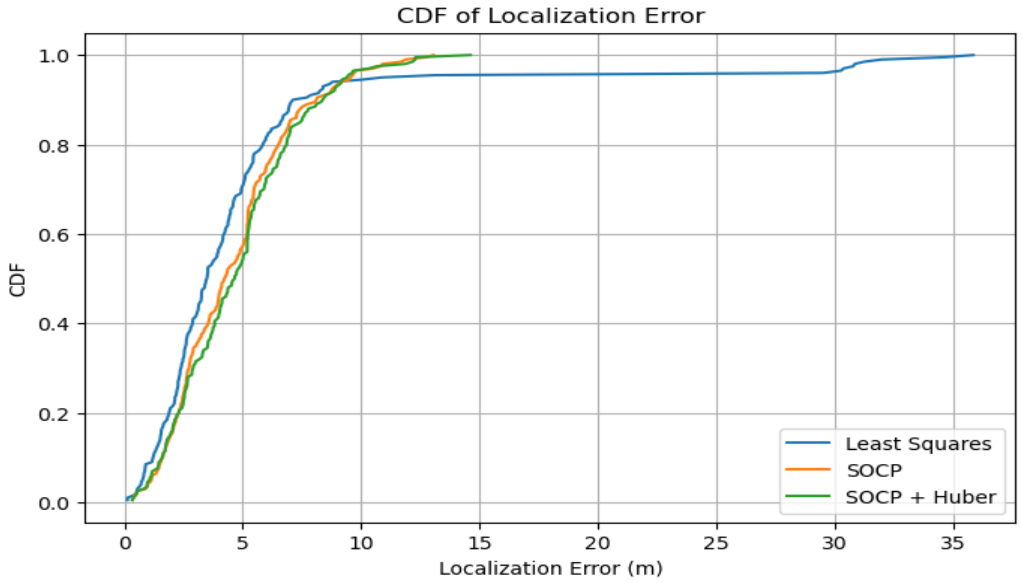

Figure 2: CDF of the localisation error.

The CDF results shown in Figure 2 further demonstrate the robustness and reliability of the proposed SOCP–Huber framework. The cumulative distribution curves represent the probability that the localisation error remains below a specified threshold. Both the conventional SOCP and SOCP–Huber methods exhibit more concentrated error distributions than Least Squares, particularly in terms of limiting large localisation errors. The LS method shows a pronounced long-tail behaviour, with errors extending to approximately 35–36 m. In contrast, the SOCP-based methods concentrate the majority of localisation errors below 10 m and reach their upper CDF plateau at approximately 12–15 m. At a localisation-error threshold of approximately 5 m, nearly 70% of LS estimates fall below this value, whereas the proposed SOCP–Huber method achieves approximately 75–78%. The steeper rise of the

SOCP–Huber curve in the low-to-moderate error region further indicates reduced error dispersion and improved localisation consistency. Overall, the CDF analysis confirms that incorporating the Huber loss into the SOCP framework improves robustness to NLOS-induced outliers and reduces the occurrence of large localisation errors.

Table 3: Complexity Comparison of Localisation Methods

Method	**Objective Function**	**Computational Complexity**	**Interpretation**
Least Squares (LS)	Squared residual minimization	$\mathcal{O}(kn^2)$	Iterative least-squares solution
Semi-Definite Programming (SDP)	Semi-definite relaxation	$\mathcal{O}(n^6)$	Large PSD matrix operations
Second-Order Cone Programming (SOCP)	Cone-constrained minimization	$\mathcal{O}(n^{3.5})$	Interior-point SOCP scaling
SOCP + Huber Loss	Huber-penalized cone minimization	$\mathcal{O}(n^{4.5})$	Additional Huber auxiliary/epigraph variables

Note. n represents the effective optimisation problem size (which scales with the number of anchors and auxiliary variables), and k represents the number of iterations for iterative LS implementations. The stated complexities are approximate order-of-growth estimates for generic interior-point implementations. Actual computational cost depends on the cone structure, variable dimensions, sparsity, solver implementation and required solution accuracy.

Table 3 compares the computational complexity of LS, SDP, SOCP, and the proposed SOCP-Huber framework. The reported values should be interpreted as indicative order-of-growth estimates rather than exact execution times, since actual computational cost depends on solver implementation, sparsity, numerical tolerance, and hardware.

LS has the lowest computational burden, approximately $\left(O(kn^2)\right)$, but its squared-error objective makes it sensitive to large NLOS residuals. SDP provides a convex relaxation but incurs a much higher computational cost, commonly approximated as $\left(O(n^6)\right)$, because of its matrix-valued variables and positive-semidefinite constraints. SOCP offers a more efficient convex alternative. For a dense primal-dual interior-point implementation, the Newton/KKT solution cost is approximately $\left(O(n^3)\right)$, while the iteration bound contributes about $\left(O\left(\sqrt{n}\log(1/\epsilon)\right)\right)$, giving an indicative complexity of

$$O!\left(n^{3.5}\log\left(\frac{1}{\epsilon}\right)\right) \quad 18$$

(Nesterov & Nemirovskii, 1994; Boyd & Vandenberghe, 2004).

The proposed SOCP–Huber method introduces additional auxiliary and epigraph variables to implement the Huber loss. These increase the practical computational burden but scale approximately linearly with the number of anchors; therefore, they mainly increase the computational constant rather than necessarily changing the asymptotic exponent. Thus, SOCP–Huber retains a complexity of the same general order as SOCP, while providing improved robustness to NLOS-induced outliers. Overall, the proposed method offers a favourable compromise between localisation accuracy, robustness, and computational efficiency.

V. CONCLUSION

This paper presented a robust hybrid TOA-RSS localisation framework based on Second-Order Cone Programming integrated with the Huber loss function for effective mitigation of NLOS-induced measurement errors. By combining complementary TOA and RSS observations within a convex

optimisation framework, the proposed method reduces the influence of large biased residuals that adversely affect conventional least-squares estimation.

Simulation results demonstrated that the proposed SOCP-Huber method provides its greatest benefit under severe NLOS conditions, where it achieved lower localisation error and a more concentrated error distribution than both conventional LS and standard SOCP. Under pure-LOS conditions, LS retained a small accuracy advantage, which reflects both its statistical efficiency under approximately Gaussian measurement errors and the small relaxation gap introduced by the SOCP formulation. This behaviour confirms that the principal advantage of the proposed framework lies in robustness to contaminated measurements rather than in improving already clean LOS observations.

From a computational perspective, the enhanced robustness is obtained at the cost of a moderate increase in complexity relative to conventional SOCP because of the additional auxiliary variables and Huber-loss constraints. Nevertheless, the computational burden remains substantially lower than that associated with semidefinite-programming-based localisation methods. The proposed method therefore provides a practical compromise between localisation accuracy, robustness and computational cost. This trade-off is particularly relevant to real-time indoor positioning systems, where resilience to NLOS errors must be achieved without introducing the substantially higher processing requirements associated with more complex convex relaxations.

Overall, the results indicate that SOCP-Huber localisation is most suitable for propagation environments in which NLOS contamination is significant and computational resources are constrained. The framework therefore offers a promising basis for robust real-time indoor positioning in wireless sensor networks, industrial facilities and other multipath-dominated environments. Future work will investigate adaptive selection of the Huber threshold, residual-statistics-based regularisation, and experimental validation using measured TOA-RSS datasets.

ABOUT THE CONFERENCE

The International Conference on Engineering Innovation for Sustainable Development (ICESID 2026) was hosted by the Faculty of Engineering, Ahmadu Bello University Zaria from 8–10 September 2026. It brought together researchers, developers, practitioners and policy makers from academia and industry across the fields of engineering, under the theme "Innovating Tomorrow: Harnessing Engineering to Drive Nigeria's Sustainable Development". This Book of Proceedings collects the peer-reviewed papers presented at the conference, a record of the knowledge sharing, networking and research collaboration it set out to foster.

CONFERENCE SUB-THEMES

01 Smart Infrastructure and Sustainable Systems for National Development

02 Engineering Innovations, Technology Commercialization and Industrial Policy

03 Emerging Technologies and Digital Transformation in Engineering Education and Practice

04 Renewable Energy Integration and Smart Grid Applications in Power Systems

05 Intelligent Systems, Automation and Control Engineering

06 Strategies for Infrastructural and Industrial Transformation through Engineering Innovations

07 Green Mobility and Next Generation Automobile Technologies

08 Sustainable Engineering Processes and Systems

09 Emerging Technologies for Safe Engineering Practices and Environmental Protection

10 Telecommunication Infrastructure for Sustainable Urban Development and Economic Growth

11 Advanced Manufacturing, Materials and Sustainable Production
